When blood comes in contact with a foreign material, such as the dialyzer, it tends to clot. We add heparin to the blood to prevent clotting.

In addition to the dialyzer, we use a dialysate delivery and monitoring system (Fig. 51.12). This system pumps the dialysate through the dialyzer, countercurrent to the blood flow. To end the treatment, saline solution returns the blood in the extracorporeal circuit back to the patient through the vascular access. The needles are removed from the patient. Firm pressure is applied to the venipuncture sites until the bleeding stops.

Before beginning treatment, assess fluid status (weight, BP, peripheral edema, lung and heart sounds), condition of vascular access, and temperature. The difference between the last postdialysis weight and the present predialysis weight determines the ultrafiltration or the amount of weight (from fluid) to be removed. While the patient is on HD, take vital signs at least every 30 to 60 minutes because rapid BP changes may occur.

Settings and Schedules for Hemodialysis

Most HD patients are treated in a community-based center and dialyze for 3 to 4 hours 3 days/week. Other schedule options are short daily HD and long nighttime HD. The patient receiving long nighttime HD has the advantage of sleeping while

Fig. 51.13 Home hemodialysis is growing in popularity, and machines are more compact. (From NxStage Medical, Inc, Lawrence, MA.)

dialyzing. Each nighttime treatment lasts 6 to 8 hours. The patient dialyzes up to 6 times per week.

Home HD may be an option (Fig. 51.13). The use of home HD often depends on a patient's family support. One of the main advantages of home HD is that it allows greater freedom in choosing dialysis times. In short daily HD, the patient dialyzes for 2½ to 3 hours per session 5 to 6 days/week. Short daily HD is usually done at home.

Patients who choose daily or nighttime dialysis may have fewer uremic symptoms, tend to need fewer medications, and have fewer HD-related side effects (e.g., hypotension, cramps). In addition, they have more autonomy. Although daily home HD offers the potential of significant health benefits, only about 2% of HD patients dialyze at home.

Complications of Hemodialysis

Hypotension

Hypotension that occurs during HD often results from rapid removal of vascular volume (hypovolemia), decreased cardiac output, and decreased systemic vascular resistance. The drop in BP may cause lightheadedness, nausea, vomiting, seizures, vision changes, and chest pain from cardiac ischemia. The usual treatment for hypotension includes decreasing the volume of fluid removed and infusing 0.9% saline solution.

Muscle Cramps

We do not completely understand the cause of muscle cramps in HD. Risk factors for developing muscle cramps include hypotension, hypovolemia, high ultrafiltration rate (UFR), and low-sodium dialysis solution. Treatment includes reducing the UFR and giving fluids (saline, glucose, mannitol). Hypertonic saline is not recommended since the sodium load can be problematic. Hypertonic glucose is preferred.

Loss of Blood

Blood loss may result from blood not being completely rinsed from the dialyzer, accidental separation of blood tubing, dialysis

membrane rupture, or bleeding after removing the needles at the end of HD. If a patient has received too much heparin or has clotting problems, postdialysis bleeding can occur. It is essential to rinse back all blood, avoid excess anticoagulation, and hold firm but nonocclusive pressure on access sites until the risk for bleeding has passed.

Hepatitis

Hepatitis B used to have an unusually high prevalence in HD patients, but the incidence today is low. Lower transfusion requirements, screening, and vaccinations have lowered the incidence. Outbreaks of hepatitis B still occur, likely from breaks in infection control practices. To prevent transmission, all patients and personnel in dialysis units receive hepatitis B vaccine.

Hepatitis C virus (HCV) causes most cases of hepatitis in HD patients (see Chapter 48). About 10% of patients receiving dialysis in the United States are positive for anti-HCV, which indicates a previous infection. Infection control precautions are mandated in caring for the patient with hepatitis C to protect the patient and staff (see Chapter 15). Currently no vaccine is available for hepatitis C.

Effectiveness of Hemodialysis

HD is still an imperfect therapy for management of ESRD. It cannot fully replace the normal biologic functions of the kidneys.[24] It can ease many of the symptoms of CKD and, if started early, can prevent certain complications. It does not alter the accelerated rate of CVD and the related high mortality rate. The yearly death rate of patients receiving maintenance HD is around 19% to 24%. CVD (stroke, MI) causes most deaths. Infectious complications are the second leading cause of death.[13,21]

Adaptation to maintenance HD varies considerably. At first, many patients feel positive about the dialysis because it makes them feel better and keeps them alive, but there is often great ambivalence about whether it is worthwhile. Dependence on a machine is a reality. In response to their illness, patients may be nonadherent, depressed, and show suicidal tendencies. Key nursing goals are to (1) help the patient to maintain a healthy self-image and (2) return the patient to the highest level of function possible, including returning to work.

CONTINUOUS RENAL REPLACEMENT THERAPY

Continuous renal replacement therapy (CRRT) is a method for treating AKI. It provides a means by which uremic toxins and fluids are removed while acid-base status and electrolytes are adjusted slowly and continuously in a hemodynamically unstable patient. The principle of CRRT is to dialyze patients in a more physiologic way (over 24 hours), just like the kidneys. CRRT is contraindicated if a patient has life-threatening manifestations of uremia (hyperkalemia, pericarditis) that need rapid treatment. CRRT can be used in conjunction with HD.

Several types of CRRT are available (Table 51.13). CRRT often uses a venovenous approach. Examples include continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF).

TABLE 51.13 Continuous Renal Replacement Therapies

Therapy	Abbreviation	Purpose
Continuous venovenous hemofiltration	CVVH	Removes fluid and solutes Requires replacement fluid
Slow continuous ultrafiltration	SCUF	Simplified version of CVVH Removes fluid No fluid replacement required
Continuous venovenous hemodialysis	CVVHD	Removes fluids and solutes Requires dialysate and replacement fluid
Continuous venovenous hemodiafiltration	CVVHDF	Removes fluids and solutes Requires dialysate and replacement fluid

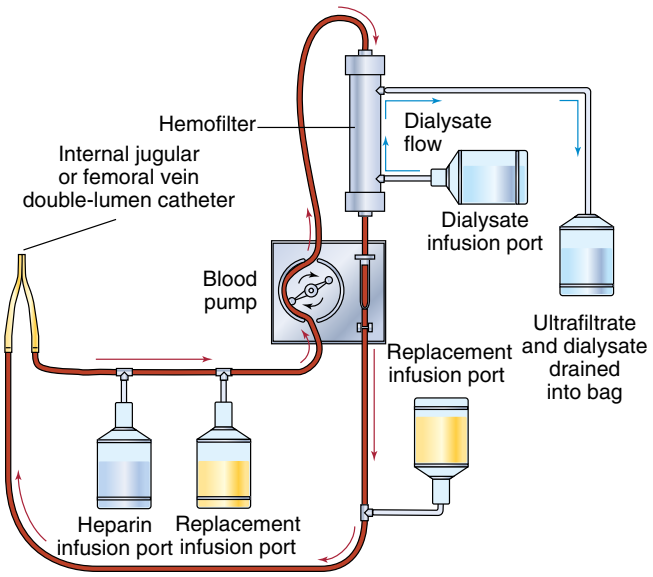

Fig. 51.14 Basic schematic of continuous venovenous therapies. A blood pump is needed to pump blood through the circuit. Replacement ports are used for instilling replacement fluids and can be given prefilter or postfilter. Dialysate port is used for infusing dialysis solution. Regardless of modality, ultrafiltrate is drained via the ultrafiltration drain port.

Vascular access for CRRT is achieved with a double-lumen catheter as used in HD (Figs. 51.10 and 51.11) placed in the jugular or femoral vein. A blood pump propels the blood through the circuit. A highly permeable, hollow-fiber hemofilter removes plasma water and nonprotein solutes, which are collectively termed *ultrafiltrate*. The UFR may range from 0 to 500 mL/h. Under the influence of hydrostatic pressure and osmotic pressure, water and nonprotein solutes pass out of the filter into the extracapillary space and drain through the ultrafiltrate port into a collection device (drainage bag) (Fig. 51.14). The remaining fluid continues through the filter and returns to the patient via the return port of the double-lumen catheter.

As ultrafiltrate drains out of the hemofilter, fluid and electrolyte replacements can be infused through a port found before or after the filter as the blood returns to the patient. Replacement

fluid is designed to replace volume and solutes, such as sodium, chloride, HCO_3^-, and glucose. The infusion rate of replacement fluid is determined by the degree of fluid and electrolyte imbalance. Replacement fluid infused into the infusion port before the hemofilter allows for greater clearance of urea and can decrease filter clotting. An infusion port after the filter dilutes intravascular fluid and decreases the concentration of unwanted solutes, such as BUN, creatinine, and potassium. Anticoagulants are given to prevent blood clotting. They may be infused as a bolus at the start of CRRT or through an infusion port before the hemofilter.

The type of CRRT is determined by the patient's needs. Some types involve giving replacement fluids. CVVHD and CVVHDF use dialysate. Dialysis fluid is attached to the distal end of the hemofilter, and the fluid is pumped countercurrent to the blood flow (Fig. 51.14). As in HD, diffusion of solutes and ultrafiltration via hydrostatic pressure and osmosis occur. This is an ideal treatment for a patient who needs both fluid and solute control but cannot tolerate the rapid fluid shifts associated with HD.

Several features of CRRT differ from HD:

- The blood pump in CRRT runs at a slower (150 mL/min average) rate. This may improve hemodynamic stability.
- Continuous rather than intermittent. Fluid volume can be removed over days (24 hours to more than 2 weeks) versus hours (3 to 4 hours).
- Solute removal can occur by *convection* (no dialysate needed) in addition to osmosis and diffusion.
- Causes less hemodynamic instability (e.g., hypotension)
- Does not need constant monitoring by a specialized HD nurse but does require a trained ICU nurse
- Does not require complicated HD equipment

CRRT can be continued as long as 30 to 40 days. Change the hemofilter every 24 to 48 hours because of loss of filtration efficiency or potential for clotting. The ultrafiltrate should be clear yellow. Specimens may be obtained for serum chemistries. If the ultrafiltrate becomes bloody or blood tinged, suspect a rupture in the filter membrane. Stop treatment to prevent blood loss.

Specific nursing care includes obtaining weights and monitoring and documenting laboratory values daily to ensure adequate fluid and electrolyte balance. Assess hourly intake and output, vital signs, and hemodynamic status. Although we expect central venous pressure and pulmonary artery pressure to decrease, there should be little change in mean arterial pressure or cardiac output. Assess and maintain the patency of the CRRT system. Care for the patient's vascular access site to prevent infection. Once the patient's AKI is resolved or there is a decision to withdraw treatment, CRRT is stopped, and the needle(s) removed.

WEARABLE ARTIFICIAL KIDNEY

The wearable artificial kidney is a miniaturized dialysis machine that can be worn on the body. The carrier resembles a tool belt. The device connects to a patient via a catheter. Like conventional dialysis machines, it filters the blood of ESRD patients. Unlike current portable or stationary dialysis machines, it can run continuously on batteries. The present version weighs about 10 lb. Future modifications could make it lighter and more streamlined.[26] The WAK has greatly improved the quality of life for some ESRD patients.

KIDNEY TRANSPLANTATION

Major advances have been made in kidney transplants since the first live donor kidney transplant was done in 1954 between identical twins. These advances include organ procurement and preservation, surgical techniques, tissue typing and matching, immunosuppressant therapy, and preventing and treating graft rejection. General information about organ transplants is in Chapter 14.

Even though a kidney transplant is the best treatment option for patients with ESRD, fewer than 4% have a transplant. This is due to the large disparity between the supply and demand for kidneys. Every year thousands are waiting for kidney transplants (more than 120,000 are currently on the list), yet only about 24,000 transplants take place every year. Most die while waiting. Transplants from a deceased (cadaveric) donor usually require a prolonged waiting period, with differences in waiting time depending on age, gender, and race. Average wait times in the United States for a deceased kidney usually range from 2 to 5 years.[27]

Kidney transplants are very successful. 1-year graft survival rates are over 90% for deceased donor transplants and 95% for live donor transplants.[27] An advantage of a kidney transplant compared with dialysis is that it reverses many of the pathophysiologic changes associated with renal disease. It eliminates the dependence on dialysis and the accompanying diet and lifestyle restrictions. A transplant is less expensive than dialysis after the first year.

Recipient Selection

Appropriate recipient selection is important for a successful outcome. Candidacy is determined by a variety of medical and psychosocial factors (Box 51.4). These factors vary among transplant centers. Some programs exclude patients who are morbidly obese or continue to smoke despite smoking cessation interventions. A careful evaluation is done to identify and minimize potential complications after the transplant. Certain patients, particularly those with CVD and diabetes, are considered high risk. They must be carefully evaluated and then monitored closely after the transplant.[28]

For a small number of patients who are approaching ESRD, a *preemptive transplant* (before dialysis is needed) is possible if they have a living donor. This approach is best for patients with diabetes because they have a much higher mortality rate on dialysis.

Contraindications to a transplant include advanced cancer, refractory or untreated heart disease, chronic respiratory failure, extensive vascular disease, chronic infection, and unresolved psychosocial disorders (e.g., nonadherence to treatment plan, alcohol use, drug use). Being HIV-positive or having hepatitis B or C infection is not a contraindication.

The patient may need other surgeries before having a transplant. Coronary artery bypass or coronary angioplasty may be needed for advanced coronary artery disease. Cholecystectomy may be necessary for patients with a history of gallstones,

BOX 51.4 ETHICAL/LEGAL DILEMMAS

Allocation of Resources

Situation

T.H., a transplant nurse coordinator, is considering her feelings about 2 patients who are being evaluated for placement on the deceased kidney transplant waiting list. One patient is a 40-year-old schoolteacher. She is married and has 2 children. The other patient is a 22-year-old unemployed man. He misses 3 or 4 dialysis treatments per month and does not take his antihypertensive drugs consistently.

Ethical/Legal Points for Consideration

- Ethical principles that are important in the allocation of human organs include utility and justice.
- Allocation policies based on utility require we use standardized outcome measures to give a rough estimate about which allocation would produce the greatest good. Factors considered include patient survival, quality of life, availability of alternative treatments, and age.
- We must give equal respect and concern to each patient. Allocation based on social characteristics (e.g., race, socioeconomic class, gender) conflict with the principle of justice and violate constitutional law.
- Constitutional laws prohibit discrimination based on race, gender, religion, and ethnic background. It is highly unlikely that these standard prohibitions will change. It is possible that definitions of unhealthy behavior, such as substance use, alcohol use, smoking, and obesity, may be used to screen out candidates.
- Nurses are concerned about social justice because of their health advocacy role. Today the situation is immensely more complex because of the cost and availability of care.

Discussion Questions

1. What does the American Nurses Association Code of Ethics say about how you as a nurse should view patients?
2. What are your thoughts about which patient should receive the next available kidney transplant?
3. Can you assign value to the lives of various patients? Who is worth more?

biliary obstruction, or cholecystitis. On rare occasions, bilateral nephrectomies are done for patients with refractory hypertension, recurrent UTIs, or grossly enlarged kidneys from polycystic kidney disease. In general, the recipient's own kidneys are not removed before receiving a kidney transplant.

Histocompatibility Studies

Histocompatibility studies, including human leukocyte antigen (HLA) testing and crossmatching, are discussed in Chapter 14.

Donor Sources

Kidneys for transplants are obtained from compatible blood-type deceased donors, blood relatives, emotionally related (close and distant) living donors (e.g., spouses, distant cousins), and altruistic living donors who are known (friends) or unknown to the recipient. Living donation accounts for around 27% of all kidney transplants in the United States. Most transplant centers regard them as the preferred donation modality.[27]

Live Donors

Live donors undergo an extensive evaluation to ensure that they are in good health and have no history of disease that would place them at risk for developing kidney disease or operative complications. Crossmatches are done at the time of the evaluation and about a week before the transplant to ensure that no antibodies to the donor are present or that the antibody titer is below the allowed level. Advantages of a live donor kidney include (1) better patient and graft survival rates regardless of histocompatibility match, (2) immediate organ availability, (3) immediate function due to minimal *cold time* (kidney out of body and not getting blood supply), and (4) the opportunity to have the recipient in the best possible health since the surgery is elective.

The potential donor sees a nephrologist for a complete history and physical assessment and laboratory and diagnostic studies. Laboratory studies include a 24-hour urine study for creatinine clearance and total protein, complete blood count, and chemistry and electrolyte profiles. Hepatitis B and C, HIV, and cytomegalovirus (CMV) testing is done to assess for transmitted diseases. An ECG and chest x-ray are done. A renal ultrasound and renal arteriogram or 3-dimensional CT scan is done to ensure that the blood vessels supplying each kidney are adequate and that no anomalies exist and to see which kidney will be used in the transplant.

A transplant psychologist or social worker determines if the person is emotionally stable and able to deal with the issues related to organ donation. All donors must be informed about the risks and benefits of donation, the potential short- and long-term complications, and what to expect during the hospitalization and recovery phases. Kidney donation is considered safe without any long-term health consequences. Although the recipient's insurance covers the costs of the evaluation and surgery, no compensation is available for lost wages during the posthospitalization recovery period. This period can last 6 weeks or longer.

When there is ABO incompatibility between a donor and recipient, paired donor exchange is a viable alternative. *Paired organ donation* occurs when one donor/recipient pair who are incompatible or poorly matched with each other find another donor/recipient pair with whom they can exchange kidneys. Thus, a spouse (person A) who wants to donate a kidney to his wife (person B) but is incompatible is paired with another donor/recipient pair involving a son with ESRD (person C) and his mother (person D). In this example, person A would donate his kidney to person C, and person D would donate her kidney to person B. Paired organ donation is the practice of matching biologically incompatible donor/recipient pairs to permit transplantation of both candidates with a well-matched organ.

Another option for ABO incompatibility or a positive crossmatch between the donor and recipient is to use plasmapheresis to remove antibodies from the recipient. This allows transplant candidates to receive kidneys from live donors with blood types that we have traditionally considered incompatible. After the transplant, the patient has more plasmapheresis treatments.

Deceased Donors

Deceased (cadaver) kidney donors are fairly healthy persons who have an irreversible brain injury and are declared brain dead. The most common causes of injury are cerebral trauma

from motor vehicle accidents or gunshot wounds, intracerebral or subarachnoid hemorrhage, and anoxic brain damage caused by cardiac arrest. The brain-dead donor must have effective CV function and be supported on a ventilator to preserve the organs.

Even if the donor carried a signed donor card, permission from the donor's legal next of kin is still requested after brain death has been declared. That is why it is important for you to talk with your family about your wishes before losing the capacity to convey your desires.

In deceased kidney donation, the kidneys are removed and preserved. They can be preserved for up to 72 hours. Most transplant surgeons prefer to transplant kidneys before the cold time (time outside of the body when being transported from the deceased donor to the recipient) reaches 24 hours. Prolonged cold time increases the chance that the kidney will not function immediately. ATN may develop.

The United Network for Organ Sharing (UNOS) distributes deceased donor kidneys using an objective computerized point system. The kidney allocation system (KAS) provides all donor kidneys a kidney donor profile index (KDPI). The KDPI includes 10 donor factors that evaluate the risk for a kidney transplant failure. The KDPI can help predict how long a kidney may function. Each kidney transplant candidate gets an Estimated Post-Transplant Survival (EPTS) score. This score ranges from 0% to 100%. The score is related to how long a candidate will need a functioning kidney transplant when compared with other candidates. For example, a person with an EPTS score of 20% is likely to need a kidney longer than 80% of other candidates. The EPTS score is based on age, length of time on dialysis, previous transplants, and having diabetes.[29]

When a donor becomes available, the donor's key information is compared with the data of all patients awaiting a transplant locally and nationwide. When a kidney arrives at the recipient's transplant center, a final crossmatch is done. It must be negative for the deceased donor transplant to proceed.

The only exception is if a patient needs an emergency transplant or if a donor and recipient match on all 6 HLA antigens (zero antigen mismatch). The patient meeting either of these criteria goes to the top of the list. Emergency transplants receive priority because the patient is facing imminent death if not transplanted. If a zero-antigen mismatch patient is found nationally, since statistically these grafts have better survival rates, one of the donor kidneys must be sent to that recipient's transplant center regardless of location.

Surgical Procedure

Live Donor

A transplant surgeon performs the live donor nephrectomy. The donor's surgery begins 1 to 2 hours before the recipient's surgery. The recipient is surgically prepared for the kidney transplant in a nearby operating room.

Laparoscopic donor nephrectomy is the most common technique for removing a kidney in a living donor. Laparoscopic nephrectomy is discussed in Chapter 50. After the kidney is removed, it is flushed with a chilled, sterile electrolyte solution and prepared for immediate transplant into the recipient. The use of this procedure is minimally invasive, with fewer risks and shorter recovery time than an open procedure. The laparoscopic approach significantly decreases hospital stay, pain, operative blood loss, debilitation, and length of time off work. For these reasons, the number of people willing to donate a kidney has increased significantly.

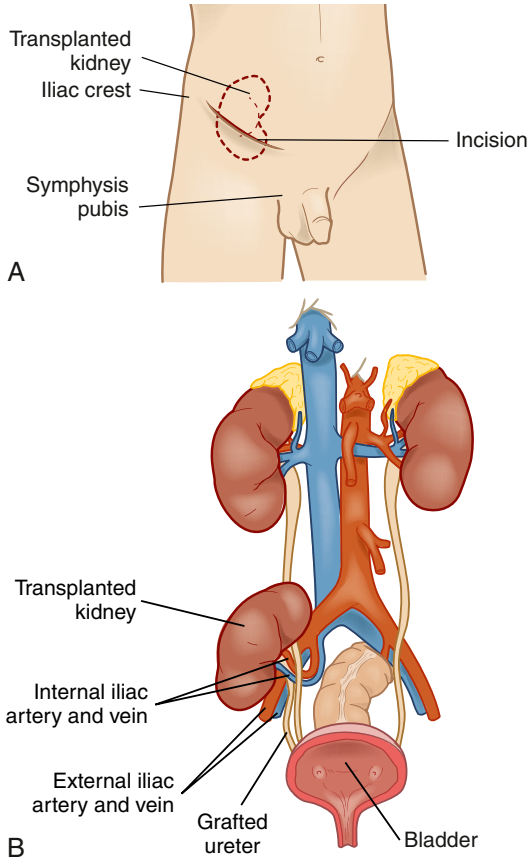

Fig. 51.15 (A) Surgical incision for a renal transplant. (B) Surgical placement of transplanted kidney.

For an open (conventional) nephrectomy, the donor is placed in the lateral decubitus position on the operating table so that the flank is exposed laterally. An incision is made at the level of the eleventh rib. The rib may have to be removed to see the kidney.

Kidney Transplant Recipient

The transplanted kidney is usually placed extraperitoneally in the iliac fossa (Fig. 51.15). The right iliac fossa is preferred to facilitate anastomoses of the blood vessels and ureter and minimize the occurrence of paralytic ileus.

Rapid revascularization is critical to prevent ischemic injury to the kidney. The donor artery is anastomosed to the recipient's internal iliac (hypogastric) or external iliac artery. The donor vein is anastomosed to the recipient's external iliac vein. When the anastomoses are complete, the clamps are released, and blood flow to the kidney is reestablished. The kidney should become firm and pink. Urine may begin to flow from the ureter at once. The donor ureter is then tunneled through the bladder submucosa before entering the bladder cavity and being sutured in place. This approach is called *ureteroneocystostomy.* This

allows the bladder wall to compress the ureter as it contracts for micturition, thereby preventing reflux of urine up the ureter into the transplanted kidney. A urinary catheter is placed into the bladder, and an antibiotic solution is instilled to distend the bladder and decrease the risk for infection. Transplant surgery takes about 3 to 4 hours.

NURSING MANAGEMENT: KIDNEY TRANSPLANT RECIPIENT

Preoperative Care

Nursing care includes emotional and physical preparation for surgery. Because the patient and caregiver may have been waiting years for the kidney transplant, a review of the operative procedure and what can be expected in the immediate postoperative recovery period is necessary. Stress that there is a chance the kidney may not function at once, and dialysis may be needed for days to weeks. Review the need for immunosuppressive drugs and measures to prevent infection.

To ensure the patient is in the best health for surgery, an ECG, chest x-ray, and laboratory studies are done. Dialysis may be needed before surgery for fluid overload or hyperkalemia. Because dialysis may be needed after the transplant, the patency of the vascular access must be maintained. Label the vascular access extremity "dialysis access, no procedures" to prevent use of that extremity for BP measurement, blood drawing, or IV infusions. A patient on PD must empty the peritoneal cavity of all dialysate solution before going to surgery and have the PD catheter capped.

Postoperative Care

Live Donor

Postoperative care for the donor is similar to that after open (conventional) or laparoscopic nephrectomy (Chapter 50). Monitor renal function to assess for impairment and the hematocrit to assess for bleeding. Donors usually have more pain than the recipient. Donors who had an open surgical approach may have more pain than those after a laparoscopic approach.

Donors who had an open approach are usually discharged from the hospital in 4 or 5 days and return to work in 6 to 8 weeks. With a laparoscopic approach, donors are discharged from the hospital in 2 to 4 days and return to work in 4 to 6 weeks. The surgeon sees the donor 1 to 2 weeks after discharge.

Nurses caring for the living donor must acknowledge the precious gift that this person has given. The donor has taken physical, emotional, and financial risks to help the recipient. It is vital that the donor is not forgotten after surgery. The donor will need support if the donated organ does not work at once or for some reason fails.

Kidney Transplant Recipient

The priority during the postoperative period is maintaining fluid and electrolyte balance. Kidney transplant recipients require close monitoring and spend the first 12 to 24 hours in the ICU. Large volumes of urine may be made soon after the blood supply to the transplanted kidney is reestablished. This diuresis is due to the (1) new kidney's ability to filter BUN, which acts as an osmotic diuretic; (2) abundance of fluids given during the surgery; and (3) initial renal tubular dysfunction, which inhibits the kidney from concentrating urine normally. Urine output during this phase may be as high as 1 L/hr and gradually decreases as the BUN and serum creatinine levels return toward normal. Urine output is replaced with fluids milliliter for milliliter hourly for the first 12 to 24 hours.

Central venous pressure readings are essential for monitoring fluid status. Dehydration must be avoided to prevent renal hypoperfusion and renal tubular damage. Assess for hyponatremia and hypokalemia. They can occur with rapid diuresis. Treatment with potassium supplements or infusion of 0.9% normal saline may be needed. IV sodium bicarbonate may be given if the patient develops metabolic acidosis from a delay in the return of kidney function.

ATN in the transplanted kidney can occur because of prolonged cold times causing ischemic damage or the use of marginal cadaveric donors (those who are medically suboptimal). While the patient is in ATN, dialysis is needed to maintain fluid and electrolyte balance. Some patients have high-output ATN with the ability to excrete fluid but not metabolic wastes or electrolytes. Other patients have oliguric or anuric ATN. These patients are at risk for fluid overload in the immediate postoperative period. Assess closely for the need for dialysis. ATN can last from days to weeks, with gradually improving kidney function. Most patients with ATN are discharged from the hospital on dialysis. This is discouraging for the patient, who needs reassurance that renal function usually improves. Dialysis is stopped when urine output increases and serum creatinine and BUN begin to normalize.

A sudden decrease in urine output in the early postoperative period is a cause for concern. It may be due to dehydration, rejection, a urine leak, or obstruction. A common cause of early obstruction is a blood clot in the urinary catheter. Maintain catheter patency since the catheter stays in the bladder for 3 to 5 days to allow the ureter-bladder anastomosis to heal. If you suspect blood clots, gentle catheter irrigation (if ordered) can reestablish patency.

Identify and address discharge planning and teaching needs early. Patient teaching ensures a smooth transition from the hospital to home. Include how to recognize signs of rejection, infection, and any complications of surgery. Frequent blood tests and clinic visits help to detect rejection early.

Immunosuppressive Therapy

The goal of immunosuppression is to adequately suppress the immune response to prevent rejection of the transplanted kidney while maintaining sufficient immunity to prevent overwhelming infection. Immunosuppressive therapy is discussed in Chapter 14.

Complications of Transplantation

Complications of PD, HD, and kidney transplants are compared in Table 51.14.

Rejection

Rejection is a major problem after a kidney transplant. Rejection can be hyperacute, acute, or chronic. The types of rejection are

TABLE 51.14 Complications of Dialysis and Transplantation

Peritoneal Dialysis (PD)	Hemodialysis (HD)	Transplantation

• Abdominal pain
• Carbohydrate abnormalities
• Catheter outflow

		• Recurrent kidney disease
		• Susceptible to infection
		• Transplant rejection
		  • Hyperacute
		  • Acute
		  • Chronic

discussed in Chapter 14. Patients with chronic rejection may be placed on the transplant list to be retransplanted before they need dialysis.

Infection

Infection is a significant cause of mortality after a transplant. The transplant recipient is at risk for infection because of suppression of the body's normal defense mechanisms by surgery, immunosuppressive drugs, and the effects of ESRD. Underlying systemic illness, such as diabetes or SLE, malnutrition, and older age, can further compound the negative effects on the immune response. The signs and symptoms of infection can be subtle. You must be astute in your assessment of the recipient because prompt diagnosis and treatment of infection improves patient outcomes.

The common infections seen in the first month after a transplant are like those of any postoperative patient. These include pneumonia, wound infections, UTIs, and IV line and drain infections. Fungal and viral infections are common due to the patient's immunosuppressed state. Fungal infections include *Candida, Cryptococcus,* and *Aspergillus* organisms and *Pneumocystis jirovecii.* Fungal infections are hard to treat, require prolonged treatment periods, and often involve the administration of nephrotoxic drugs. Transplant recipients usually receive prophylactic antifungal drugs to prevent these infections, such as clotrimazole, fluconazole, and trimethoprim/sulfamethoxazole.

Viral infections, including CMV, Epstein-Barr virus, herpes simplex virus (HSV), and varicella-zoster virus, can be primary infections or reactivations of existing disease. Primary infections occur as new infections from an exogenous source such as the donated organ or a blood transfusion. Reactivation occurs when a virus exists in a patient and becomes reactivated because of immunosuppression.

CMV is one of the most common viral infections. If a recipient has never had CMV and receives an organ from a donor with a history of CMV, antiviral prophylaxis will be needed (e.g., ganciclovir, valganciclovir). To prevent HSV infections, the patient receives oral acyclovir for several months after the transplant.

Cardiovascular Disease

CVD is the leading cause of death after a kidney transplant.[28] Transplant recipients have an increased incidence of atherosclerotic vascular disease. Hypertension, dyslipidemia, diabetes, smoking, rejection, infections, and increased homocysteine levels (many of which existed prior to the transplant) can all contribute to CVD. Immunosuppressants can worsen hypertension and dyslipidemia.

Teach the patient to control risk factors, such as high cholesterol, triglycerides, and blood glucose and weight gain. Adherence to the prescribed antihypertensive regimen is essential to prevent CV events and damage to the new kidney.

Cancers

The overall incidence of cancer in kidney transplant recipients is greater than in the general population, mainly because of immunosuppressive therapy. Not only do immunosuppressants suppress the immune system to prevent rejection, but they suppress the ability to fight infection and the production of abnormal cells, including cancer cells.

The most common types of cancer after transplant are (1) skin cancers—basal and squamous cell cancers and melanoma—and (2) posttransplant lymphoproliferative disorder (PTLD). Most PTLDs are of B-cell origin, related to Epstein-Barr virus (EBV). They cause aggressive lymphomas (Hodgkin and non-Hodgkin lymphoma). Most cases of PTLD occur within the first year of transplant.

Patients are also at risk for cancers of the colorectum, breast, cervix, liver, stomach, oropharynx, anus, vulva, and penis. Regular screening for cancer is an important part of the transplant recipient's preventive care. Teach the patient to avoid sun exposure by using protective clothing and sunscreens to minimize the incidence of skin cancers.

Recurrence of Original Kidney Disease

Recurrence of the original disease that destroyed the native kidneys occurs in some kidney transplant recipients. It is most common with certain types of glomerulonephritis, immunoglobulin A (IgA) nephropathy, diabetic nephropathy, and focal segmental sclerosis. Disease recurrence can result in the loss of a functioning kidney transplant. We must advise patients before the transplant if they have a disease known to recur.

Corticosteroid-Related Complications

Aseptic necrosis of the hips, knees, and other joints can result from chronic corticosteroid therapy and renal osteodystrophy. Other problems related to corticosteroids include peptic ulcer disease, diabetes, cataracts, dyslipidemia, infections, and cancers. The use of tacrolimus and other immunosuppressants has allowed corticosteroid doses to be much lower than they were in the past.

Many transplant programs have started corticosteroid-free drug regimens because of the problems of long-term

corticosteroid use. Other centers withdraw patients from corticosteroids after the transplant. For patients who stay on corticosteroids, vigilant monitoring for side effects and prompt treatment is essential. Corticosteroid therapy as immunosuppression is discussed in Chapter 14.

Gerontologic Considerations: Chronic Kidney Disease

The incidence of CKD in the United States is increasing most rapidly in older adults. The most common diseases leading to CKD in older adults are hypertension and diabetes.[30]

The care of older patients is particularly challenging because of the normal physiologic changes of aging and the increased presence of disabilities, chronic diseases, and comorbid problems. Physiologic changes include decreased cardiopulmonary function, bone loss, immunodeficiency, altered protein synthesis, impaired cognition, and altered drug metabolism. Malnutrition is common in these patients for a variety of reasons. These include lack of mobility, social isolation, physical disability, and impaired cognitive function.

When conservative therapy for CKD is no longer effective, the older patient needs to consider the best treatment modality based on physical and emotional health, personal preferences, and availability of support. Quality-of-life measures show no justification for excluding the older adult from dialysis programs. Rationing dialysis based on age alone is not a reasonable decision for health care professionals to make. Older adults have successfully used dialysis, especially PD. Many choose treatment with in-center HD due to a lack of help in the home and reluctance to manage the technology of home HD or PD. Establishing vascular access for HD may be difficult because of atherosclerotic changes.

Although a transplant is an option, older adults are carefully screened to ensure that the benefits outweigh the risks.[31] Although a living donor is preferable, this may not be an option for many older patients.

The most common cause of death in older ESRD patients is CVD (MI, stroke), followed by withdrawal from dialysis. If a competent patient decides to withdraw from dialysis, it is essential to support the patient and family. Ethical issues (Box 51.5) include patient competency, benefit versus burden of treatment, and futility of treatment. Withdrawal from treatment is not a failure if the patient is well informed and comfortable with the decision.

BOX 51.5 ETHICAL/LEGAL DILEMMAS

Withdrawing Treatment

Situation

L.R., a 70-year-old patient with diabetes and ESRD, has been on dialysis for 10 years. He tells you that he wants to stop his dialysis. His quality of life has declined during the past 2 years since his wife died. He is not a transplant candidate.

Ethical/Legal Points for Consideration

- Informed consent includes the legal right to refuse treatment. However, the right to refuse may be difficult if (1) it is contrary to the wishes of family and friends, (2) the treatment is still effective, and (3) the treatment has been in place for some time.
- Quality-of-life decisions often outweigh the benefit against the burden of treatment. When a treatment becomes too burdensome, the patient, if competent, may request to withdraw the treatment.
- It must be determined whether some other treatable problem, such as depression, may be clouding the patient's judgment.
- Although there is no ethical or legal difference between withdrawing treatment and withholding treatment, withdrawing treatment feels different because it requires an action.
- Some health care professionals become conflicted when asked to withdraw treatment, since they may think they are contributing to the patient's premature death.
- If a decision is made to withdraw treatment, the interprofessional care team, patient, and family should develop a follow-up plan that includes palliative care and hospice support.

Discussion Questions

1. How should you respond to L.R.'s request?
2. What is the American Nurses Association's position on withdrawing or withholding treatment that no longer benefits the patient or causes suffering?

Case Study

Chronic Kidney Disease

(© iStockphoto/Thinkstock.)

Patient Profile

M.B. is a 56-year-old college professor. He is having a well visit with his primary HCP. He has not seen an HCP in a little over a year. M.B. reports malaise, frequent urination, and "increasing thirst." His history includes borderline hypertension and dyslipidemia. He smokes 1 pack of cigarettes per day. His efforts to quit have been unsuccessful.

Subjective Data

- Family history: father died of an MI at age 62, brother had coronary artery bypass graft (CABG) at age 50, mother died from complications of diabetes
- Becomes "winded" when walking from his car to his office at the university
- Wakes up at night to urinate and has more frequent urination
- Increasing thirst

Objective Data

Laboratory Data

- Calculated creatinine clearance using the MDRD equation: 42 mL/min/1.73 m^2
- Serum creatinine 6.5 mg/dL
- BUN 85 mg/dL
- Serum glucose 264 mg/dL
- Hgb 13 g/dL
- Serum cholesterol 236 mg/dL

Physical Assessment

- Weight 220 lb, height 5 ft, 11 in
- BP 168/104 mm Hg

Case Study—cont'd

Chronic Kidney Disease

Discussion Questions

1. ***Recognize:*** What may have caused M.B.'s kidney disease?
2. ***Analyze:*** What stage of chronic kidney disease does he have?
3. ***Analyze:*** Identify the abnormal diagnostic study results and why each would occur.
4. ***Plan:*** How can the interprofessional team work together with M.B. to plan the best form of renal replacement therapy?
5. ***Prioritize:*** Based on the assessment data provided, what are the priority clinical problems?
6. ***Prioritize:*** What are the most important treatment measures that the interprofessional team can provide for M.B.?
7. ***Act:*** What interventions would help promote M.B.'s self-management of his disease?
8. ***Act:*** M.B. tells you that he has not been taking his BP medications regularly. When he asks you how important they are, what will you tell him?

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. The nurse using RIFLE to determine the early stage of AKI evaluates the patient's
   - **a.** blood pressure and urine osmolality.
   - **b.** fractional excretion of urinary sodium.
   - **c.** estimation of GFR with the MDRD equation.
   - **d.** serum creatinine or urine output from baseline.
2. During the oliguric phase of AKI, the nurse monitors the patient for *(select all that apply)*
   - **a.** hypotension.
   - **b.** ECG changes.
   - **c.** hypernatremia.
   - **d.** pulmonary edema.
   - **e.** urine with high specific gravity.
3. When a patient is in the diuretic phase of AKI, the nurse must monitor for which serum electrolyte imbalances?
   - **a.** Hyperkalemia and hyponatremia
   - **b.** Hyperkalemia and hypernatremia
   - **c.** Hypokalemia and hyponatremia
   - **d.** Hypokalemia and hypernatremia
4. The nurse assesses the patient with chronic kidney disease with the understanding that this condition is characterized by
   - **a.** progressive irreversible destruction of the kidneys.
   - **b.** a rapid decrease in urine output with an elevated BUN.
   - **c.** an increasing creatinine clearance with a decrease in urine output.
   - **d.** prostration, somnolence, and confusion with coma and imminent death.
5. Nurses can screen patients at risk for developing chronic kidney disease. Those considered to be at increased risk include *(select all that apply)*
   - **a.** older Black patients.
   - **b.** patients more than 60 years old.
   - **c.** those with a history of pancreatitis.
   - **d.** those with a history of hypertension.
   - **e.** those with a history of type 2 diabetes.
6. Which points must the nurse consider when planning nutrition support for patients with chronic kidney disease? *(select all that apply)*
   - **a.** Sodium may be restricted in someone with advanced CKD.
   - **b.** Fluid is not usually restricted for patients on peritoneal dialysis.
   - **c.** Decreased fluid intake and a low-potassium diet are needed for a patient on hemodialysis.
   - **d.** Decreased fluid intake and a low-potassium diet are needed for a patient on peritoneal dialysis.
   - **e.** Decreased fluid intake and a diet in protein-rich foods are part of a diet for a patient on hemodialysis.
7. An ESRD patient receiving hemodialysis is considering asking a relative to donate a kidney for a transplant. In helping the patient decide about treatment, the nurse informs the patient that
   - **a.** successful transplant usually provides better quality of life than that offered by dialysis.
   - **b.** if rejection of the transplanted kidney occurs, no further treatment for the renal failure is available.
   - **c.** hemodialysis replaces normal kidney functions, and they do not have to live with the continual fear of rejection.
   - **d.** immunosuppressive therapy after a transplant makes the person ineligible to receive other treatments if the kidney fails.
8. To assess the patency of a newly placed arteriovenous graft, the nurse should *(select all that apply)*
   - **a.** monitor the BP in the affected arm.
   - **b.** irrigate the graft daily with low-dose heparin.
   - **c.** palpate the area of the graft to feel a normal thrill.
   - **d.** listen with a stethoscope over the graft to detect a bruit.
   - **e.** assess the pulses and neurovascular status distal to the graft.
9. A kidney transplant recipient has had fever, chills, and dysuria over the past 2 days. What is the *first* action that the nurse should take?
   - **a.** Assess temperature and start workup to rule out infection.
   - **b.** Reassure the patient that this is common after a transplant.
   - **c.** Provide warm covers to the patient and give 1 gram oral acetaminophen.
   - **d.** Notify the nephrologist that the patient has manifestations of acute rejection.

1. d; 2. b, d; 3. c; 4. a; 5. a, b, d, e; 6. a, b, c; 7. a; 8. c, d, e; 9. a.

Case Study

Applying Clinical Judgment With Multiple Patients

You are working on the medical-surgical unit and have been assigned to care for the following 4 patients. You are also assigned to receive the next admission. You have 1 AP on your team to help you.

(© iStockphoto/ Thinkstock)	A.K., a 28-year-old man, was admitted with several kidney stones in the left ureter. He is receiving IV morphine sulfate for pain. His current pain level is 4 (1 to 10 scale). He is voiding dark, smoky-colored urine. He has positive costovertebral tenderness. Vital signs: 156/70, 94, RR 24.
(© iStockphoto/ Thinkstock.)	S.U., a 29-year-old woman with type 1 diabetes, was admitted with acute pyelonephritis from a recent UTI. She has bilateral flank pain and abdominal tenderness. UA shows pyuria and hematuria. Blood culture results are pending. The next dose of IV antibiotics is due at 0900. Laboratory results: WBC 14,800/μL, glucose 215 mg/dL. Vital signs: 126/74, 94, RR 20, temp 101.5°F (38.6°C).
(© iStockphoto/ Thinkstock.)	M.B., a 56-year-old man, was admitted with uncontrolled hypertension and CKD. He smokes 1 pack of cigarettes per day and is having some nicotine withdrawal symptoms. BP on admission was 224/102. He is receiving IV metoprolol (Lopressor) 5 mg q4h prn for SBP >180 mm Hg. Laboratory results: BUN 85 mg/dL, creatinine 6.5 mg/dL, glucose 264 mg/dL. Vital signs: 178/86, 88, RR 18.
(© iStockphoto/ Thinkstock.)	D.M., an 82-year-old woman, was admitted with dehydration, heart failure, and acute kidney injury. She is confused. Her potassium is 6.3 mEq/L. Her urine output for the past 8 hours was 90 mL. Vital signs: 142/86, 98, RR 22.

1. Highlight all the findings above that require your follow-up.
2. After receiving report, which patient should you see first? Second?
3. Which tasks could you delegate to the AP? (*select all that apply*)
   a. Obtain vital signs on M.B.
   b. Strain A.K.'s voided urine.
   c. Report D.M.'s potassium level to the HCP.
   d. Measure D.M.'s urine output and report the results to the RN.
   e. Assess S.U. for manifestations of sepsis and diabetic ketoacidosis.
4. As you are assessing D.M., the AP tells you that M.B.'s BP is 190/96. He is asymptomatic. Then the charge nurse calls and tells you that you will receive a patient with heart failure from the ED in the next 20 min. Which action would be *most* appropriate?
   a. Ask the charge nurse to assign the new admission to someone else.
   b. Have the AP admit the new patient while you administer M.B.'s IV metoprolol.
   c. Call the ED and have them hold the new admission until after you have assessed all your patients.
   d. Ask the charge nurse to give M.B.'s IV metoprolol while you complete your assessment of D.M. and S.U.

Case Study Progression

As you complete your assessment of D.M., you note she has 1+ pitting edema in her lower extremities. Her BP is 160/90 mm Hg, heart rate 108 beats/min, and respiratory rate 32/min. Auscultation reveals crackles in the lung bases and O_2 saturation is 88% on room air. The skin is cool, and she is reporting dyspnea.

5. Based on these assessment findings, you suspect D.M. is experiencing _____**1**_____. You notify the HCP, expecting orders for _____**2**_____, _____**2**_____, and _____**2**_____.

Options for 1	Options for 2
Pulmonary edema	12-lead ECG and continuous ECG monitoring
Pulmonary embolism	furosemide
Unstable angina	heparin
	nitroglycerin
	O_2 therapy

6. A.K. is reporting pain rated as 8 (1 to 10 scale) and requests IV morphine. What would you do first?
   a. Assess the patency of A.K.'s IV site.
   b. Prepare the dose using sterile technique.
   c. Determine the last time A.K. received IV morphine.
   d. Scan A.K.'s ID band and the medication according to agency policy.
7. You begin S.U.'s scheduled infusion of IV ceftriaxone and perform her assessment. Use an X for the nursing actions listed below that are Indicated (appropriate or necessary), Contraindicated (could be harmful), or Nonessential (makes no difference or not necessary) for S.U. at this time.

Nursing Action	Indicated	Contraindicated	Nonessential
Monitor BUN and creatinine levels.			
Maintain intake and output.			
Medicate with ibuprofen every 6 hr as needed for pain.			
Initiate a fluid restriction.			
Encourage her to void every 3–4 hr while awake.			
Assess for the presence of bowel sounds every 4 hr.			

8. Which statement would be *most* appropriate when teaching S.U. about her kidney infection?
   a. "The damage to your kidneys will likely require dialysis."
   b. "You will need to be in the hospital for a 2-week course of IV antibiotics."
   c. "It is very important that you maintain adequate hydration to flush your kidneys."
   d. "You will not need further antibiotics once you are discharged from the hospital."

Continued

Case Study—cont'd

9. As the AP prepares the room for the patient being admitted from the ED, you overhear her telling a coworker that she does all your work for you. What is your *best* initial action?
   a. Report the incident to the charge nurse for follow-up.
   b. Ask the AP to discuss her concerns with you in private.
   c. Tell the AP how much you appreciate and value her input on your team.
   d. Immediately clarify the situation by telling the AP all the tasks you are completing.
10. You are reviewing S.U.s latest assessment findings. For each assessment finding, use an X to indicate whether the interventions were Effective (helped to meet expected outcomes), Ineffective (did not help to meet expected outcomes), or Unrelated (not related to the expected outcomes).

Assessment Finding	Effective	Ineffective	Unrelated
BUN 55 mg/dL, creatinine 3.5 mg/dL			
Reports wiping front to back after voiding			
No flank pain or dysuria			
Voiding clear, yellow urine 5–6 times per day			
Lungs clear to auscultation			
UA shows hematuria			

52

Assessment: Endocrine System

Julia A. Hitch

http://evolve.elsevier.com/Lewis/medsurg/

CONCEPTUAL FOCUS

Homeostasis
Hormonal Regulation
Reproduction
Stress

LEARNING OUTCOMES

1. Describe the common characteristics and functions of hormones.
2. Identify the locations of the endocrine glands.
3. Describe the functions of hormones secreted by the pituitary, thyroid, parathyroid, and adrenal glands and the pancreas.
4. Obtain significant subjective and objective assessment data related to the endocrine system from a patient.
5. Perform a physical assessment of the endocrine system using the appropriate techniques.
6. Link age-related changes in the endocrine system to differences in assessment findings.
7. Distinguish normal from common abnormal findings of a physical assessment of the endocrine system.
8. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the endocrine system.

KEY TERMS

aldosterone
antidiuretic hormone (ADH)
catecholamines
circadian rhythm
corticosteroid
cortisol
hormones
insulin
negative feedback
positive feedback
thyroxine (T_4)
triiodothyronine (T_3)
tropic hormones

STRUCTURES AND FUNCTIONS OF ENDOCRINE SYSTEM

Glands

Endocrine glands include the hypothalamus, pituitary, thyroid, parathyroids, adrenals, pancreas, ovaries, testes, and pineal gland (Fig. 52.1). These glands make and release special chemical messengers called *hormones.* The endocrine system has 5 general functions: (1) a role in reproductive and central nervous system (CNS) development in the fetus, (2) stimulating growth and development during childhood and adolescence, (3) sexual reproduction, (4) maintaining homeostasis, and (5) responding to emergency demands.

Hormones

Hormones are chemical substances made by endocrine glands that control and regulate the activity of certain target cells or organs. Many are made in one part of the body and control and regulate the activity of certain cells or organs in another part of the body. The thyroid gland makes the hormone thyroxine, which affects many body tissues when released directly into the circulation. Other hormones act locally on cells where they are released and never enter

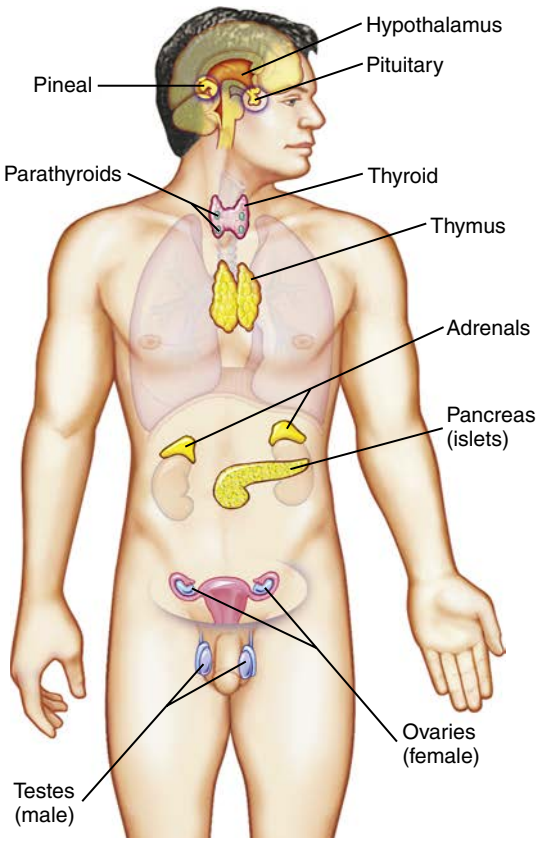

Fig. 52.1 Location of the major endocrine glands. The parathyroid glands lie on the posterior surface of the thyroid gland. (Modified from Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.)

the bloodstream. We call this local effect *paracrine action.* The action of sex steroids on the ovary is an example of paracrine action.

Most hormones have common characteristics. They are (1) secreted in small amounts at variable but predictable rates, (2) regulated by feedback systems, and (3) able to bind to specific target cell receptors. Table 52.1 reviews the main hormones, the glands or tissues that make the hormones, their target organs or tissues, and their functions.

The endocrine system and nervous system have a strong connection. *Catecholamines* (e.g., epinephrine), secreted by the adrenal gland, travel through the bloodstream and affect multiple organ systems. When secreted by nerve cells in the brain and peripheral nervous system, these same substances act as neurotransmitters, sending important impulses across nerve synapses.

Organs can act as endocrine glands by secreting hormones. For example, the kidneys secrete erythropoietin. It stimulates red blood cell production. The heart secretes atrial natriuretic peptide (ANP). The gastrointestinal (GI) tract secretes many peptide hormones (e.g., gastrin) that aid in digestion. These hormones are discussed in their respective assessment chapters.

Hormone Receptors

Hormones exert their effects by recognizing their target tissues and attaching to receptor sites in a "lock-and-key" type of mechanism. This means a hormone will act only on cells with a receptor specific to that hormone (Fig. 52.2).

Lipid-Soluble and Water-Soluble Hormones

We classify hormones by their chemical structure as lipid soluble or water soluble. The difference in solubility is important in understanding how the hormone interacts with the target cell (Fig. 52.3). Lipid-soluble hormones (steroids, thyroid) are bound to plasma proteins as they travel to target cells. They cross the cell membrane by simple diffusion. Water-soluble hormones (insulin, growth hormone [GH], prolactin) circulate freely in the blood and act directly on target tissues.

Regulation of Hormonal Secretion

Specific mechanisms control endocrine activity by either stimulating or inhibiting hormone synthesis and secretion. These include positive and negative feedback, nervous system control, and physiologic rhythms.

Simple feedback. **Negative feedback** relies on the blood level of a hormone or other chemical compound regulated by the hormone (e.g., glucose). It is the most common type of endocrine feedback system. It results in the gland increasing or decreasing the release of a hormone. An example of negative feedback is calcium and parathyroid hormone (PTH) regulation. Low blood levels of calcium stimulate the parathyroid gland to release PTH. PTH acts on the bone, intestine, and kidneys to increase blood calcium levels. The increased blood calcium level then inhibits further PTH release (Fig. 52.4).

With **positive feedback**, increasing hormone levels cause another gland to release a hormone that stimulates further release of the first hormone. Something must stop the release of the first hormone (e.g., follicle death), or its release will continue. The ovarian hormone estradiol works by this type of feedback. Increased estradiol levels made by the follicle during the menstrual cycle result in the production and release of follicle-stimulating hormone (FSH) by the anterior pituitary. FSH causes further increases in estradiol until the death of the follicle. This results in a drop in FSH serum levels.

Nervous system control. Nervous system activity directly affects some endocrine glands. Pain, fear, sexual excitement, and other stressors can stimulate the nervous system to control hormone secretion. For example, when the CNS senses or perceives stress, the sympathetic nervous system (SNS) secretes catecholamines (e.g., epinephrine), which maximize heart and lung function and vision to deal with the stress more effectively. Chronic exposure to some stressors can cause persistent increases in heart rate and BP and changes in the endocrine system. This puts patients at risk for chronic disease, such as hypertension and heart disease. Stress-related effects are discussed in Chapter 7.

Rhythms. A common physiologic rhythm is the **circadian rhythm**. It is a 24-hour rhythm that is driven by sleep-wake or dark-light 24-hour (diurnal) cycles. Hormone levels and the responsiveness of target tissues fluctuate predictably during these cycles. Cortisol, made by the adrenal cortex, rises early in the day, declines toward evening, and rises again toward

TABLE 52.1 Endocrine Glands and Hormones

Hormones	Target Tissue	Functions
Anterior Pituitary (Adenohypophysis)		
Adrenocorticotropic hormone (ACTH)	Adrenal cortex	Fosters growth of adrenal cortex Stimulates corticosteroid secretion
Gonadotropic hormones • Follicle-stimulating hormone (FSH) • Luteinizing hormone (LH)	Reproductive organs	Stimulates sex hormone secretion, reproductive organ growth, reproductive processes
Growth hormone (GH), or somatotropin	All body cells	Promotes protein anabolism (growth, tissue repair) and lipid mobilization and catabolism
Melanocyte-stimulating hormone (MSH)	Melanocytes in skin	↑ Melanin production in melanocytes
Prolactin	Ovary and mammary glands in women	Stimulates milk production in lactating women. ↑ Response of follicles to LH and FSH
	Testes in men	Stimulates testicular function in men
Thyroid-stimulating hormone (TSH), or thyrotropin	Thyroid gland	Stimulates synthesis and release of thyroid hormones, growth and function of thyroid gland
Posterior Pituitary (Neurohypophysis)		
Antidiuretic hormone (ADH)	Renal tubules, vascular smooth muscle	Promotes reabsorption of water from the renal tubules, vasoconstriction
Oxytocin	Uterus, mammary glands	Stimulates milk secretion, uterine contractility
Thyroid		
Calcitonin	Bone tissue	Regulates calcium and phosphorus serum levels. ↓ Serum Ca^{2+} levels
Thyroxine (T_4)	All body tissues	Precursor to T_3
Triiodothyronine (T_3)	All body tissues	Regulates metabolic rate of all cells and processes of cell growth and tissue differentiation
Parathyroids		
Parathyroid hormone (PTH) or parathormone	Bone, intestine, kidneys	Regulates calcium and phosphorus serum levels. Promotes bone demineralization and ↑ intestinal absorption of Ca^{2+}. ↑ Serum Ca^{2+} levels
Adrenal Medulla		
Epinephrine (adrenaline)	Catecholamine	↑ In response to stress. Enhances and prolongs effects of sympathetic nervous system
Norepinephrine (noradrenaline)	Catecholamine	↑ In response to stress. Enhances and prolongs effects of sympathetic nervous system
Adrenal Cortex		
Androgens (e.g., dehydroepiandrosterone [DHEA], androsterone) and estradiol	Reproductive organs	Promotes growth spurt in adolescence, secondary sex characteristics, and libido in both sexes
Corticosteroids (e.g., cortisol, hydrocortisone)	All body tissues	Promotes metabolism. ↑ In response to stress. Antiinflammatory
Mineralocorticoids (e.g., aldosterone)	Kidney	Regulates sodium and potassium balance and thus water balance
Pancreas (Islets of Langerhans)		
Amylin (from β cells)	Liver, stomach	↓ Gastric motility, glucagon secretion, and endogenous glucose release from liver. ↑ Satiety
Glucagon (from α cells)	General	Stimulates glycogenolysis and gluconeogenesis
Insulin (from β cells)	General	Promotes glucose transport from the blood into the cell
Pancreatic polypeptide	General	Influences regulation of pancreatic exocrine function and metabolism of absorbed nutrients
Somatostatin	Pancreas	Inhibits insulin and glucagon secretion
Gonads		
Women: Ovaries		
Estrogen	Reproductive system, breasts	Stimulates development of secondary sex characteristics, preparation of uterus for fertilization, and fetal development. Stimulates bone growth
Progesterone	Reproductive system	Maintains lining of uterus needed for successful pregnancy
Men: Testes		
Testosterone	Reproductive system	Stimulates development of secondary sex characteristics, spermatogenesis

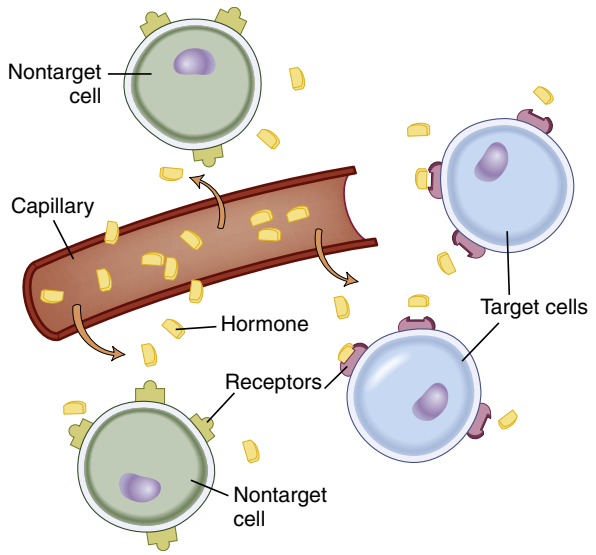

Fig. 52.2 The target cell concept. Hormones act only on cells with receptors specific to that hormone since the receptor's shape determines which hormone can react with it. This is an example of the lock-and-key model of biochemical reactions.

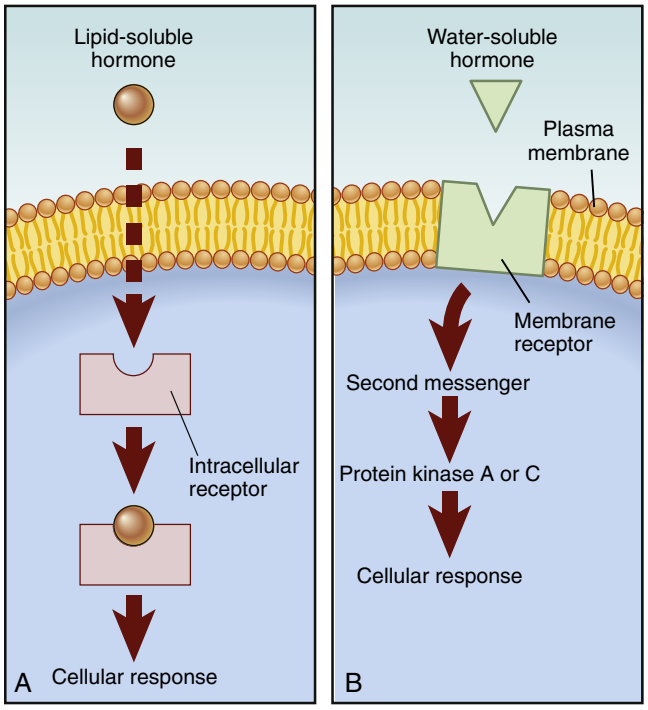

Fig. 52.3 (A) Lipid-soluble hormones (e.g., steroid hormones) penetrate the cell membrane and interact with intracellular receptors. (B) Water-soluble hormones (e.g., protein hormones) bind to receptors in the cell membrane. The hormone-receptor interaction stimulates various cell responses. (Modified from McCance KL, Huether SE: *Pathophysiology: the biologic basis for disease in adults and children*, ed 6, St Louis, 2010, Mosby.)

the end of sleep to peak by morning (Fig. 52.5). GH, thyroid-stimulating hormone (TSH), and prolactin levels peak during sleep. Reproductive cycles are often longer than 24 hours *(ultradian)*. An example is the menstrual cycle. We must consider these rhythms when interpreting laboratory results for hormone levels.

Hypothalamus

Although many call the pituitary gland the "master gland" of the endocrine system, most of its functions rely on its interrelationship with the hypothalamus. The hypothalamus releases substances that either stimulate or inhibit the production and release of hormones from the pituitary gland (Table 52.2). Examples of these hormones include corticotropin-releasing hormone (CRH) and thyrotropin-releasing hormone (TRH). Somatostatin inhibits GH release.

Neurons in the hypothalamus receive input from the CNS, including the brainstem, limbic system, and cerebral cortex. These neurons create a circuit that helps coordinate the endocrine system and autonomic nervous system (ANS). The hypothalamus also coordinates the expression of complex behavioral responses, such as anger, fear, and pleasure.

Pituitary

The pituitary gland *(hypophysis)* is in the sella turcica under the hypothalamus at the base of the brain above the sphenoid bone (Fig. 52.1). The infundibular *(hypophyseal)* stalk connects the pituitary and hypothalamus. The stalk relays information between the hypothalamus and pituitary, creating a strong neuroendocrine connection. The pituitary consists of 2 main parts, the anterior lobe *(adenohypophysis)* and posterior lobe *(neurohypophysis)*. A smaller intermediate lobe makes melanocyte-stimulating hormone (MSH).

Anterior Pituitary

The anterior lobe of the pituitary accounts for 80% of the gland by weight. The hypothalamus regulates the anterior lobe through releasing and inhibiting hormones. These hypothalamic hormones reach the anterior pituitary through a network of capillaries known as the *hypothalamus-hypophyseal portal system.* These releasing and inhibiting hormones, in turn, affect the secretion of 6 hormones from the anterior pituitary (Fig. 52.6).

We refer to several hormones secreted by the anterior pituitary as **tropic hormones**. Tropic hormones control the secretion of hormones by other glands. TSH stimulates the thyroid gland to secrete thyroid hormones. Adrenocorticotropic hormone (ACTH) stimulates the adrenal cortex to secrete corticosteroids. FSH stimulates secretion of estrogen and the development of ova in women and sperm in men. Luteinizing hormone (LH) stimulates ovulation in women and secretion of sex hormones in both men and women.

Growth hormone affects the growth and development of all body tissues. It has many biologic actions, including a role in protein, fat, and carbohydrate metabolism. *Prolactin,* or lactogenic hormone, stimulates the breast development needed for lactation after childbirth.

Posterior Pituitary

The posterior pituitary is composed of nerve tissue and is essentially an extension of the hypothalamus. Communication

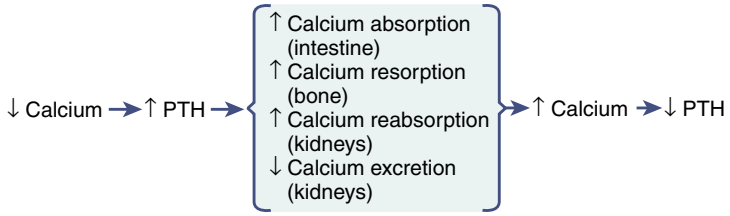

Fig. 52.4 Feedback mechanism between PTH and calcium.

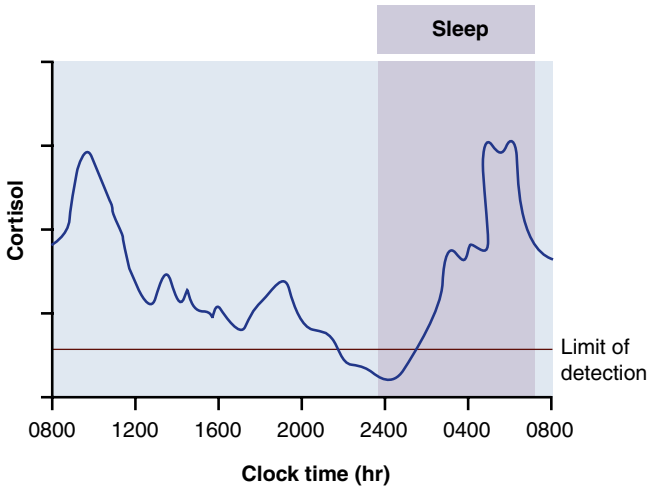

Fig. 52.5 Circadian rhythm of cortisol secretion.

TABLE 52.2 Hormones of the Hypothalamus

The following hormones from the hypothalamus target the anterior pituitary:

Releasing Hormones
- Corticotropin-releasing hormone (CRH)
- Thyrotropin-releasing hormone (TRH)
- Growth hormone–releasing hormone (GHRH)
- Gonadotropin-releasing hormone (GnRH)
- Prolactin-releasing factor (PRF)

Inhibiting Hormones
- Somatostatin (inhibits growth hormone release)
- Prolactin-inhibiting factor (PIF)

between the hypothalamus and posterior pituitary occurs through nerve tracts. The hormones secreted by the posterior pituitary, **antidiuretic hormone (ADH)** and oxytocin, are made in the hypothalamus. These hormones travel down the nerve tracts from the hypothalamus to the posterior pituitary and are stored there until stimuli trigger their release (Fig. 52.6).

The main physiologic role of ADH *(arginine vasopressin)* is to regulate fluid volume. It causes the renal tubules to reabsorb water, making the urine more concentrated. A rise in plasma osmolality or hypovolemia causes specialized neurons in the hypothalamus, called *osmoreceptors,* to stimulate ADH release from the posterior pituitary (Fig. 52.7). When ADH release is inhibited, renal tubules do not reabsorb water, resulting in more dilute urine. Volume receptors in large veins, heart atria, and carotid arteries that sense pressure changes (from hypovolemia) also contribute to ADH control. ADH is also a potent vasoconstrictor.

Pineal Gland

The pineal gland is in the brain. It is composed of photoreceptive cells. Its primary function is the secretion of the hormone *melatonin.* Melatonin secretion increases in response to exposure to the dark and decreases in response to light exposure. The gland helps to regulate circadian rhythms and the reproductive system at the onset of puberty.

Thyroid Gland

The thyroid gland is in the anterior part of the neck in front of the trachea. It consists of 2 encapsulated lateral lobes connected by a narrow isthmus (Fig. 52.8). The thyroid gland is highly vascular. Its size is related to TSH secretion by the anterior pituitary. The 3 hormones made and secreted by the thyroid gland are thyroxine (T_4), triiodothyronine (T_3), and calcitonin.

Thyroxine and Triiodothyronine

Thyroxine (T_4) accounts for 90% of thyroid hormone made by the thyroid gland. **Triiodothyronine (T_3)** is much more potent and has greater metabolic effects. The thyroid gland directly secretes about 20% of circulating T_3. The rest comes from the conversion of T_4 after its release into the bloodstream. Iodine is needed to synthesize T_3 and T_4. Both hormones affect metabolic rate, caloric requirements, O_2 consumption, carbohydrate and lipid metabolism, growth and development, brain function, and other nervous system activities. More than 99% of thyroid hormones are bound to plasma proteins, especially thyroxine-binding globulin made by the liver. Only the unbound "free" hormones are biologically active.

TSH from the anterior pituitary gland stimulates thyroid hormone production and release. When circulating levels of thyroid hormone are low, the hypothalamus releases TRH. TRH causes the anterior pituitary to release TSH. High circulating thyroid hormone levels inhibit the secretion of both TRH from the hypothalamus and TSH from the anterior pituitary gland.

Calcitonin

Calcitonin is made by C cells (parafollicular cells) of the thyroid gland in response to high circulating calcium levels.

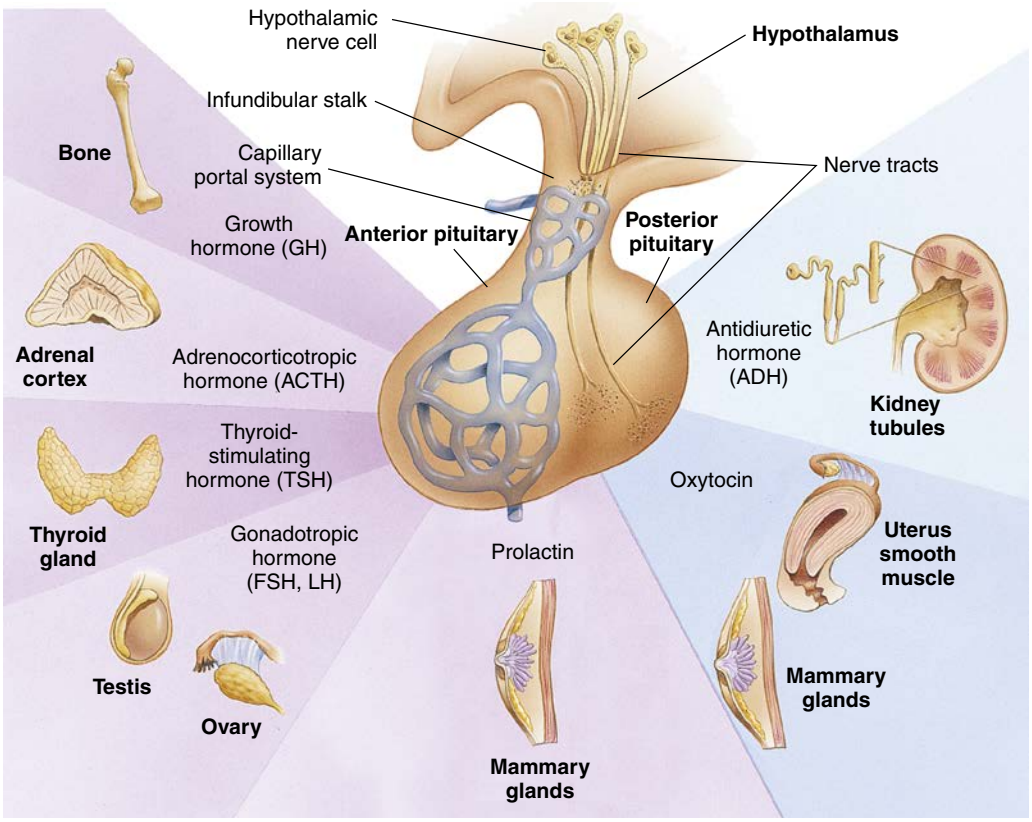

Fig. 52.6 Relationship between the hypothalamus, pituitary, and target organs. The hypothalamus communicates with the anterior pituitary via a capillary system and with the posterior pituitary via nerve tracts. The anterior and posterior pituitary hormones are shown with their target tissues. (Modified from Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.)

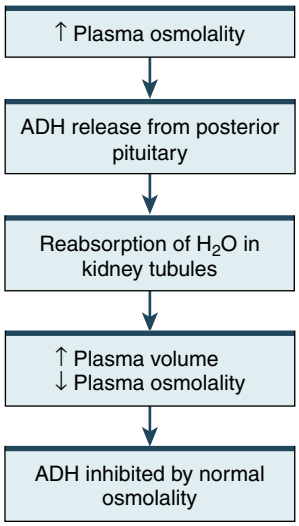

Fig. 52.7 Relationship of plasma osmolality to ADH release and action.

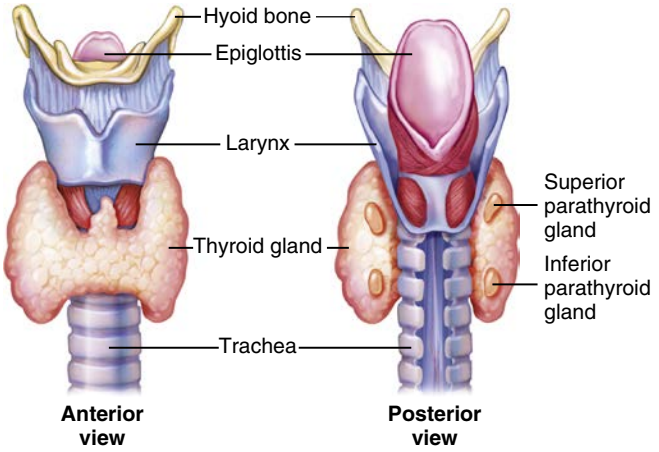

Fig. 52.8 Thyroid and parathyroid glands. Note the surrounding structures. (From Thibodeau GA, Patton KT: *The human body in health and disease,* ed 4, St Louis, 2005, Mosby.)

Calcitonin lowers serum calcium levels by (1) inhibiting the transfer of calcium from the bone to blood, (2) increasing calcium storage in bone, and (3) increasing renal excretion of calcium and phosphorus. Calcitonin and PTH regulate calcium balance.

Parathyroid Glands

There are usually 2 pairs of parathyroid glands lying behind each thyroid lobe (Fig. 52.8). Although there are usually 4 glands, their number may range from 2 to 6.

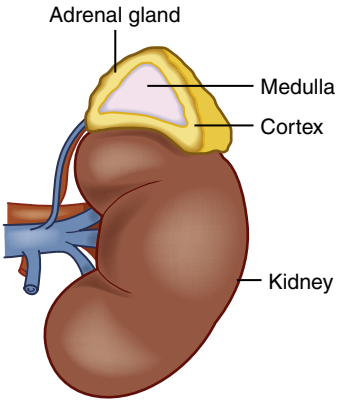

Fig. 52.9 The adrenal gland is composed of the adrenal cortex and the adrenal medulla.

Parathyroid Hormone

The parathyroid glands secrete PTH, or *parathormone*. Its major role is to regulate serum calcium levels. PTH increases serum calcium levels by acting on bone, the kidneys, and indirectly on the GI tract. PTH stimulates the transfer of calcium from the bone into the blood. In the kidney, PTH promotes calcium reabsorption (moving calcium from the renal tubules back into the bloodstream) and phosphate excretion. PTH stimulates the renal conversion of vitamin D to its most active form (1,25-dihydroxyvitamin D_3). This form of vitamin D promotes calcium and phosphorus absorption in the GI tract. PTH secretion is regulated by a negative feedback system. When serum calcium or magnesium levels are low, PTH secretion increases. When serum calcium or active vitamin D levels are high, PTH secretion falls.

Adrenal Glands

The adrenal glands are small, paired, highly vascular glands located on the upper part of each kidney. Each gland consists of 2 parts: medulla and cortex (Fig. 52.9). Each part has distinct functions and acts independently from the other.

Adrenal Medulla

The adrenal medulla is the inner part of the adrenal gland. It consists of sympathetic postganglionic neurons. The medulla secretes the **catecholamines** *epinephrine* (adrenaline), *norepinephrine* (noradrenaline), and *dopamine*. We consider catecholamines neurotransmitters when secreted by neurons and hormones when secreted by the adrenal medulla. They are an essential part of the SNS's "fight or flight" response.

Adrenal Cortex

The adrenal cortex is the outer part of the adrenal gland. It secretes several steroid hormones, including *glucocorticoids, mineralocorticoids,* and *androgens.* Cholesterol is the precursor for steroid hormone synthesis. Glucocorticoids (e.g., cortisol) are named for their effects on glucose metabolism. They inhibit the inflammatory response and are considered antiinflammatory. Mineralocorticoids (e.g., aldosterone) are essential for maintaining fluid and electrolyte balance. The term **corticosteroid** refers to both glucocorticoids and mineralocorticoids.

Cortisol. **Cortisol**, the most abundant and potent glucocorticoid, is necessary to maintain life and protect the body from stress. It is secreted in a diurnal pattern (Fig. 52.5). A negative feedback mechanism controls cortisol secretion. The release of CRH from the hypothalamus stimulates the anterior pituitary to secrete ACTH.

A key function of cortisol is regulating blood glucose concentration by stimulating hepatic glucose formation *(gluconeogenesis).* Cortisol inhibits peripheral glucose use in the fasting state, inhibits protein synthesis, and stimulates the mobilization of glycerol and free fatty acids. It helps maintain vascular integrity and fluid volume through its action on mineralocorticoid receptors. Cortisol decreases the inflammatory response by stabilizing the membranes of cellular lysosomes and preventing increased capillary permeability. Stress, burns, infection, fever, acute anxiety, and hypoglycemia increase cortisol levels.

Aldosterone. **Aldosterone** is a potent mineralocorticoid that maintains extracellular fluid volume. It acts on the renal tubule to promote renal reabsorption of sodium and excretion of potassium and hydrogen ions. Hyponatremia, hyperkalemia, and angiotensin II stimulate aldosterone synthesis and secretion. ANP and hypokalemia inhibit aldosterone synthesis and release.

Adrenal androgens. The adrenal cortex secretes small amounts of androgens. They are converted to sex steroids in peripheral tissues: testosterone in men and estrogen in women. The most common adrenal androgens are dehydroepiandrosterone (DHEA) and androstenedione. Because they are precursors to other sex steroids, their actions are like those of testosterone and estrogen. In postmenopausal women, the main source of estrogen is the peripheral conversion of adrenal androgens to estrogen.

Pancreas

The pancreas is a long, tapered, lobular, soft gland located behind the stomach and anterior to the first and second lumbar vertebrae. The pancreas has both exocrine and endocrine functions. The hormone-secreting part of the pancreas is the *islets of Langerhans.* The islets account for less than 2% of the gland. They consist of 4 types of hormone-secreting cells: α, β, delta, and F cells. The α cells make and secrete the hormone glucagon. The β cells make and secrete insulin and amylin. Delta cells make and secrete somatostatin. F (or PP) cells secrete pancreatic polypeptide.

Glucagon

Pancreatic α cells release *glucagon* in response to low blood glucose levels, protein ingestion, and exercise. Glucagon increases blood glucose, providing fuel for energy by stimulating glycogenolysis (breakdown of glycogen into glucose), gluconeogenesis (formation of glucose from noncarbohydrate molecules), and ketogenesis. Glucagon and insulin function in a reciprocal manner to maintain normal blood glucose levels.

Insulin

Insulin is the main regulator of metabolism and storage of ingested carbohydrates, fats, and proteins. Insulin facilitates glucose transport into cells, transport of amino acids across muscle membranes, and the synthesis of amino acids into protein in the peripheral tissues. However, the brain, nerves, lens of the eye, hepatocytes, erythrocytes, and cells in the intestinal mucosa and kidney tubules are not dependent on insulin for glucose uptake. After a meal, insulin is responsible for how we use and store nutrients *(anabolism)*. An increased blood glucose level is the major stimulus for insulin synthesis and secretion. Low blood glucose levels, glucagon, somatostatin, hypokalemia, and catecholamines usually inhibit insulin secretion.

Gerontologic Considerations: Effects of Aging on Endocrine System

Normal aging has many effects on the endocrine system (Table 52.3). These include (1) decreased hormone production and secretion, (2) altered hormone metabolism and biologic activity, (3) decreased responsiveness of target tissues to hormones, and (4) changes in circadian rhythms.

Assessing the effects of aging on the endocrine system may be difficult. The subtle changes of aging may mimic manifestations of endocrine problems. Endocrine problems may manifest differently in an older adult. Older adults may have multiple co-morbidities and take medications that change the body's usual response to endocrine function. Symptoms of endocrine problems, such as fatigue, constipation, or mental impairment, may be attributed to aging, resulting in delayed treatment.

TABLE 52.3 GERONTOLOGIC ASSESSMENT DIFFERENCES

Endocrine System

Changes	Clinical Significance
Thyroid	
Atrophy of thyroid gland ↓ T_3, T_4, TSH secretion ↑ Nodules	↑ Incidence of hypothyroidism Most older adults maintain adequate thyroid function Thyroid hormone replacement dose lower in older adults
Parathyroid	
↑ PTH secretion ↑ Basal level of PTH	↑ Calcium resorption from bone Hypercalcemia, hypercalciuria (may reflect defective renal mechanism)
Adrenal Cortex	
Adrenal cortex becomes more fibrotic and slightly smaller ↓ Cortisol metabolism ↓ Plasma levels of adrenal androgens and aldosterone	↓ Metabolic clearance rate for glucocorticoids
Adrenal Medulla	
↑ Secretion and basal level of norepinephrine ↓ β-Adrenergic receptor response to norepinephrine	↓ Responsiveness to β-adrenergic agonists and receptor blockers May partly explain ↑ incidence of hypertension with aging
Pancreas	
↑ Fibrosis and fatty deposits in pancreas ↑ Glucose intolerance with ↓ sensitivity to insulin	May partly contribute to ↑ incidence of diabetes with advanced aging
Gonads	
Women: ↓ Estrogen secretion	Have menopausal symptoms ↑ Risk for arteriosclerosis and osteoporosis
Men: ↓ Testosterone secretion	Men may or may not have symptoms

Case Study

Patient Introduction

(© iStockphoto/Thinkstock.)

L.M. is a 35-year-old woman who comes to the clinic saying she is "just not feeling well." Her husband, H.M., is with her. L.M. states that she has gained a lot of weight despite trying to watch her diet and just seems to be getting more and more tired. H.M. voices concerns about the changes in his wife's energy level.

Discussion Questions

1. What are the possible causes of L.M.'s weight gain, fatigue, and irritability?
2. What would be your priority assessment of L.M.?
3. What questions would you ask L.M.?

You will learn more about L.M. and her condition as you read this assessment chapter.

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

ASSESSMENT OF ENDOCRINE SYSTEM

Endocrine problems generally result from too much or too little of a specific hormone. The onset of symptoms is often gradual. Subtle or vague symptoms are often attributed to other physiologic or psychologic causes. Patients may present with fluid and electrolyte imbalances, altered tissue perfusion, changes in heart rhythm, or changes in skin integrity that can be interpreted as other problems. Some patients may present with acute symptoms that are life threatening and need immediate intervention.

Subjective Data

Information obtained from the patient can provide important clues about endocrine system function. Obtain a thorough history from the patient and/or a caregiver if the patient's mental acuity is compromised.

Important Health Information

Health history. Patients with endocrine problems often present with nonspecific complaints. They may report not just one but a group of symptoms. The most common presenting problems include fatigue, weakness, menstrual problems, and weight changes. It is important to determine if the onset of symptoms has been gradual or sudden and what the patient has done about them.

Because some of the more general signs of problems are the easiest to overlook, evaluate any reported or observed changes in weight, appetite, skin, libido, mental acuity, emotional stability, or energy levels.

Medications. Ask about the use of all medications, herbs, and diet supplements. Ask about the reason for taking the drug, the dosage, and the length of time the drug has been taken. Are they using hormone replacements, such as insulin, thyroid hormone, or corticosteroids (e.g., prednisone)? This will alert you to potential adverse drug events. For example, corticosteroids may increase blood glucose levels and cause bone loss with long-term use. Thyroid agents may cause tachycardia or dysrhythmias. Drug-to-drug interactions and adverse effects of nonhormonal medications can contribute to endocrine problems.

Surgery or other treatments. Ask about medical, surgical, and obstetric history. Include the number of pregnancies and live births. Assess growth patterns and stages of physical and emotional development. For example, knowing about radiation therapy to the head and neck is important when you suspect thyroid or pituitary problems.

Functional Health Patterns

Key questions to ask the patient with an endocrine problem are outlined in Table 52.4.

TABLE 52.4 HEALTH HISTORY

Endocrine System

Health Perception–Health Management
- What is your usual day like?
- Have you noticed any changes in your ability to perform your usual activities compared with last year? 5 years ago?[a]

Nutritional-Metabolic
- What are your weight and height?
- How much do you want to weigh?
- Have there been any changes in your appetite or weight?[a]
- Have you noticed any changes in the distribution of the hair anywhere on your body?[a]
- Have you noticed any changes in the color of your skin, especially on your face, neck, hands, or body creases?[a]
- Has the texture of your skin changed? For example, does it seem thicker and drier than it used to?[a]
- Have you noticed any problems swallowing, throat pain, or hoarseness? Is the top button on your shirt or blouse hard to button?[a]
- Do you feel more nervous than you used to? Do you notice your heart pounding or that you sweat when you do not think you should be sweating?
- Is it hard to hold things because of shakiness of your hands?[a]
- Do you feel that most rooms are too hot or too cold? Do you often have to put on a sweater, or feel as though you need to open windows when others in the room seem comfortable?[a]
- Do you have, or have you had any wounds that were slow to heal?[a]

Elimination
- Do you have to get up at night to urinate? If so, how many times? Do you keep water by your bed at night?
- Have you ever had a kidney stone?[a]
- Describe your usual bowel pattern. Have you noted any bowel changes?[a]
- Do you use anything, such as laxatives, to help you move your bowels?[a]

Activity-Exercise
- What is your usual activity pattern during a typical day?
- Do you have a planned exercise program? If yes, what is it and have you had to make any changes in this routine lately? If so, why, and what kinds of changes?
- Do you have fatigue with or without activity?[a]
- Have you had any trouble breathing?[a]

Sleep-Rest
- How many hours do you sleep at night? Do you feel rested on awakening?
- Are you ever awakened by sweating during the night?[a]
- Do you have nightmares?[a]

Cognitive-Perceptual
- How is your memory? Have you noticed any changes?[a]
- Have you had any blurring or double vision?[a]
- When was your last eye examination?

Self-Perception–Self-Concept
- Have you noticed any changes in your physical appearance or size?[a]
- Are you concerned about your weight?[a]
- Do you feel you are able to do what you think you can do? If not, why not?
- Does your health problem affect how you feel about yourself?[a]

Role-Relationship
- Do you have a support system or partner? Are you married? Do you have any children? Do you think you are able to take care of your family and home? If not, why not?
- Where do you work? What kind of work do you do? Are you able to do what is expected of you and what you expect of yourself?
- Are you retired? What type of work did you do before you retired? How do you spend your time now that you have retired?

Sexuality-Reproductive

Women
- When did you start to menstruate? Was this earlier or later than other women in your family?
- When was your last menstrual period? Do you have scant, heavy, or irregular menstrual flows?
- How many children have you had? How much did they weigh at birth? Were you told you had diabetes during any pregnancy?[a]
- Are you menopausal? If so, for how long?
- Are you trying to get pregnant but cannot?[a]
- Are you postmenopausal? If so, do you have any bleeding from your uterus?

Men
- Have you noticed any changes in your ability to get and maintain an erection?[a]
- Are you trying to have children but cannot?[a]

Coping–Stress Tolerance
- What kind of stressors do you have?
- How do you deal with stress or problems?
- What is your support system? To whom do you turn when you have a problem?

Value-Belief
- Do you think medicine should still be taken even though you feel okay?
- Do any of your prescribed therapies cause any conflict in your value-belief system?[a]

[a]If yes, describe.

BOX 52.1 GENETIC RISK ALERT

Pituitary

- Nephrogenic diabetes insipidus can be inherited as a sex-linked or autosomal disorder.

Thyroid

- Genetics has a role in many cases of hypothyroid and hyperthyroid problems.
- Hashimoto thyroiditis, the most common cause of hypothyroidism, and Graves' disease, a cause of hyperthyroidism, are autoimmune disorders. Both likely result from a combination of genetic and environmental factors.

Multiple Endocrine Neoplasia (MEN)

- MEN involves tumors in 2 or more different endocrine glands.
- The features of MEN are relatively consistent within a family.
- Medullary thyroid cancer is common in MEN type 2.[2]

Diabetes

- Genetics has a strong role in the development of type 1 and type 2 diabetes.

Health perception–health management pattern. Heredity plays a key role in the development of endocrine problems (Box 52.1). Ask about first-degree relatives with diabetes, thyroid disease, or endocrine gland cancers since these conditions have a familial tendency. A genetic assessment of family members may be needed.

Nutritional-metabolic pattern. Changes in appetite and weight can indicate an endocrine problem. Ask about a history of weight distribution and changes. Weight loss with increased appetite may occur with hyperthyroidism or diabetes. Weight gain may occur with hypothyroidism or hypocortisolism. Obese persons are more likely to develop type 2 diabetes.

Ask if there have been problems with nausea, vomiting, or diarrhea. An enlarged thyroid gland can cause problems swallowing or a change in neck size. Increased SNS activity, including nervousness, palpitations, sweating, and tremors, may occur with thyroid problems or a rare tumor of the adrenal medulla *(pheochromocytoma)*. Heat or cold intolerance occurs with hyperthyroidism or hypothyroidism, respectively.

Ask about changes in the patient's skin, especially on the face, neck, hands, or body creases. Changes in skin texture and skin that seems thicker or drier may suggest an endocrine problem. A patient with hypothyroidism or excess GH may have skin that feels coarse or leathery. Ask if the patient has noticed any change in the distribution of hair anywhere on the body.

Elimination pattern. Because maintaining fluid balance is a key role of the endocrine system, questions related to fluid intake and elimination patterns may uncover endocrine problems. For example, increased thirst and urination can indicate diabetes (pancreas problem) or diabetes insipidus (pituitary problem). Ask about the frequency and consistency of bowel movements. Diarrhea can occur with hyperthyroidism or thyroid cancer. Constipation occurs with hypothyroidism, hypoparathyroidism, and hypopituitarism.

Activity-exercise pattern. Determine if there are any acute or gradual changes in energy level or persistent fatigue. A patient with chronic fatigue from hypothyroidism, hypocortisolism, or diabetes may report changes in activity level.

Sleep-rest pattern. Ask the patient how many hours they typically sleep and if they feel rested on awakening. Sleep problems can result from nocturia, nightmares, anxiety, depression, or insomnia that occur with diabetes or thyroid problems.

Cognitive-perceptual pattern. Memory deficits may occur with hypothyroidism and changes in sodium levels. Inappropriate secretion of antidiuretic hormone (SIADH) or pituitary tumors can cause hyponatremia. These issues can occur gradually. Gathering information from the patient and family about memory, cognitive abilities, and balance can increase the chances of an earlier diagnosis.

Self-perception–self-concept pattern. Many endocrine problems may affect a patient's self-esteem because of associated changes in physical appearance. For example, weight gain from hypothyroidism or exophthalmos and goiter from hyperthyroidism can cause body image concerns.

Role-relationship pattern. Questions related to roles and relationships can highlight depression, chronic fatigue, and sleep problems. With chronic fatigue, depression, and anxiety, patients and their families will have stressed relationships. Questions related to home life and the patients' ability to fulfill their role in the family will aid in identifying problems.

Sexuality-reproductive pattern. The endocrine system regulates GH, prolactin, LH, FSH, testosterone, and estrogen. Therefore, menstrual problems, hirsutism, infertility, decreased libido, and growth problems can result from endocrine problems. Some women develop hypothyroidism during or after menopause. Other patients begin to develop type 2 diabetes during middle age when sex hormones are changing. Assess for abnormal secondary sex characteristics, such as facial hair *(hirsutism)* in women. Obtain a detailed history of menstruation and pregnancy. Menstrual problems can occur with disorders of the ovaries and pituitary, thyroid, and adrenal glands. A history of large-birth-weight babies or gestational diabetes increases the risk of developing type 2 diabetes. Male sexual problems may include impotence, infertility, or the lack of development of secondary sexual characteristics. Retrograde ejaculation can occur in diabetes.

Coping–stress tolerance pattern. Because stress worsens some endocrine conditions, ask patients about their stress level and usual coping patterns. Patients with adrenal insufficiency have difficulty dealing with stress. These patients are at risk for developing hypotension and fluid and electrolyte imbalance.

Value-belief pattern. Determining a patient's ability to make lifestyle changes is an important nursing function. Identify the patient's value-belief patterns so that you can help to determine appropriate treatment plans. This is especially important in a condition such as diabetes, which may require major lifestyle changes. Other disorders, such as hypothyroidism, may be managed with medications but need lifelong monitoring.

Case Study

Subjective Data

(© iStockphoto/Thinkstock.)

A focused subjective assessment of L.M. revealed the following information:

- ***Medical History:*** Denies any medical or surgical history. Has not seen an HCP for 8 years.
- ***Medications:*** None.
- ***Health Perception–Health Management:*** L.M. works as a receptionist for a local law firm and says it is all she can do to make it through the workday. She often wakes up with a headache and goes to bed with the same headache, describing it as a dull, throbbing ache between her eyes. She rates the pain as a 4 on a scale of 0 to 10 and states that ibuprofen does not ease the pain. The pain is typically worse on arising in the morning. It slowly decreases during the day. She does not have the energy she had 6 months ago. She used to enjoy gardening and going out with friends but now can barely manage work and coming home.
- ***Nutritional-Metabolic:*** L.M. reports a steady weight gain over the past 6 months, mainly in her abdominal area. She feels as if she looks pregnant but knows that is not possible. Her appetite has decreased, but she is not able to lose any weight. She says she feels "bloated." She reports growth of facial hair and notices she is bruising easily. L.M. denies problems with swallowing, hoarseness, palpitations, or tremors.
- ***Elimination:*** Denies any changes or problems with urination or bowel movements.
- ***Activity-Exercise:*** L.M. states that she has no ambition to exercise. She is just too tired at the end of the workday and has no energy on the weekends either. She reports leg cramps with walking.
- ***Sleep-Rest:*** Sleeps 10+ h at night but does not feel rested on awakening.
- ***Cognitive-Perceptual:*** L.M. finds herself easily angered and irritable, often snapping at coworkers and her husband. She says this is not her usual self. At first, she thought it was because she was dealing with a constant, dull headache. Lately, she has noticed that her vision is blurry, making work and life more stressful.
- ***Self-Perception–Self-Concept:*** L.M. says that she cannot believe what she sees when she looks in the mirror. She feels as if she has aged 10 years over the past 6 months. She has gained weight in her face, neck, and trunk. Her scalp hair is thinning, and she is growing a beard. She tells you she feels "old and ugly"!
- ***Coping–Stress Tolerance:*** L.M. states that she is finding it harder to cope with the stresses of her job, her relationship with her husband, and life in general. She believes her emotions are very "raw and labile," so different from the easy-going, smiling person she had once prided herself in being.

Discussion Questions

1. Which subjective assessment findings concern you most?
2. Based on the subjective assessment findings, what should you include in the physical assessment? What would you be looking for?

You will learn more about the physical assessment of the endocrine system in the next section.

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

Objective Data

Assessment is performed using objective data from the physical assessment and diagnostic tests. Except for the thyroid and testes, most endocrine glands are inaccessible to direct assessment. It is essential to understand the actions of hormones to assess the function of a gland by monitoring the target tissue.

Physical Assessment

Use the following general assessment when evaluating endocrine function. Specific clinical findings for the various endocrine problems are discussed in Chapters 53 and 54. Endocrine problems may cause changes in mental and emotional status. Throughout the assessment, note the patient's orientation, alertness, memory, cognitive abilities, affect, personality, and appropriateness of their behavior.

Take a full set of vital signs. Variations in temperature, heart rate, and BP can occur with a variety of endocrine problems. Obtain height and weight. Calculate body mass index (BMI) to assess nutrition status.

Integument. Assess the color and texture of the skin, hair, and nails. Note the overall skin color and pigment. Decreased skin pigment can occur in hypopituitarism, hypothyroidism, and hypoparathyroidism. Hyperpigmentation, or "bronzing" of the skin, especially on knuckles, elbows, knees, genitalia, and palmar creases, is a classic finding with Addison disease. Palpate the skin for texture and moisture. Examine hair distribution on the head, face, trunk, genitalia, and extremities. Assess the hair's appearance and texture. Hair loss, excess hair growth, or dull, brittle hair may suggest endocrine problems. Changes in genital hair distribution can occur with hormone problems. Assess for bruising and delayed wound healing.

Head. Inspect the size and contour of the head. Facial features should be symmetric. Hyperreflexia and facial muscle contraction upon percussion of the facial nerve *(Chvostek sign)* may occur in hypoparathyroidism. Inspect the eyes for position, symmetry, and shape. Large and protruding eyes (exophthalmos) can occur with hyperthyroidism. Assess visual acuity. Visual field loss may occur with a pituitary tumor. In the mouth, inspect the buccal mucosa, condition of teeth, and tongue size. Note hair distribution on the scalp and face. Vision and hearing loss are common in acromegaly from excess GH.[3]

Neck. The thyroid gland is not usually visible during inspection. A feature that distinguishes the thyroid from other masses in the neck is its upward movement on swallowing. Inspect the neck while the patient swallows a sip of water. The neck should appear symmetric without lumps or bulging.

Palpate the thyroid for size, shape, symmetry, tenderness, and any nodules. *Goiter,* an enlarged thyroid gland, can occur with hyperthyroidism or hypothyroidism. Do not press too hard or massage an enlarged thyroid gland. This can cause a sudden release of thyroid hormone into an already overloaded system. An experienced clinician should perform palpation in patients with a known diagnosis of hyperthyroidism.

Perform palpation using a posterior or anterior approach. For *anterior palpation,* stand in front of the patient with the patient's neck flexed. Place your thumb horizontally with the upper edge along the lower border of the cricoid cartilage. Then move your thumb over the isthmus as the patient swallows water. Place your fingers laterally to the anterior border of the sternocleidomastoid muscle and palpate each lateral lobe before and while the patient swallows water.[4]

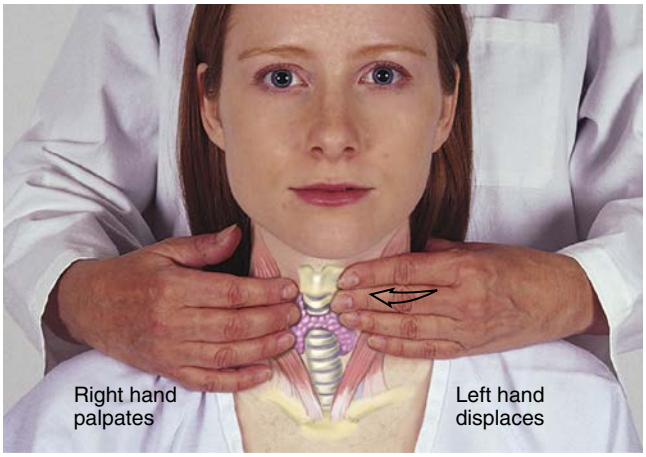

Fig. 52.10 Posterior palpation of the thyroid gland. (From Jarvis C: *Physical examination and health assessment,* ed 6, St Louis, 2012, Saunders.)

For *posterior palpation,* stand behind the patient (Fig. 52.10). With the thumbs of both hands resting on the nape of the patient's neck, use your index and middle fingers of both hands to feel for the thyroid isthmus and the anterior surfaces of the lateral lobes. Ask the patient to flex the neck slightly forward and to the right to relax the neck muscles. Displace the thyroid cartilage to the right with your left hand and fingers. Palpate with your right hand after placing the thumb deep and behind the sternocleidomastoid muscle with the index and middle fingers in front of it. Ask the patient to swallow water and feel for the thyroid to move up. In a normal person, the thyroid is often not palpable. If palpable, it usually feels smooth with a firm consistency. It is not tender with gentle pressure.[4]

If nodules, enlargement, asymmetry, or hardness (abnormal findings) are present, refer the patient for further evaluation. Auscultate the lateral lobes of an enlarged thyroid gland with the stethoscope bell to hear a *bruit,* a soft swishing sound that can occur with a goiter or hyperthyroidism.

Thorax. Inspect the thorax for shape and characteristics of the skin. Note the presence of breast gynecomastia in men. Auscultate lung sounds and heart sounds. Note any adventitious lung sounds (wheezing, decreased sounds) or extra heart sounds. Signs of fluid overload or heart failure may be present in patients with SIADH or hypothyroidism.

Abdomen. Inspect the contour of the abdomen. Note the symmetry and color. Cushing syndrome (hypercortisolism) causes the skin to be fragile, resulting in purple-blue striae across the abdomen. Note general obesity or truncal obesity. Auscultate bowel sounds.

Extremities. Assess the size, shape, symmetry, and general proportion of hands and feet. Patients with acromegaly from pituitary tumors may have large hands and feet. Inspect the skin for pigment changes, lesions, and edema. Assess muscle strength and deep tendon reflexes. Are there any tremors? Muscle spasms of the hand elicited on application of an occlusive BP cuff for 3 minutes *(Trousseau sign)* may occur in hypoparathyroidism.

Genitalia. Assessment abnormalities related to the endocrine system are outlined in Table 52.5. A focused assessment of the endocrine system is shown in Box 52.2.

Case Study

Objective Data: Physical Assessment

(© iStockphoto/ Thinkstock.)

A focused assessment of L.M. reveals the following:

L.M. appears somewhat anxious. Her BP is 190/80, heart rate 84, respiratory rate 20, temp 98.6°F (37°C). Her weight is 160 lb. She is 5 ft, 4 in tall. L.M.'s face is reddened and puffy. She appears to have a lump on the back of her neck and shoulders. There is some acne on her face and some hair growth on her upper lip and chin area. Her abdomen is protruding, but her arms and legs are thin. She has +1 edema in her ankles bilaterally. There are several bruises on her upper and lower extremities, as well as purple stretch marks on her abdomen.

Discussion Questions

1. Which physical assessment findings concern you most?
2. Based upon the subjective and objective assessment data presented so far, what are 3 priority clinical problems?
3. What diagnostic studies would you expect to be ordered?

You will learn more about diagnostic studies related to the endocrine system in the next section.

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

DIAGNOSTIC STUDIES OF ENDOCRINE SYSTEM

Diagnostic studies of the endocrine system are shown in Tables 52.6 and 52.7. Pertinent findings from the history and physical assessment guide the selection of diagnostic studies. Imaging studies can identify pituitary tumors, thyroid nodules, or adrenal tumors. Laboratory studies may include direct measurement of the hormone level or an indirect measure of gland function by evaluating blood or urine components affected by the hormone, such as glucose or electrolytes. We can measure releasing and stimulating hormones. For example, we can evaluate thyroid function by measuring TSH.

We can assess hormones with constant basal levels, such as T_4, with a single measurement. Note the time of the sample collection on the laboratory slip. Information about night shift work is important for hormones with circadian or sleep-related secretion (e.g., cortisol). Evaluating other hormones may require multiple blood samplings. Examples include suppression tests (e.g., dexamethasone) and stimulation tests (e.g., glucose tolerance). In these situations, it is often necessary to obtain IV access to give the testing medication and fluids and draw multiple blood samples.

Pituitary gland problems can manifest in a wide variety of ways because of the number of hormones produced. Many diagnostic studies evaluate these hormones either directly or indirectly.

Several tests are available to evaluate thyroid function. The most sensitive and accurate laboratory test is the measurement of TSH. It is often the first test performed to evaluate thyroid function.[5]

TABLE 52.5 ASSESSMENT ABNORMALITIES

Endocrine System

Finding	Description	Possible Etiology and Significance
Cardiovascular		
Chest pain	Angina caused by increased metabolic demands, effusions	Hyperthyroidism, hypothyroidism
Dysrhythmias	Tachycardia, atrial fibrillation	Hypothyroidism, hyperthyroidism, hypoparathyroidism, hyperparathyroidism, pheochromocytoma
Fluid overload or signs of heart failure	Crackles in the lungs, peripheral edema, shortness of breath	SIADH, hypothyroidism, myxedema
Hypertension	High BP caused by ↑ metabolic demands and catecholamines	Hyperthyroidism, pheochromocytoma, Cushing syndrome
GI		
Constipation	Passage of infrequent hard stools	Hypothyroidism, hyperparathyroidism
Head and Neck		
Exophthalmos	Eyeball protrusion from orbits	Hyperthyroidism because of fluid accumulation in eye and retroorbital tissue
Goiter	Generalized enlargement of thyroid gland	Hyperthyroidism, hypothyroidism, iodine deficiency
Moon face	Periorbital edema and facial fullness	Cushing syndrome because of ↑ cortisol secretion
Myxedema	Puffiness, periorbital edema, masklike affect	Hydrophilic mucopolysaccharides infiltrating dermis in patients with hypothyroidism
Thyroid nodule(s)	Localized enlargement of thyroid gland	May be benign or malignant
Vision changes	↓ Visual acuity and/or ↓ peripheral vision	Pituitary gland enlargement or tumor leading to pressure on optic nerve
Integument		
Bruises easily	Multiple bruises over various parts of body	Cushing syndrome
Changes in hair distribution	Hair loss	Hypothyroidism, hyperthyroidism, ↓ pituitary secretion
	↓ Axillary and pubic hair	Cortisol deficiency
	Hirsutism (excess facial hair on women)	Cushing syndrome, prolactinoma (a pituitary tumor)
Changes in skin texture	Thick, cold, dry skin	Hypothyroidism
	Thick, leathery, oily skin	GH excess (acromegaly)
	Warm, smooth, moist skin	Hyperthyroidism
Depigmentation (vitiligo)	Patchy areas of light skin	May be a marker of autoimmune endocrine problems
Edema	Generalized edema	Mucopolysaccharide accumulation in tissue in hypothyroidism
Hyperpigmentation	Darkening of the skin, especially in skinfolds and creases	↑ Secretion of MSH from Addison disease, acanthosis nigricans
Skin ulcers	Areas of ulcerated skin, most often found on legs and feet	Peripheral neuropathy and peripheral vascular disease, which are contributory factors in the development of diabetic foot ulcers
Striae	Purplish red marks below the skin surface. Usually seen on abdomen, breasts, and buttocks	Cushing syndrome
Musculoskeletal		
Changes in muscular strength or muscle mass	Generalized weakness and/or fatigue	Common with many endocrine problems, including pituitary, thyroid, parathyroid, and adrenal problems
		Diabetes, diabetes insipidus
	↓ Muscle mass	GH deficiency and Cushing syndrome from protein wasting
Enlargement of bones and cartilage	Coarsening of facial features. ↑ In size of hands and feet over several years	GH excess in adults. Seen in acromegaly due to pituitary dysfunction
Neurologic		
↑ Deep tendon reflexes	Hyperreflexia	Hyperthyroidism, hypoparathyroidism
Lethargy	State of mental sluggishness or somnolence	Hypothyroidism
Seizure	Sudden involuntary contraction of muscles	Pituitary tumor
		Hypervolemia and hyponatremia with SIADH
		Complication of diabetes, severe hypothyroidism
Tetany	Intermittent involuntary muscle spasms usually involving the extremities	Severe hypocalcemia that can occur with hypoparathyroidism
Nutrition		
Changes in weight	Weight loss	Hyperthyroidism caused by ↑ in metabolism, type 1 diabetes
	Weight gain	Hypothyroidism, Cushing syndrome, type 2 diabetes

Continued

TABLE 52.5 ASSESSMENT ABNORMALITIES—cont'd

Endocrine System

Finding	Description	Possible Etiology and Significance
Glucose levels altered	↑ Serum glucose	Diabetes, Cushing syndrome, GH excess
Reproductive		
Changes in reproductive function	Menstrual irregularities, ↓ libido, ↓ fertility, impotence	Pituitary hypofunction, GH excess, thyroid problems, adrenocortical problems
Other		
↓ Urine output	↓ Water reabsorption from kidney tubules	SIADH
Polydipsia	Excessive thirst	Extreme water losses in diabetes (with severe hyperglycemia), diabetes insipidus, dehydration
Polyuria	Excess urine output	Diabetes (from hyperglycemia) or diabetes insipidus (due to ↓ ADH)
Thermoregulation	Cold insensitivity	Hypothyroidism caused by a slowing of metabolic processes
	Heat intolerance	Hyperthyroidism caused by excessive metabolism

BOX 52.2 FOCUSED ASSESSMENT

Endocrine System

Use this checklist to ensure you complete key assessment steps.

Subjective

Ask the patient about any of the following and note responses.

Excessive or increased thirst	Y	N
Excess or decreased urination	Y	N
Excessive hunger	Y	N
Heat or cold intolerance	Y	N
Excessive sweating	Y	N
Recent weight gain or loss	Y	N

Objective: Diagnostic

Check the following laboratory results for critical values.

Potassium	✓
Glucose	✓
Sodium	✓
Glycosylated hemoglobin (A1C)	✓
Thyroid studies: TSH, T_3, T_4	✓
Serum osmolality	✓

Objective: Physical Assessment

Inspect/Measure

Body temperature	✓
Height and weight	✓
Alertness and emotional state	✓
Skin for changes in color and texture	✓
Hair for changes in color, texture, and distribution	✓

Auscultate

Heart rate, BP	✓

Palpate

Extremities for edema	✓
Skin for texture and temperature	✓
Neck for thyroid size, shape	✓

Follow-up tests ordered when the TSH level is abnormal include total T_4, free T_4, and total T_3. Free T_4 is the unbound thyroxine. It more accurately reflects thyroid function than total T_4.

The only hormone secreted by the parathyroid glands is PTH. Because PTH regulates serum calcium and phosphate levels, these levels reflect problems with PTH secretion. For this reason, parathyroid gland testing typically includes PTH, serum calcium, and serum phosphate levels.

Tests assessing adrenal cortex function focus on measuring blood plasma and urine levels of the 3 types of hormones secreted: glucocorticoids, mineralocorticoids, and androgens. Urine studies often require a 24-hour urine collection to eliminate the impact of short-term fluctuations in plasma hormone levels.

The tests used to evaluate glucose metabolism are important in the diagnosis and management of diabetes. See Chapter 53 for information about diagnostic studies for diabetes.

Case Study

Objective Data: Diagnostic Studies

(© iStockphoto/Thinkstock.)

The HCP orders the following initial diagnostic studies to be drawn in the morning after an 8-h fast:

- CBC, basic metabolic panel (electrolytes, BUN, creatinine)
- Fasting blood glucose (FBG)
- TSH, free T_4
- Plasma cortisol levels
- Plasma ACTH levels

CBC results reveal a WBC of 12,200/μL and a decreased lymphocyte count at 800 cells/μL. The rest of the CBC is within normal limits (WNL). The FBG is 130 mg/dL. The plasma cortisol and ACTH levels are high. Thyroid studies are WNL.

Discussion Questions

1. Which diagnostic study results are of most concern to you?
2. Do you expect the HCP to order any other diagnostic studies for L.M.?
3. What are our care priorities for L.M. at this time?

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

TABLE 52.6 Serology and Urine Studies

Endocrine System

Study	Reference Interval	Purpose and Description	Nursing Responsibility
Adrenal Studies			
Blood Studies			
Adrenal steroid precursors • Androstenediones (AD) • Dehydroepiandrosterone (DHEA) • Dehydroepiandrosterone sulfate (DHEA S) • 11-Deoxycortisol	AD • *Female:* 0.05–2.05 ng/mL • *Male:* 0.04–1.06 ng/mL DHEA • *Female:* 0.14–7.88 ng/mL • *Male:* 0.11–6.73 ng/mL DHEA S • *Female:* 7–488 mcg/dL • *Male:* 7–371 mcg/dL 11-Deoxycortisol • *Adults:* 10–79 ng/dL	Assesses for congenital adrenal hyperplasia, sex hormones abnormalities, adrenal or gonadal tumors.	*Before*: Tanner stage I–V of physical development needed for accurate assessment. Determine date of last menstrual period (LMP) for females. Test should be done 1 week before or after menstrual cycle. *After*: Note date of LMP on laboratory slip.
Adrenocorticotropic hormone (ACTH, corticotropin)	• *Female:* 6–58 pg/mL • *Male:* 7–69 pg/mL	Measures amount of ACTH made by the anterior pituitary gland. Levels determine if there is an overproduction or underproduction of cortisol and whether cause is an adrenal gland or pituitary gland abnormality.	*Before:* Patient should be NPO after midnight. Do morning blood draw between 6 and 8 AM. *During:* Use prechilled blood tube and place on ice.
ACTH stimulation test with cosyntropin (Cortisol stimulation test)	*Rapid test:* Cortisol levels increase more than 7 mcg/dL higher than baseline *24-Hr test:* Cortisol levels >40 mcg/dL *3-Day test:* Cortisol levels greater than 40 mcg/dL	Used to evaluate cause of adrenal insufficiency. If cortisol levels increase after cosyntropin injection, the cause of adrenal insufficiency is the pituitary gland. If there is no or little rise in cortisol levels, the cause of adrenal insufficiency is the adrenal gland.	*Before*: Obtain baseline cortisol level at beginning of cosyntropin infusion. *During*: Inject bolus of IV cosyntropin with a plastic syringe. Draw cortisol samples 30 and 60 min after bolus. Monitor site and rate of IV infusion. Ensure sample collection at appropriate times.
Aldosterone	*Supine:* 3–10 ng/dL (0.08–0.30 nmol/L) *Upright:* • *Female:* 5–30 ng/dL (0.14–0.08 nmol/L) • *Male:* 6–22 ng/dL (0.17–0.61 nmol/L)	Used to identify hyperaldosteronism. Helps distinguish primary aldosteronism from adrenal disease versus secondary aldosteronism from extraadrenal disease.	*Before:* Morning blood sample is preferred. Tell patient that the required position (supine/sitting/standing) must be maintained for 2 h before specimen is drawn.
Cortisol (hydrocortisone, serum cortisol)	• *8 AM:* 5–23 mcg/dL (138–635 nmol/L) • *4 PM:* 3–13 mcg/dL (83–359 nmol/L)	Measures serum cortisol level to evaluate adrenal activity. Cortisol levels are normally highest in the morning, slowly drop during the day, and are lowest around midnight.	*Before:* Sample should be drawn in morning. Note if patient works night shift. Mark time of blood draw on laboratory slip. Stress and excess physical activity produce elevated results.
Dexamethasone suppression (DST, prolonged/rapid DST, cortisol suppression test, ACTH suppression test)	Prolonged method: • *Low dose:* >50% reduction of plasma cortisol and 17-hydroxycorticosteroid (17-OCHS) • *High dose:* >50% reduction of plasma cortisol and 17-OCHS Rapid (overnight) method: • Plasma cortisol levels suppressed to <2 mcg/dL	Helps to identify and determine cause of adrenal hyperactivity (e.g., Cushing syndrome).	*Before*: Patient should fast for 8–10 hr prior. Do not test acutely ill patients or those under stress. Stress-stimulated ACTH may override suppression. Screen patient for drugs, such as estrogen and corticosteroids, which may give false-positive results. *Overnight method:* Dexamethasone 1 mg (low dose) or 4 mg (high dose) is given at 2300 to suppress secretion of corticotropin-releasing hormone. Plasma cortisol sample is drawn at 0800.
Metanephrine, plasma free (fractionated metanephrine)	*Normetanephrine:* <0.5 nmol/L or 18–111 pg/mL by HPLC *Metanephrine:* <0.9 nmol/L or 12–60 pg/mL by HPLC	Used to identify pheochromocytoma of the adrenal or extraadrenal glands.	*Before:* Ask about recent history of vigorous exercise, high stress levels, or starvation (may artificially ↑ levels). Assess for drugs (e.g., caffeine, alcohol, levodopa, nitroglycerin, acetaminophen, and those containing epinephrine or norepinephrine) that can alter results.

Continued

TABLE 52.6 Serology and Urine Studies—cont'd

Endocrine System

Study	Reference Interval	Purpose and Description	Nursing Responsibility
Urine Studies			
Cortisol (hydrocortisone, urine cortisol, free cortisol)	24-Hr specimen: <100 mcg/24 hr (<276 nmol/day)	Measures urine cortisol level to evaluate adrenal activity.	*Before*: Explain 24-hr urine collection and need to avoid stressful situations and excessive physical exercise. Assess for drug use (e.g., reserpine, diuretics, phenothiazines, insulin, amphetamines) that may alter results.
17-Hydroxycorticosteroids (17-OCHS)	24-Hr specimen: *Adults:* • *Male:* 3–10 mg/24 hr (8.3–27.6 μmol/day) • *Female:* 2–8 mg/24 hr (5.2–22.1 μmol/day)	Measures 17-OCHS, a cortisol metabolite, to evaluate adrenocortical function. Older adults may have slightly lower values.	*Before*: Explain 24-hr urine collection and need to avoid stressful situations and excess physical exercise. Assess for drug use (e.g., erythromycin, spironolactone) that may alter results.
17-Ketosteroids (17-KS)	24-Hr specimen: • *Male:* 6–20 mg/24 hr (20–70 μmol/day) • *Female:* 6–17 mg/24 hr (20–60 μmol/day)	Evaluates adrenocortical and gonadal functions by measuring urinary androgen metabolites. Older adults may have slightly lower values.	*Before:* Explain 24-hr urine collection.
Vanillylmandelic acid (VMA)	24-Hr specimen: <6.8 mg/24 hr (<35 μmol/24 hr)	Measures the excretion of catecholamine metabolite. Used to identify catecholamine-producing tumors, such as pheochromocytoma.	*Before*: Explain 24-hr urine collection. Must follow VMA-restricted diet 2–3 days before and during the urine collection. *During*: Keep 24-hr urine collection at pH <3.0 with HCl acid as preservative. Keep on ice.
Pancreatic Studies			
Blood Studies			
C-Peptide (connecting peptide insulin, insulin C-peptide, proinsulin C-peptide)	*Fasting:* 0.78–1.89 ng/mL (0.26–0.62 nmol/L) *1 hr after glucose load:* 5–12 ng/mL	Measures amount of C-peptide, which is released with insulin. Distinguishes between type 1 (low levels) and type 2 diabetes (normal or high levels).	*Before:* Patient should fast 8–12 hr prior. Water intake is allowed.
Glucagon	50–100 pg/mL (50–100 ng/L)	Assesses for glucagonoma (α islet cell tumor). Evaluates pancreatic function, especially in people with diabetes who have low blood glucose (hypoglycemia).	*Before:* Patient should fast 8–12 hr prior. Water intake is allowed.
Glucose (blood sugar, fasting blood glucose [FBG])	*Fasting* (defined as no caloric intake for at least 8 hr): 74–106 mg/dL (4.1–5.9 mmol/L) *Casual* (defined as any time of day): ≤200 mg/dL (<11.1 mmol/L)	Aids in the diagnosis of diabetes.	*Before:* Patient should fast 8–12 hr prior. Water intake is allowed. Assess for the many drugs that may influence results.
Glucose, postprandial (2-hour postprandial glucose [2-h PPG])	*0–50 years:* <140 mg/dL (<7.8 mmol/L) *50–60 years:* <150 md/dL *60 years and older:* <160 mg/dL	Aids in the diagnosis of diabetes.	*Before:* Patient should fast 8–12 hr, then eat a meal of at least 75 g of carbohydrate. Patient must fast after eating this meal until blood is drawn. No exercise during test.
Glucose tolerance test (GTT, oral glucose tolerance [OGTT])	*Nonpregnancy:* *Fasting:* <110 mg/dL (<6.1 mmol/L *1 hr:* <180 mg/dL (<11.1 mmol/L) 2 *hr:* <140 mg/dL (<7.8 mmol/L)	Assesses glucose levels in people with symptoms of (hypoglycemia). Aids in the diagnosis of diabetes.	*Before:* Patient should fast 8–12 hr prior. Many drugs may influence results, including caffeine and smoking. Ensure that patient's diet 3 days before test includes 150–300 g of carbohydrate with intake of at least 1500 cal/day.
Glycosylated hemoglobin (GHb, GHB, glycohemoglobin, hemoglobin A1C [Hb A1C], diabetic control index, glycated protein)	*Nondiabetic adult/child:* 4%–5.6%	Measures the average blood glucose for the past 90 days. Used to diagnose and screen diabetes treatment plans.	*Before:* Tell patient that fasting is not necessary and that blood sample will be drawn.

TABLE 52.6 Serology and Urine Studies—cont'd

Endocrine System

Study	Reference Interval	Purpose and Description	Nursing Responsibility
Insulin assay	6–26 μU/mL (43–186 pmol/L)	Assesses insulin levels in people with symptoms of hypoglycemia. Assesses for insulinomas and carbohydrate and lipid absorption abnormalities.	*Before:* Patient should fast 8–12 hr prior. Water intake is allowed.
Urine Studies			
Glucose (urine sugar)	*Random specimen:* negative *24-hr specimen:* 50–300 mg/day (0.3–1.7 mmol/day)	Measures amount of glucose in the urine. Assesses diabetes management.	*Before:* Use freshly voided urine. Many drugs alter glucose readings. Follow directions exactly to avoid errors.
Ketones	None or negative	Measures amount of ketones in the urine. Assesses for diabetic ketoacidosis, a life-threatening condition seen most often in people with type 1 diabetes.	*Before:* Use freshly voided urine specimen. Test is often done with glucose test. Follow directions exactly. Certain drugs can produce false-positive or false-negative results.
Parathyroid Studies			
Blood Studies			
Calcium (total)	9.0–10.5 mg/dL (2.25–2.62 mmol/L)	Assesses the function of the parathyroid gland and calcium absorption.	*Before:* Patient must fast 8–12 hr prior. Assess for drug use (e.g., albuterol, heparin, diuretics) that may alter results. *After:* Keep sample on ice.
Calcium (ionized)	4.5–5.6 mg/dL (1.05–1.3 mmol/L)	Free form of total calcium. Unchanged by inconsistent serum albumin levels that occur in certain populations, such as critically ill patients.	As above.
Parathyroid hormone (PTH, parathormone)	*Intact (whole):* 10–65 pg/mL (10–65 ng/L) *N terminal:* 8–24 pg/mL *C terminal:* 50–330 pg/mL	Used to determine the cause of changes in calcium levels caused by parathyroid or nonparathyroid problems. Monitored in patients with chronic kidney disease, especially those on dialysis.	*Before:* Patient should fast 8–12 hr prior. Obtain sample in the morning. *During*: Obtain serum calcium level at same time. *After:* Mark time of blood draw on laboratory slip.
Phosphate (PO4), phosphorus (P)	3.0–4.5 mg/dL (0.97–1.45 mmol/L)	Measures amount of inorganic phosphate in the blood. Assesses for problems related to calcium and phosphorus disorders.	*Before:* Patient must fast 8–12 hr prior. If possible, hold IV fluids containing glucose for 8 hr prior.
Pituitary Studies			
Blood Studies			
Antidiuretic hormone (ADH, vasopressin, Arginine vasopressin [AVP])	1–5 pg/mL	Assesses for diabetes insipidus (DI) or SIADH.	*Before:* Patient must fast 8–12 hr prior.
Gonadotropins • Follicle-stimulating hormone (FSH) assay • Luteinizing hormone (LH assay, Lutropin)	*FSH (Adult)* • *Male:* 1.42–15.4 IU/L • *Female:* *Follicular phase*: 1.37–9.9 IU/L *Ovulatory phase*: 6.17–17.2 IU/L *Luteal phase*: 1.09–9.2 IU/L *Postmenopause*: 19.3–100.6 IU/L *LH (Adult)* • *Male:* 1.24–7.8 IU/L • *Female:* *Follicular phase*: 1.68–15 IU/L *Ovulatory phase*: 21.9–56.6 IU/L *Luteal phase*: 0.61–16.3 IU/L *Postmenopause*: 14.2–52.3 IU/L	Assesses for pituitary, puberty or infertility conditions, and menopause.	*Before:* Tell patient that fasting is not necessary and that blood sample will be drawn. *During:* Note on the laboratory slip time of LMP or whether woman is menopausal.

Continued

TABLE 52.6 Serology and Urine Studies—cont'd

Endocrine System

Study	Reference Interval	Purpose and Description	Nursing Responsibility
Growth hormone (GH, human growth hormone [HGH], somatotropin hormone [SH])	• *Men:* <5 ng/mL • *Women:* <10 ng/mL	Evaluates GH secretion and pituitary gland function.	*Before:* Patient must fast 8–12 hr prior. Emotional and physical stress may alter results. Indicate patient fasting status and recent activity level on the laboratory slip.
GH stimulation (GH provocation, insulin tolerance test [ITT], arginine test)	GH levels >10 mg/mL	Aids in identifying GH deficiency and conditions caused by decreased pituitary hormone production.	*Before*: Patient must fast 10–12 hr prior. Water is allowed on morning of test. Establish IV access for medication administration and blood sampling. *During*: Continually assess for hypoglycemia and hypotension. Keep 50% dextrose and 5% dextrose IV solution at the bedside in case severe hypoglycemia occurs.
Insulin-like growth factor (IGF-1, somatomedin C, insulin-like growth factor binding proteins [IGF BP])	42–110 ng/mL	Evaluates GH and pituitary gland function. Provides a more accurate reflection of mean plasma concentration of GH because it is not subject to circadian rhythm and fluctuations.	*Before:* Patient must fast 8–12 hr prior.
Urine Studies			
Water deprivation (ADH stimulation)	*Neurogenic DI:* >9% rise in urine osmolality *Nephrogenic DI:* <9% rise in urine osmolality *Psychogenic polydipsia:* <9% rise in urine osmolality	Distinguishes among neurogenic, nephrogenic, or psychogenic DI.	*Before*: Obtain baseline weight and urine and plasma osmolality. Should be done only if serum sodium is normal and urine osmolality is <300 mOsm/kg. *During*: Patient may need to fast. Severe dehydration may occur. Assess urine hourly for volume and specific gravity. Send hourly urine samples to laboratory for osmolality determination. Send blood samples for sodium and osmolality every 2 hr. Stop test and rehydrate if patient's weight drops >2 kg at any time. *After*: Rehydrate with oral fluids. Check orthostatic BP and pulse to ensure adequate fluid volume.
Thyroid Studies			
Blood Studies			
Antithyroglobulin antibody (thyroid autoantibody, thyroid antithyroglobulin antibody, thyroglobulin antibody, thyroid peroxidase antibody [TPO])	<116 IU/mL	Measures thyroid antibody levels. Aids in diagnosing autoimmune thyroid disease and separates it from other forms of thyroiditis. One or more antibody tests may be ordered depending on symptoms.	*Before:* Explain blood draw procedure to the patient.
Thyroglobulin (Tg, thyrogen-stimulated thyroglobulin)	• *Male:* 0.5–53 ng/mL • *Female:* 0.5–43.0 ng/mL	Identifies functioning thyroid tissue and thyroid cancer cells. Used primarily as a tumor marker for patients being treated for thyroid cancer.	As above.
Thyroid-stimulating hormone (TSH, thyrotropin)	2–10 μU/mL	Most sensitive diagnostic test for evaluating thyroid function. Helps in distinguishing primary (thyroid), secondary (pituitary), and tertiary (hypothalamus) hypothyroidism.	As above.
Thyroxine-binding globulin (TBG, thyroid-binding globulin)	*10–19 years:* • *Male:* 1.4–2.6 mg/dL • *Female:* 1.4–3.0 mg/dL *20 years:* 1.7–3.6 mg/dL *Oral contraceptives:* 1.5–5.5 mg/dL	Measures TBG, the main thyroid hormone protein carrier. Used to assess thyroid function when T_4 and T_3 levels are abnormal.	As above.

TABLE 52.6 Serology and Urine Studies—cont'd

Endocrine System

Study	Reference Interval	Purpose and Description	Nursing Responsibility
Thyroxine, total and Free (T_4, thyroxine screen, FT_4)	*Free T_4: 0.8–2.8 ng/dL (10–36 pmol/L)* *Total T_4:* • *Male:* 4–12 mcg/dL (51–154 nmol/L) • *Female:* 5–12 mcg/dL (64–154 nmol/L) • >60 years: 5–11 mcg/dL (64–142 nmol/L)	Used to evaluate thyroid function and monitor thyroid replacement or suppressive therapy. Free T_4 levels not affected by protein levels like total T_4 is, so it is thought to be more precise marker of thyroid function.	As above.
Triiodothyronine (total T_3 radioimmunoassay [T_3 by RIA], free T_3)	*16–20 years:* 80–210 ng/dL *20–50 years:* 70–205 ng/dL (1.2–3.4 nmol/L) *>50 years:* 40–180 ng/dL (0.6–2.8 nmol/L)	Evaluates thyroid function. Free T_3 measures the active component of total T_3. Used to diagnose hyperthyroidism if TSH is abnormal and T_4 levels are normal. May be used to monitor drug therapy.	As above.
T_3 uptake (thyroid hormone–binding ratio [THBR], T_3 resin uptake)	24%–39%	Used with T_4 to assess thyroid function. Indirectly measures binding capacity of thyroid-binding globulin	As above.

TABLE 52.7 Radiologic Studies

Endocrine System

Study	Description and Purpose	Nursing Responsibility
Adrenal arteriography (angiography; adrenal)	Assesses for arterial obstructive conditions and/or tumors of the adrenal glands.	*Before*: Assess for allergies, especially to contrast dye. Have patient fast 6–12 hr prior. Give sedative and other drugs, as ordered. *During*: Patient will feel flushed when dye is injected. *After:* Check pressure dressing site after procedure. Monitor BP, pulse, and circulation distal to injection site. Place compression device over site. Maintain IV and/or oral fluid intake.
Computed tomography (CT)	*Abdominal:* Used to detect adrenal hyperplasia and tumors or pancreatic abnormalities, such as pancreatitis, tumors, or cysts. *Brain:* Used to detect a pituitary tumor and its size. *Neck:* Can locate thyroid nodules and assess for thyroid cancer.	*Before:* Before contrast medium used, evaluate renal function. Assess if patient is allergic to shellfish since the contrast is iodine based. Patient may need to be NPO 4 hr prior to study. If the patient is taking metformin, hold it the day of the test to prevent hypoglycemia or acidosis. *During:* Warn patient that contrast injection may cause a feeling of being warm and flushed. Patient must lie completely still during scan. *After:* Encourage patient to drink fluids to avoid renal problems with any contrast.
Magnetic resonance cholangiopancreatography (MRCP)	Assesses for the source of pancreatitis and can detect pancreatobiliary tumors.	*Before*: Patient may need to be fasting. Oral and/or IV contrast injection may be used. Check for pregnancy, allergies, and renal function. *During*: Patient must lie completely still during scan.
Magnetic resonance imaging (MRI)	*Abdominal:* Can distinguish benign tumors from adrenal cancers. *Brain:* Study of choice for radiologic evaluation of the pituitary gland and hypothalamus. Used to identify tumors in these glands.	*Before:* Oral and/or IV contrast injection may be used. Check for pregnancy, allergies, and renal function before test. Have patient remove all metal objects. Ask about any history of surgical insertion of staples, plates, dental bridges, or other metal appliances. Remove metallic foil patches. Patient may need to be fasting. Assess for claustrophobia and the need for antianxiety medication. *During:* Patient must lie completely still during scan.
Parathyroid scan (parathyroid scintigraphy)	Used to find the parathyroid glands. Radioactive isotopes are taken up by cells in parathyroid glands. Obtains image of the glands and any abnormally active areas.	*Before:* Check for iodine allergy. Some foods and medications are restricted a few weeks before the scan.
Radioactive iodine (RAIU) uptake	Direct measure of thyroid activity and evaluates function of thyroid nodules. *For 2–4 hr:* 3%–19%. *For 24 hr:* 11%–30%.	*Before:* Radioactive iodine given orally or IV. Check for allergies. *During:* Uptake by the thyroid gland is measured with a scanner at several time intervals, such as 2–4 hr and at 24 hr. *After:* Encourage patient to increase fluid intake as radionuclide takes 6–24 hr to be eliminated from body.
Thyroid scan	Used to evaluate nodules of thyroid. Benign nodules appear as warm spots because they take up radionuclide. Cancer tumors appear as cold spots because they tend not to take up radionuclide.	*Before:* Radioactive isotopes are given orally or IV. Check for allergies. *After*: Encourage patient to increase fluid intake as radionuclide takes 6–24 hr to be eliminated from body.
Thyroid ultrasound	Evaluates thyroid nodules to determine size and characteristics (cystic or solid tumors). Used to observe management and surveillance of nodules and unaffected portions of the gland.	*Before:* Explain that gel and a transducer will be used over the neck. The test lasts 15 min. No fasting or sedation required.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A characteristic common to all hormones is that they
   - **a.** circulate in the blood bound to plasma proteins.
   - **b.** influence cellular activity of specific target tissues.
   - **c.** accelerate the metabolic processes of all body cells.
   - **d.** enter a cell and change the cell's metabolism or gene expression.
2. A patient is receiving radiation therapy for renal cancer. The nurse monitors the patient for signs and symptoms of damage to the
   - **a.** pancreas.
   - **b.** thyroid gland.
   - **c.** adrenal glands.
   - **d.** posterior pituitary gland.
3. A patient has a serum sodium level of 152 mEq/L (152 mmol/L). The normal hormonal response to this situation is
   - **a.** release of ADH.
   - **b.** release of ACTH.
   - **c.** secretion of aldosterone.
   - **d.** secretion of corticotropin-releasing hormone.
4. When obtaining subjective data from a patient during assessment of the endocrine system, the nurse asks specifically about
   - **a.** energy level.
   - **b.** intake of vitamin C.
   - **c.** employment history.
   - **d.** frequency of sexual intercourse.
5. An appropriate technique to use during physical assessment of the thyroid gland is
   - **a.** asking the patient to hyperextend the neck during palpation.
   - **b.** percussing the neck for dullness to define the size of the thyroid.
   - **c.** having the patient swallow water during inspection and palpation of the gland.
   - **d.** using deep palpation to determine the extent of a visibly enlarged thyroid gland.
6. Endocrine problems often go unrecognized in the older adult because
   - **a.** symptoms are often attributed to aging.
   - **b.** older adults rarely have identifiable symptoms.
   - **c.** endocrine problems are uncommon in an older adult.
   - **d.** older adults usually have endocrine problems with lesser symptoms.
7. Abnormal findings during an endocrine assessment include *(select all that apply)*
   - **a.** excess facial hair on a woman.
   - **b.** blood pressure of 100/70 mm Hg.
   - **c.** soft, formed stool every other day.
   - **d.** 3-lb weight gain over last 6 months.
   - **e.** hyperpigmented coloration in lower legs.
8. A patient has a total serum calcium level of 3 mg/dL (1.5 mEq/L). If this finding reflects hypoparathyroidism, the nurse expects further diagnostic testing to reveal
   - **a.** decreased serum PTH.
   - **b.** increased serum ACTH.
   - **c.** increased serum glucose.
   - **d.** decreased serum cortisol levels.

1. b; 2. c; 3. a; 4. a; 5. c; 6. a; 7. a, e; 8. a.

CONCEPTUAL FOCUS

Glucose Regulation
Infection
Nutrition
Self-Management
Sensory Perception

LEARNING OUTCOMES

1. Describe the pathophysiology and clinical manifestations of diabetes.
2. Distinguish between type 1 and type 2 diabetes.
3. Describe the interprofessional care of a patient with diabetes.
4. Describe the role of nutrition and exercise in managing diabetes.
5. Discuss the nursing management of a patient with newly diagnosed diabetes.
6. Describe the nursing management of a patient with diabetes in the ambulatory and home care settings.
7. Relate the pathophysiology of acute and chronic complications of diabetes to the clinical manifestations.
8. Explain the interprofessional care and nursing management of a patient with acute and chronic complications of diabetes.

prediabetes
Somogyi effect

This chapter presents the pathophysiology, manifestations, complications, and management of diabetes (DM). The potential for long-term complications from DM makes it a challenging disease. DM is associated with adult blindness, end-stage renal disease (ESRD), and nontraumatic lower-limb amputations. People with DM have a higher risk of heart disease and stroke. Managing DM requires making daily decisions about food intake, blood glucose monitoring (BGM), medication, and exercise. You play a vital role in promoting the patient's self-management of DM through providing comprehensive patient and caregiver education.

DIABETES

Diabetes mellitus (DM), or diabetes, is a chronic multisystem disease characterized by hyperglycemia from abnormal insulin production, impaired insulin use, or both. DM is a prevalent and growing health problem throughout the world. In the United States, an estimated 34.2 million people, or 10.5% of the population, have DM. Prediabetes affects 88 million adults.[1] About 7.3 million people with DM have not been diagnosed and are unaware that they have the disease. DM is the 7th leading cause of death in the United States.[2]

Etiology and Pathophysiology

Current theories link the causes of DM, singly or in combination, to genetic, autoimmune, and environmental factors (e.g., virus, higher weight). Regardless of its cause, DM is mainly a disorder of glucose metabolism related to absent or insufficient insulin supply and/or ineffective use of the available insulin.

The American Diabetes Association (ADA) recognizes 4 different classes of DM. The 2 most common are type 1 and type

TABLE 53.1 Comparison of Type 1 and Type 2 DM

Factor	Type 1 DM	Type 2 DM
Age at onset	More common in young people but can occur at any age	More common in adults but can occur at any age Incidence increasing in children
Type of onset	Signs and symptoms usually abrupt, although disease process may be present for several years	Gradual, may go undiagnosed for years
Prevalence	Accounts for 5%–10% of all types of DM	Accounts for 90%–95% of all types of DM
Endogenous insulin	Absent	Initially increased in response to insulin resistance. Secretion decreases over time
Environmental factors	Virus, toxins	Higher weight, lack of exercise
Islet cell antibodies	Often present at onset	Absent
Primary defect	Absent or minimal insulin production	Insulin resistance, decreased insulin production over time, and changes in adipokines production
Symptoms	Polydipsia, polyuria, polyphagia, fatigue, weight loss without trying	Often none. Fatigue, recurrent infections. May also have polyuria, polydipsia, and polyphagia, blurred vision
Ketosis	Present at onset or during insulin deficiency	Usually not present; can occur during infection or high stress
Insulin therapy	Required for all	Required for some. Progressive disease. Insulin may need to be added to treatment plan
Body type	Thin, normal, or obese	Often overweight or obese with visceral adiposity ("apple shape"). May be normal
Nutrition therapy	Essential	Essential
Vascular and neurologic complications	Frequent	Frequent

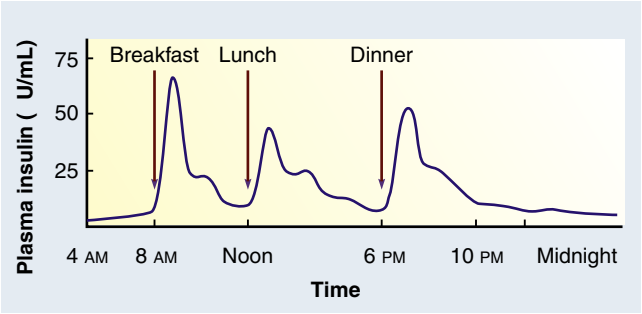

Fig. 53.1 Normal endogenous insulin secretion. After meals, insulin concentrations rise rapidly in blood and peak at about 1 hour. Then insulin concentrations promptly decline toward preprandial values as carbohydrate absorption from the GI tract declines. After carbohydrate absorption from the GI tract is complete and during the night, insulin concentrations are low and fairly constant, with a slight increase at dawn.

2 DM (Table 53.1). Another type is maturity onset diabetes of the young (MODY). The 2 other classes are gestational DM and other specific types of DM with various causes.

Normal Glucose and Insulin Metabolism

Insulin is a hormone made by the β cells in the islets of Langerhans of the pancreas. Under normal conditions, the pancreas continuously releases insulin into the bloodstream in small amounts. Release increases when we ingest food (Fig. 53.1). Insulin lowers glucose and facilitates a stable, normal glucose range of about 74 to 106 mg/dL (4.1 to 5.9 mmol/L). The amount of insulin secreted daily by an adult is about 40 to 50 U or 0.6 U/kg of body weight.

Insulin promotes glucose transport from the bloodstream across the cell membrane to the cytoplasm of the cell (Fig. 53.2).

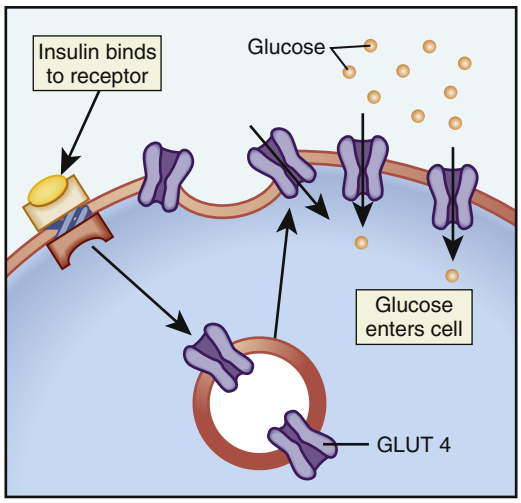

Fig. 53.2 Normal glucose metabolism. Insulin binds to receptors along the cell walls of muscle, adipose, and liver cells. Glucose transport proteins *(GLUT 4s)* then attach to the cell wall and allow glucose to enter the cell. There it is either stored or used to make energy.

Cells break down glucose to make energy. Liver and muscle cells store excess glucose as glycogen. The rise in plasma insulin after a meal inhibits gluconeogenesis, enhances fat deposition of adipose tissue, and increases protein synthesis. For this reason, insulin is an *anabolic*, or storage, hormone. The fall in insulin level during normal overnight fasting promotes the release of stored glucose from the liver, protein from muscle, and fat from adipose tissue.

Skeletal muscle and adipose tissue have specific receptors for insulin and are considered insulin-dependent tissues. Insulin is required to "unlock" these receptor sites, allowing the transport of glucose into the cells to be used for energy. Other tissues (e.g., brain, liver, blood cells) do not directly depend on insulin for

BOX 53.1 GENETICS IN CLINICAL PRACTICE

Diabetes

Type 1 DM	Type 2 DM	MODY
Genetic Basis		
• Increased susceptibility (40%–50%) when a person has specific human leukocyte antigens (HLA-DR3 and HLA-DR4) • Polygenic (>40 genes influence susceptibility)	• Polygenic (>25 genes influence susceptibility)	• Autosomal dominant • Monogenic (single gene) • Caused by mutations in any of 6 MODY genes (types 1–6) • Gene mutations lead to β-cell dysfunction
Risk to Offspring		
• Risk to offspring of mothers with DM is 1%–4% • Risk to offspring of fathers with DM is 5%–6% • When 1 identical twin has type 1 DM, the other gets DM about 30%–40% of the time	• Risk to offspring is 8%–14% • When 1 identical twin has type 2 DM, the other gets DM about 60%–75% of the time	• If 1 parent has MODY, a child has a 50% chance of developing DM • If 1 parent has MODY, a child has a 50% chance of being a carrier
Clinical Implications		
• Result of complex interaction of genetic, autoimmune, and environmental factors	• Result of complex genetic interactions and other metabolic factors • Environmental factors, such as body weight and exercise, can sometimes modify metabolic factors	• Accounts for 1%–5% of people with DM • Young age of onset (often before age 25) • Not related to obesity or hypertension • Treatment depends on the genetic mutation that caused MODY

glucose transport but require an adequate glucose supply for normal function. Although liver cells are not insulin-dependent tissue, insulin receptor sites on the liver facilitate uptake of glucose and its conversion to glycogen.

Other hormones (glucagon, epinephrine, growth hormone [GH], cortisol) work against the effects of insulin. They are *counterregulatory hormones.* These hormones increase glucose levels by (1) stimulating glucose production and release by the liver and (2) decreasing the movement of glucose into the cells. The counterregulatory hormones and insulin work together to maintain glucose levels within the normal range by regulating the release of glucose for energy during food intake and periods of fasting.

Insulin is synthesized from its precursor, proinsulin. Enzymes split proinsulin to form insulin and C-peptide. The 2 substances are released in equal amounts. Therefore, measuring C-peptide in serum and urine is a useful indicator of pancreatic β-cell function and insulin levels.

Type 1 Diabetes

Type 1 diabetes accounts for about 5% to 10% of all people with DM. Type 1 DM generally affects people under 40 years of age, although it can occur at any age.[3]

Etiology and pathophysiology. Type 1 DM is an autoimmune disorder in which the body develops antibodies against insulin and/or the pancreatic β cells that make insulin. This eventually results in not enough insulin for a person to survive. A genetic predisposition and exposure to a virus are factors that may contribute to developing immune-related type 1 DM (Box 53.1).

Genetic Link

Predisposition to type 1 DM is related to human leukocyte antigens (HLAs) (see Chapter 14). In theory, when a person with certain HLA types is exposed to a viral infection, the β cells of the pancreas are destroyed, either directly or through an autoimmune process. The HLA types with an increased risk for type 1 DM include HLA-DR3 and HLA-DR4.

Idiopathic diabetes is a form of type 1 DM that is strongly inherited and not related to autoimmunity. It only occurs in a small number of people with type 1 DM. They are most often of Hispanic, African, or Asian ancestry.[4] *Latent autoimmune diabetes in adults* (LADA) is a slowly progressing autoimmune form of type 1 DM. It occurs in adults and is often mistaken for type 2 DM.

Onset of disease. In type 1 DM, the islet cell autoantibodies responsible for β-cell destruction are present for months to years before the onset of symptoms. Manifestations develop when the person's pancreas can no longer make enough insulin to maintain normal glucose. Once this occurs, the onset of symptoms is usually rapid. Patients often present with impending or actual ketoacidosis. The patient usually has a history of recent and sudden weight loss and the classic symptoms of *polydipsia* (excessive thirst), *polyuria* (frequent urination), and *polyphagia* (excessive hunger).

The person with type 1 DM requires insulin from an outside source *(exogenous insulin)* to sustain life. Without insulin, the patient will develop diabetes-related ketoacidosis (DKA), a life-threatening condition causing metabolic acidosis. Newly diagnosed patients may have a remission, or "honeymoon period," for 3 to 12 months after starting treatment. During this time, the patient needs little injected insulin because β-cell insulin production is still sufficient for healthy glucose levels. Eventually, as more β cells are destroyed, and glucose levels increase, the honeymoon period ends. The patient then requires insulin on a permanent basis.

Type 2 Diabetes

Type 2 diabetes accounts for about 90% to 95% of people with DM.[5] Many risk factors contribute to developing type 2 DM. These include having a family history of type 2 DM, being

BOX 53.2 PROMOTING HEALTH EQUITY

DM

- Native Americans and Alaska Natives have the highest prevalence of DM (23.5%)[6]
- Rates of DM are higher among Blacks (20.4%), Hispanics (22.1%), than among Whites (12.1%), and Asians (14.0%)[6]

overweight or obese, and being older. Although it occurs less often in children, the incidence is increasing due to the increasing prevalence of childhood obesity. Type 2 DM is more prevalent in some ethnic populations (Box 53.2). This increase is related to genetic predisposition, environmental factors, and diet choices.

Etiology and pathophysiology. Type 2 DM is characterized by a combination of inadequate insulin secretion and insulin resistance. The pancreas usually makes some *endogenous* (self-made) insulin. However, the body either does not make enough insulin, does not use it effectively, or both. The presence of endogenous insulin is a major distinction between type 1 and type 2 DM. In type 1 DM, there is an absence of endogenous insulin.

Genetic Link

Although we do not fully understand the genetics of type 2 DM, it is likely that multiple genes are involved (Box 53.1). We have found genetic mutations that lead to insulin resistance and a higher risk for obesity in many people with type 2 DM. Persons with a first-degree relative with the disease are 10 times more likely to develop type 2 DM.

Metabolic abnormalities have a role in developing type 2 DM (Fig. 53.3). The first factor is **insulin resistance**. This is a condition in which body tissues do not respond to the action of insulin because insulin receptors are unresponsive, insufficient in number, or both. Most insulin receptors are located on skeletal muscle, fat, and liver cells. When insulin is not properly used, the entry of glucose into the cell is impeded, causing hyperglycemia. In the early stages of insulin resistance, the pancreas responds to high glucose levels by producing more insulin (if β cell function is normal). This creates a temporary state of hyperinsulinemia that coexists with hyperglycemia.

A second factor in developing type 2 DM is a marked decrease in the ability of the pancreas to make insulin. The β cells become fatigued from the compensatory overproduction of insulin or when β-cell mass is lost. We do not know the reason the β cells fail to adapt. It may be due to the adverse effects of chronic hyperglycemia or high circulating free fatty acids. In addition, the α cells of the pancreas increase production of glucagon.

This leads to a third factor, which is inappropriate glucose production by the liver. Instead of properly regulating the release of glucose in response to blood levels, the liver does so in a haphazard way that does not correspond to the body's needs at the time.

A fourth factor is the production of hormones and cytokines by adipose tissue *(adipokines)*. Adipokines secreted by adipose

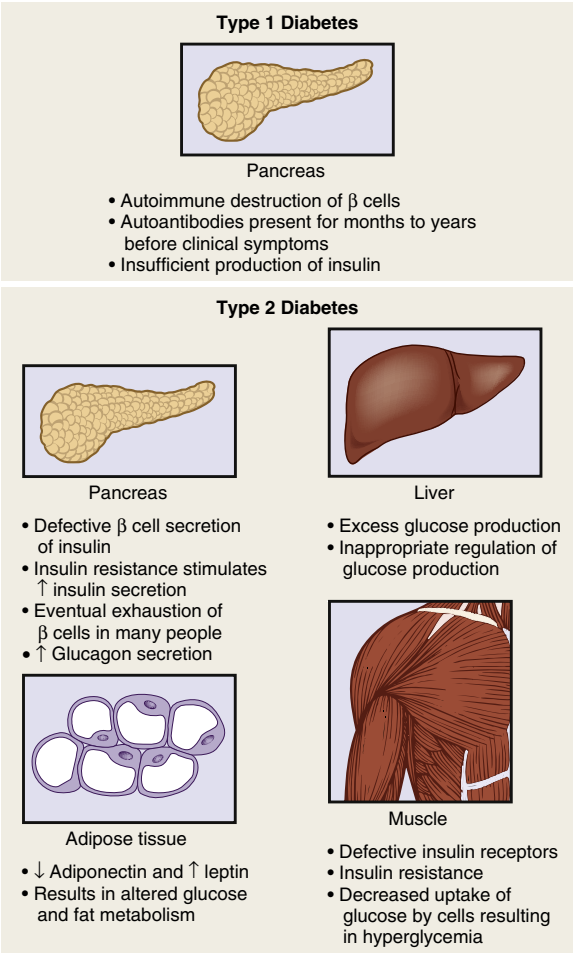

Fig. 53.3 Altered mechanisms in type 1 and type 2 DM.

tissue appear to play a role in glucose and fat metabolism. They are likely to contribute to developing type 2 DM.[7] We think adipokines cause chronic inflammation, a factor involved in insulin resistance, type 2 DM, and cardiovascular disease (CVD). The 2 main adipokines thought to affect insulin sensitivity are adiponectin and leptin. Finally, the brain, kidneys, and gut have roles in developing type 2 DM. We are continuously learning more about metabolic factors and developing type 2 DM.

People with *metabolic syndrome* have an increased risk of developing type 2 DM. Metabolic syndrome has 5 components: increased glucose levels, abdominal obesity, high BP, high triglyceride levels, and decreased high-density lipoprotein (HDL) levels (see Table 45.11). A person with 3 of the 5 components is considered to have metabolic syndrome.[8] Overweight persons with metabolic syndrome can reduce their risk for DM through food choices and regular physical activity. See Chapter 45 for more about metabolic syndrome.

Onset of disease. The disease onset in type 2 DM is usually gradual. The person may go for many years with undetected hyperglycemia and few, if any, symptoms. Many people are diagnosed on routine laboratory testing or when they undergo treatment for other conditions, and they have high glucose or glycosylated hemoglobin (A1C) levels. The signs and symptoms of hyperglycemia develop when about 50% to 80% of β cells are

no longer secreting insulin. At the time of diagnosis, the average person has had type 2 DM for 6½ years.

Prediabetes

Persons diagnosed with prediabetes are at increased risk for developing type 2 DM. **Prediabetes** is defined as **impaired glucose tolerance (IGT), impaired fasting glucose (IFG)**, or both. It is an intermediate stage between normal glucose homeostasis and DM. Glucose levels are high but not high enough to meet the diagnostic criteria for DM.[4] A diagnosis of IGT is made if the 2-hour oral glucose tolerance test (OGTT) values are 140 to 199 mg/dL (7.8 to 11.0 mmol/L). IFG is diagnosed when fasting glucose levels are 100 to 125 mg/dL (5.56 to 6.9 mmol/L).

Persons with prediabetes usually do not have symptoms. However, long-term damage to the body, especially the heart and blood vessels, may already be occurring. It is important for people to undergo screening and understand risk factors for DM. People with prediabetes can take action to prevent or delay their developing type 2 DM. Encourage those with prediabetes to have their glucose level and A1C checked regularly and monitor for symptoms of DM, such as fatigue or frequent infections. Maintaining a healthy weight, exercising regularly, and making healthy food choices reduce the risk for developing type 2 DM in those with prediabetes.

Gestational Diabetes

Gestational diabetes develops during pregnancy and occurs in about 2% to 10% of pregnancies in the United States.[9] Women with gestational DM have a higher risk for cesarean delivery. Their babies are at increased risk for perinatal death, birth injury, and neonatal complications. Women who are at high risk for gestational DM are screened at the first prenatal visit. Those at high risk include women who are obese, are of advanced maternal age, or have a family history of DM. We screen women with an average risk for gestational DM using an OGTT at 24 to 28 weeks of gestation. Most women with gestational DM have normal glucose levels within 6 weeks postpartum. Women with a history of gestational DM have up to a 63% chance of developing type 2 DM within 16 years. Gestational DM and managing the pregnant patient with DM are specialized areas not covered in detail here. Consult an obstetric text for more information.

Other Specific Types of Diabetes

DM occurs in some people because of another medical condition or treatment of a medical condition that causes abnormal glucose levels. Conditions that may cause DM can result from injury to, interference with, or destruction of the β-cell function in the pancreas. These include Cushing syndrome, hyperthyroidism, pancreatitis, cystic fibrosis, hemochromatosis, and parenteral nutrition. Common drugs that can induce DM include corticosteroids (prednisone), thiazides, phenytoin (Dilantin), and atypical antipsychotics (e.g., clozapine [Clozaril]). DM caused by medical conditions or drugs can resolve when the underlying condition is treated or the drug is discontinued.

Clinical Manifestations

Type 1 Diabetes

Because the onset of type 1 DM is rapid, the first manifestations are usually acute. The classic symptoms are *polyuria, polydipsia,* and *polyphagia.* The osmotic effect of excess glucose in the bloodstream causes polydipsia and polyuria. Polyphagia is a result of cell malnourishment when insulin deficiency prevents cells from using glucose for energy. Weight loss may occur because the body cannot get glucose and instead breaks down fat and protein to try to make energy. Weakness and fatigue may result because cells lack needed energy from glucose. DKA, a complication most common in those with untreated type 1 DM, has additional manifestations.

Type 2 Diabetes

The manifestations of type 2 DM are often nonspecific. Although not common, it is possible for a person with type 2 DM to have classic symptoms associated with type 1 DM, including polyuria, polydipsia, and polyphagia. Some of the common manifestations of type 2 DM are fatigue, recurrent infections, recurrent vaginal yeast or candida infections, prolonged wound healing, and vision problems.

Diagnostic Studies

The diagnosis of DM is made using 1 of 4 methods (Table 53.2). If a patient has a hyperglycemic crisis or clear symptoms of hyperglycemia (polyuria, polydipsia, polyphagia) with a random plasma glucose level of 200 mg/dL or greater, repeat testing is not needed. Otherwise, criteria 1 through 3 require confirmation by repeat testing to rule out laboratory error. The repeat test should be the same test used initially. For example, if a random high glucose was the initial measurement, that same measure should be used to confirm a diagnosis.

The accuracy of laboratory results depends on patient preparation and attention to the many factors that influence the results. Factors that can falsely increase values include recent severe restrictions of carbohydrate intake, acute illness, drugs (e.g., contraceptives, corticosteroids), and restricted activity, such as bed rest. A patient with impaired gastrointestinal (GI) absorption or who has recently taken acetaminophen may have false-negative results.

A1C measures the amount of glycosylated hemoglobin (Hgb) as a percentage of total Hgb. For example, an A1C of 6.5% means that 6.5% of the total Hgb has glucose attached

TABLE 53.2 Diagnostic Criteria

DM

The diagnosis of DM is made using 1 of 4 methods:

1. A1C of 6.5% or higher
2. Fasting plasma glucose (FPG) level of 126 mg/dL (7.0 mmol/L) or greater. *Fasting* is defined as no caloric intake for at least 8 hours
3. A 2-hour plasma glucose level of 200 mg/dL (11.1 mmol/L) or greater during an OGTT, using a glucose load of 75 g
4. In a person with classic symptoms of hyperglycemia (polyuria, polydipsia, unexplained weight loss) or hyperglycemic crisis, a random plasma glucose level of 200 mg/dL (11.1 mmol/L) or greater

to it. The amount of glycosylated Hgb depends on the glucose level. When glucose levels are high over time, the amount of glucose attached to Hgb increases. This glucose stays attached to the red blood cell (RBC) for the life of the cell (about 120 days). Therefore, A1C provides an average measure of glucose levels over the previous 2 to 3 months. Increases in the A1C reflect higher average glucose levels. A1C does not, however, consider fluctuations in glucose. It does not give a good indicator of how often someone has high or low glucose levels. An advantage of the A1C includes greater convenience since fasting is not needed. Diseases affecting RBCs (e.g., iron deficiency anemia, sickle cell anemia) can influence the A1C and should be considered when interpreting results.

Teach patients with DM and prediabetes to have their A1C regularly monitored to determine how well they are meeting their glycemic goals. The ADA identifies an A1C goal for patients with DM of less than 7.0%. The American College of Endocrinology recommends an A1C of less than 6.5%. When the A1C is maintained at near-normal levels, the risk for developing microvascular and macrovascular complications is greatly reduced. For people with prediabetes, monitoring the A1C can detect overt DM and provide feedback on efforts to prevent DM.

More people with DM are using continuous glucose monitoring (CGM). CGM reports include "time in range." It is a more accurate way to look at daily glucose levels and fluctuations than A1C. Until CGM is more widely used, A1C remains a good tool for monitoring glucose over time.

Fructosamine is another way to assess glucose levels. It is formed by a chemical reaction of glucose with plasma protein. It reflects glycemia in the previous 1 to 3 weeks. Fructosamine levels may show a change in glucose levels before A1C does. It is used for people with hemoglobinopathies or short-term measurement of glucose levels, for instance, after a change in medication or during pregnancy.

Islet cell autoantibody testing can help distinguish between autoimmune type 1 DM and DM from other causes. Autoantibodies can develop into 1 or several autoantigens, including GAD65, IA-2, or insulin.

Interprofessional Care

The goals of DM management are to reduce symptoms, promote well-being, prevent acute complications related to hyperglycemia and hypoglycemia, and prevent or delay the onset and progression of long-term complications. These goals are most likely to be met when the patient maintains glucose levels as near to normal as possible. Meeting goals for what we refer to as the "ABCs of Diabetes" can help patients manage DM and lower their risk for heart attack and stroke. The ABCs refer to (1) A1C, (2) blood pressure, and (3) cholesterol. Only 19.2% of adults meet the target goals for all 3 steps.[10] Patient teaching, which enables the patient to self-manage their own care, is essential to achieve glycemic goals. Nutrition therapy, drug therapy, exercise, and BGM are the tools used in managing DM (Table 53.3).

The 3 major types of glucose-lowering agents (GLAs) used in DM treatment are insulin, oral agents (OAs), and noninsulin injectable agents.[11] All persons with type 1 DM require insulin. For some people with type 2 DM, a healthy eating plan, regular physical activity, and maintaining a healthy body weight are enough to attain safe glucose levels. Eventually, most people will need medication because type 2 DM is a progressive disease.

TABLE 53.3 Interprofessional Care

DM

Diagnostic Assessment

- History and physical assessment
- Blood tests, including glucose levels (Table 53.2), A1C, fructosamine, lipid profile, BUN and creatinine, electrolytes, islet cell autoantibodies
- Urine for complete urinalysis, albuminuria, and acetone (if indicated)
- BP
- ECG (if indicated)
- Funduscopic examination (dilated eye examination)
- Dental examination
- Neurologic examination, including monofilament test for sensation to lower extremities
- Ankle-brachial index (ABI) (if indicated)
- Foot (podiatric) examination
- Monitoring of weight

Management

- Patient and caregiver teaching and follow-up programs
- Nutrition therapy (Table 53.9)
- Exercise therapy (Tables 53.10 and 53.11)
- Blood glucose monitoring (BGM) (Table 53.12)

Drug Therapy

- Insulin (Fig. 53.3 and Tables 53.4 and 53.5)
- Oral agents (OAs) and noninsulin injectable agents (Table 53.8)
- Enteric-coated aspirin (81–162 mg/day)
- ACE inhibitors (see Table 36.6)
- Angiotensin II receptor blockers (ARBs) (see Table 36.6)
- BP medications (see Table 36.6)

Drug Therapy: Insulin

Exogenous (injected) insulin is needed when someone has inadequate insulin to meet specific metabolic needs. People with type 1 DM require exogenous insulin to survive. They often use multiple daily injections of insulin (often 4 or more) or continuous insulin infusion via an insulin pump to adequately manage glucose levels. People with type 2 DM may need exogenous insulin during periods of severe stress, such as illness or surgery. Since type 2 DM is progressive, over time, the combination of nutrition, exercise, OAs, and noninsulin injectable agents may no longer adequately manage glucose levels. At that point, we add exogenous insulin to their management plan. People with type 2 DM may also need up to 4 injections per day to adequately maintain their glucose levels. Insulin pumps may be an option for patients with type 2 DM.

Types of Insulin

Today, people use genetically engineered human insulin made in laboratories. The insulin is derived from common bacteria (e.g., *Escherichia coli*) or yeast cells using recombinant DNA technology. Types of insulin differ by their onset, peak action, and duration (Fig. 53.4). They are categorized as rapid-acting, short-acting, intermediate-acting, and long-acting insulin (Table 53.4).

INSULIN PREPARATION	ONSET, PEAK, DURATION	EXAMPLE
Rapid acting lispro (Humalog) aspart (NovoLog, Fiasp) glulisine (Apidra)	*Onset:* 10–30 min *Peak:* 30 min–3 hr *Duration:* 3–5 hr	Short acting Regular (Humulin R, Novolin R)	*Onset:* 30 min–1 hr *Peak:* 2–5 hr *Duration:* 5–8 hr	Intermediate acting NPH (Humulin N, Novolin N)	*Onset:* 1.5–4 hr *Peak:* 4–12 hr *Duration:* 12–18 hr	Long acting glargine (Lantus, Toujeo, Basaglar) detemir (Levemir) degludec (Tresiba)	*Onset:* 0.8–4 hr *Peak:* Less defined or no pronounced peak *Duration:* 16–24 hr	Inhaled insulin Afrezza	*Onset:* 12–15 min *Peak:* 60 min *Duration:* 2.5–3 hr	
Fig. 53.4 Commercially available insulin preparations showing onset, peak, and duration of action. Patient responses to each type of insulin are different and affected by many factors.

TABLE 53.4 Drug Therapy

Types of Insulin

Classification	Examples
Rapid-acting insulin	aspart (NovoLog, Fiasp) glulisine (Apidra) lispro (Humalog)
Short-acting insulin	regular (Humulin R, Novolin R)
Intermediate-acting insulin	NPH (Humulin N, Novolin N)
Long-acting insulin	degludec (Tresiba) detemir (Levemir) glargine (Basaglar, Lantus, Toujeo) insulin glargine (Basaglar)
Combination therapy (premixed)	aspart protamine/aspart 70/30[a] (NovoLog Mix 70/30) degludec/aspart 70/30 (Ryzodeg) lispro protamine/lispro 75/25[a] (Humalog Mix 75/25) lispro protamine/lispro 50/50[a] (Humalog Mix 50/50) NPH/regular 70/30[a] (Humulin 70/30, Novolin 70/30) NPH/regular 50/50[a] (Humulin 50/50)
More concentrated insulin	Humulin R U-500 Toujeo U-300 (insulin glargine) Humalog U-200 (insulin lispro)
Inhaled insulin	Afrezza

[a]These numbers refer to percentages of each type of insulin.

Insulin Plans

Table 53.5 shows examples of insulin plans. The insulin approach that most closely mimics endogenous insulin production is the **basal-bolus plan** (often called *intensive or physiologic insulin therapy*). It consists of multiple daily insulin injections or an insulin pump together with frequent BGM or CGM. Injections include rapid- or short-acting (bolus) insulin before meals and intermediate- or long-acting (basal) background insulin once or twice a day. The goal is to achieve a glucose level as close to normal as possible, as much of the time as possible. We refer to this as "time in range."

Other, less intense plans can promote healthy glucose levels for some people. Ideally, the patient and the HCP work together to choose a plan. Selection criteria are based on the desired and feasible glucose levels and the patient's lifestyle, food choices, and activity. If a less intense plan is not giving the person optimal results, the HCP may encourage a more intense approach.

Mealtime Insulin (Bolus)

To manage postprandial glucose levels, the timing of rapid- and short-acting insulin in relation to meals is crucial. Rapid-acting synthetic insulin analogs, which include aspart (NovoLog, Fiasp), glulisine (Apidra), and lispro (Humalog), have an onset of action of about 15 minutes. They should be injected within 15 minutes of eating. The rapid-acting analogs most closely mimic natural insulin secretion in response to a meal.

TABLE 53.5 Drug Therapy

Insulin Plans

Plan	Type of Insulin and Frequency	Action Profile	Comments
Once a day Single dose	Intermediate (NPH) *At bedtime*		1 injection should provide nighttime coverage.
	OR Long-acting (degludec [Tresiba], detemir [Levemir], glargine [Lantus]) *In am or at bedtime*		1 injection may last up to 24 hr with fewer defined peaks and less chance for hypoglycemia. Does not cover postprandial glucose levels.
Twice a day Split-mixed dose	NPH and regular or rapid (both regular and rapid are shown on the diagram) *Before breakfast and at dinner*		2 injections provide coverage for 24 hr. Person must eat at certain times to avoid hypoglycemia.
Three times a day Combination of mixed and single dose	NPH and regular or rapid (both regular and rapid are shown on the diagram) *Before breakfast* + Regular or rapid *Before dinner* + NPH *At bedtime*		3 injections provide coverage for 24 h, especially during early AM hours. Decreased potential for 2–3 AM hypoglycemia.
Basal-bolus Multiple dose	Regular or rapid (both regular and rapid are shown on the diagram) *Before breakfast, lunch, and dinner* + Long-acting (degludec, detemir, or glargine) *Once or twice a day* *OR*		More flexibility at mealtimes and for amount of food intake. Good postprandial coverage. Preprandial glucose checks and following a patient-centered plan are beneficial. People with type 1 DM require basal insulin to cover 24 hr. Most physiologic approach, other than pump.
	Regular or rapid (both regular and rapid are shown on the diagram) *Before breakfast, lunch, and dinner* + NPH *Twice a day*		

Rapid-acting (lispro, aspart, glulisine) insulin.
Short-acting (regular) insulin.
Intermediate-acting (NPH) or long-acting (glargine, detemir, degludec) insulin.

Short-acting regular insulin has an onset of action of 30 to 60 minutes. It is injected 30 to 45 minutes before a meal to ensure that the insulin is working at the same time as meal absorption. Because timing an injection 30 to 45 minutes before a meal is hard for some people to do with their lifestyles, those taking insulin with their meals often prefer the flexibility of rapid-acting insulins. Short-acting insulin is more likely to cause hypoglycemia because of a longer duration of action.

Long- or Intermediate-Acting (Basal) Background Insulin

In addition to mealtime insulin, people with type 1 DM use a long- or intermediate-acting basal (background) insulin to maintain glucose levels in between meals and overnight. Without 24-hour background insulin, people with type 1 DM are more prone to developing DKA. Many people with type 2 DM who use OAs will need basal insulin to adequately manage glucose levels.

The long-acting insulins include degludec (Tresiba), detemir (Levemir), and glargine (Lantus, Toujeo, Basaglar). Long-acting insulin is released steadily and continuously. For most people, it does not have a peak of action. The action time for long-acting insulin varies (Fig. 53.4). Although they can be given once daily, detemir is often given twice daily. Because they lack peak action time, the risk for hypoglycemia with this type of insulin is greatly reduced. Glargine and detemir must not be diluted or mixed with any other insulin or solution in the same syringe. If

OAs and long-acting insulin are not adequate to achieve glycemic goals, people with type 2 DM may need to add mealtime insulin.

Intermediate-acting insulin (NPH) can be used as basal insulin. It has a duration of 12 to 18 hours. The disadvantage of NPH is that its action peaks 4 to 12 hours after injection, which can result in hypoglycemia. NPH can be mixed with short- and rapid-acting insulins. It is never given IV.

CHECK YOUR PRACTICE

You are preparing your patient's order for NPH insulin. When you look at the vial, you notice that it is cloudy. You think that you should throw away the vial because it has become contaminated.

- Before you take this action, what should you do?

All insulins are clear solutions except NPH, lispro protamine, and aspart protamine. They are cloudy because they contain a protein called protamine, which makes them work longer. These insulins must be gently agitated before administration.

Combination Insulin Therapy

For those who want to use only 1 or 2 injections per day, a short- or rapid-acting insulin is mixed with intermediate-acting insulin in the same syringe. This allows the person to have both mealtime and basal coverage without having to give 2 separate injections. Although this may be more appealing, most people achieve target glucose levels with basal-bolus therapy. Patients may mix the 2 types of insulin themselves or use a commercially premixed formula or pen (Table 53.4). Premixed formulas offer convenience as people do not have to draw up and mix insulin from 2 different vials. This is helpful to those who lack the visual, manual, or cognitive skills to mix insulin themselves. However, it is harder to achieve target glucose levels because there is less opportunity for flexible dosing based on need.

Insulin Storage

As a protein, insulin has special storage considerations. Extreme temperatures alter insulin and can make it less effective. Insulin vials and pens in use may be left at room temperature for up to 4 weeks. The room temperature cannot be higher than 86°F (30°C) or below freezing (<32°F [0°C]). Teach patients to avoid exposing their insulin to direct sunlight. A person who is traveling in hot climates may store insulin in a thermos or cooler to keep it cool (not frozen). Store unopened insulin vials and pens in the refrigerator.

People who are traveling or caregivers of patients with impaired vision or who cannot fill their own syringes may prefill insulin syringes. Prefilled syringes with 2 different insulins are stable for up to 1 week when stored in the refrigerator. Syringes with only 1 type of insulin are stable for up to 30 days.

Teach patients to store syringes in a vertical position with the needle pointed up to avoid clumping of suspended insulin in the needle. Before injection, gently roll prefilled syringes between the palms 10 to 20 times to warm the insulin and resuspend the particles. Some insulin combinations cannot be prefilled and stored because the mixture can alter the onset, action, and/or peak times of either insulin. Consult a reference as needed when mixing and prefilling different types of insulin.

Insulin Administration

Routine doses of insulin are given by subcutaneous injection. Regular insulin can be given IV when immediate onset of action is desired. Insulin is not taken orally because it is inactivated by gastric fluids. Teach patients to avoid injecting insulin IM because rapid and unpredictable absorption could result in hypoglycemia.

Insulin injection. The steps in giving a subcutaneous insulin injection are outlined in Table 53.6. Teach this technique to new insulin users and review it periodically with long-term users. Never assume that because the patient already uses insulin, they know and practice the correct insulin injection technique. The patient may not have understood prior instructions, or changes in eyesight may result in incorrect preparation.[12] The patient may not see air bubbles in the syringe or may improperly read the scale on the syringe. The patient receiving mixed insulins in the same syringe needs to learn the right technique for combining them if they are not using commercially prepared premixed insulin.

The speed with which peak serum concentrations are reached varies with the injection site. The fastest subcutaneous absorption is from the abdomen, followed by the arm, thigh, and buttock. Although the abdomen is often the preferred injection site, other sites work well (Fig. 53.5). Caution the patient about injecting into a site that will be exercised. For example, injecting into the thigh and then going jogging could increase body heat and circulation. This could increase the rate of insulin absorption and speed the onset of action, causing hypoglycemia.

Teach patients to rotate the injection within and between sites. This allows for better insulin absorption. It may be helpful

TABLE 53.6 PATIENT & CAREGIVER TEACHING

Preparing an Insulin Injection

Include the following instructions when teaching the patient and caregiver about insulin therapy:

1. Wash hands thoroughly.
2. Always inspect insulin bottle before using it. Make sure that it is the right type and concentration, expiration date has not passed, and top of bottle is in perfect condition. Insulin solutions (except for NPH, lispro protamine, aspart protamine) should look clear and colorless. Discard if it appears discolored or you see particles in the solution.
3. For intermediate-acting insulins (which are normally cloudy), gently roll the insulin bottle between the palms of hands to mix the insulin. Do not agitate clear insulins. Do not shake insulin to minimize introduction of air bubbles.
4. Choose right injection site (Fig. 53.5).
5. Ensure that the site is clean and dry.
6. Push the needle straight into the skin (90-degree angle). If you are very thin, muscular, or using an 8- or 12-mm needle, you may need to pinch the skin and/or use a 45-degree angle.
7. Push the plunger all the way down, leave needle in place for 5 sec to ensure that all insulin is injected, and then remove needle.
8. Destroy and dispose of single-use syringe safely.

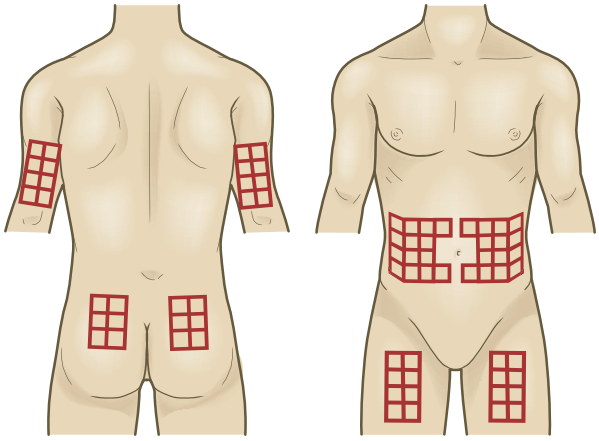

Fig. 53.5 Insulin injection sites.

to think of the abdomen as a checkerboard, with each ½-in square representing an injection site. Injections are rotated systematically across the board, with each injection site at least ½ to 1 inch away from the previous injection site. It can be helpful to inject fast-acting insulin into faster-absorbing sites and slow-acting insulin into slower absorbing sites.

Most commercial insulin is available as U100. This means that 1 mL contains 100 U of insulin. U100 insulin must be used with a U100-marked syringe. Disposable plastic insulin syringes are available in a variety of sizes, including 1.0, 0.5, and 0.3 mL. The 0.5-mL size is for doses of 50 U or less. The 0.3-mL syringe is for doses of 30 U or less. The 0.5- and 0.3-mL syringes are in 1-unit increments. This provides more accurate delivery when the dose is an odd number. The 1.0-mL syringe is necessary for patients who inject more than 50 U of insulin. The 1.0-mL syringe is in 2-unit increments. When patients change from a 0.3- or a 0.5-mL to a 1.0-mL syringe, tell them of the dose increment difference.

Insulin syringe needles come in 3 lengths: 5 mm (3/16 in), 8 mm (5/16 in), and 12.7 mm (½ in).[13] Needle gauges vary among syringes. The needle gauges available are 28, 29, 30, and 31. The higher the gauge number, the smaller the diameter. This results in a more comfortable injection. Only the person using the syringe should recap the needle. Patients performing self-injection can prepare the site with routine hygiene, such as washing with soap and rinsing with water.

SAFETY ALERT

- Never recap a needle used for a patient.
- When injecting a patient, prepare the site with alcohol to prevent health care–associated infection.

Insulin is typically injected at a 90-degree angle. For very thin or muscular patients in the hospital, perform injections at a 45-degree angle. At home, patients inject at a 90-degree angle using the shortest needle desired. We no longer pinch up the skin to avoid IM injection because of the use of short needles.

An insulin pen is a compact device loaded with an insulin cartridge that serves the same function as a needle and syringe (Fig. 53.6). Pen needles are available in lengths of 4 mm (5/32 in), 5 mm (3/16 in), 8 mm (5/16 in), and 12.7 mm (½ in) and in 3 gauges: 29, 31, and 32. Insulin pens offer convenience and flexibility. They are portable, are more discreet than using a vial and syringe, and provide consistent and accurate dosing. For patients with poor vision, the pen is a better option. They can hear the pen click as they dial the dose. Insulin pens come packaged with printed instructions, including pictures of the steps to take when using the pen. These instructions are helpful when teaching new pen users and reviewing technique with current users. Smart pens connect with a phone app that provides many reminders and helps people calculate doses.

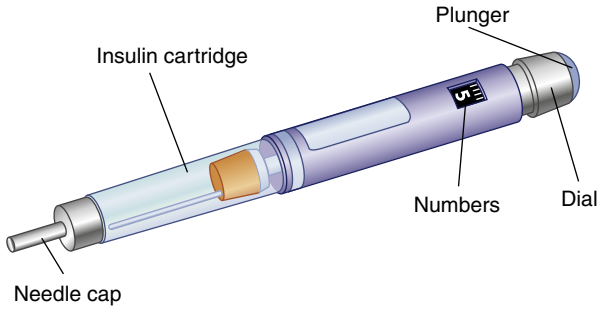

Fig. 53.6 Parts of insulin pen.

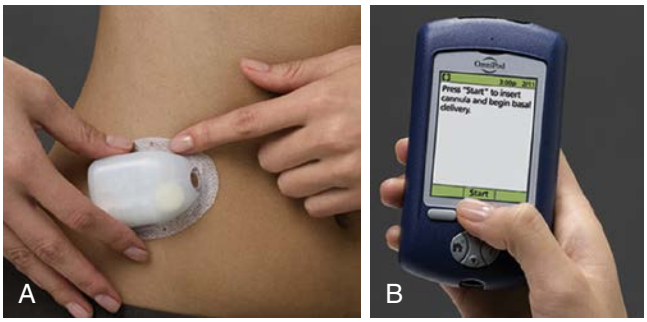

Fig. 53.7 (A) OmniPod Insulin Management System. The Pod holds and delivers insulin. (B) The Personal Diabetes Manager (PDM) wirelessly programs insulin delivery via the Pod. The PDM has a built-in glucose meter. (Courtesy of Insulet Corporation.)

Insulin pump. An *insulin pump* delivers a continuous subcutaneous insulin infusion through a small device worn on the belt, in a pocket, or under clothing.[14] Insulin pumps use rapid-acting insulin. It is loaded into a reservoir or cartridge and connected via plastic tubing to a catheter inserted into the subcutaneous tissue. Insulet Corporation has an insulin pump that is a tubing-free system (Fig. 53.7). All insulin pumps are programmed to deliver a continuous infusion of rapid-acting insulin 24 hours a day, known as the *basal rate*. Basal insulin can be temporarily increased or decreased based on carbohydrate intake, activity, or illness. Pump users need different basal rates at different times of the day.

At mealtime, the user programs the pump to deliver a bolus infusion of insulin appropriate to the amount of carbohydrate ingested and an additional amount, if needed, to bring down or "correct" high preprandial glucose. The infusion set is changed every 2 to 3 days and placed in a new site to avoid infection and promote good insulin absorption. Insulin pump users check

their glucose level at least 4 times per day and/or use a CGM system. Monitoring 8 times or more per day is common.

A major advantage of the insulin pump is the potential for keeping glucose levels in a tighter range with the goal of eliminating both high and low glucose. With careful programming and constant monitoring, this is possible because insulin delivery is similar to the normal physiologic pattern. Pumps offer users more flexibility with meals and activities. Potential challenges of pump therapy include infection at the insertion site, an increased risk for DKA if the infusion is disrupted, the cost of the pump and supplies, and being attached to a device.

Hybrid closed-loop insulin pumps deliver insulin automatically by adjusting basal doses constantly throughout the day. The person must program bolus doses, which is why they are called "hybrid."

Problems With Insulin Therapy

Problems associated with insulin therapy include hypoglycemia, allergic reactions, lipodystrophy, and the Somogyi effect. Hypoglycemia is discussed later in this chapter. Table 53.7 outlines guidelines for assessing patients treated with insulin and other GLAs.

Allergic reactions. Local inflammatory reactions to insulin may occur. These include itching, redness, and burning around the injection site. Local reactions may be self-limiting within 1 to 3 months or may improve with a low dose of antihistamine. A true insulin allergy is rare. It is manifested by a systemic response with urticaria and possibly anaphylactic shock. Preservatives in the insulin and the latex or rubber stoppers on the vials have caused allergic reactions.

Lipodystrophy. *Lipodystrophy* (changes in subcutaneous fatty tissue) may occur if the same injection sites are used frequently. *Atrophy*, which is uncommon, is the wasting of subcutaneous tissue. It presents as indentations in injection sites. *Hypertrophy* happens more often and is a thickening of the subcutaneous tissue. It eventually regresses if the person does not use the site for at least 6 months. Injecting into a hypertrophied site may cause erratic insulin absorption.

Somogyi effect and dawn phenomenon. Hyperglycemia in the morning may be due to the **Somogyi effect**. A high dose of insulin causes a decline in glucose levels during the night. As a result, counterregulatory hormones (e.g., glucagon, epinephrine, GH, cortisol) are released. They stimulate lipolysis, gluconeogenesis, and glycogenolysis, which in turn cause rebound hyperglycemia. The danger of this effect is that when glucose levels are measured in the morning, hyperglycemia is present, and the patient (or the HCP) may increase the insulin dose.

If a patient has morning hyperglycemia, checking glucose levels between 2:00 and 4:00 AM for hypoglycemia will help determine if the cause is the Somogyi effect. The patient may report headaches on awakening and recall having night sweats or nightmares.

The **dawn phenomenon** is also characterized by hyperglycemia that is present on awakening. Two counterregulatory hormones (GH and cortisol), which are excreted in increased amounts in the early morning hours, may be the cause of this phenomenon. The dawn phenomenon affects many people with DM. It tends to be most severe when GH is at its peak in adolescence and young adulthood.

Careful assessment is needed to diagnose the Somogyi effect or dawn phenomenon because the treatment for each differs. The treatment for Somogyi effect is a bedtime snack, reducing the dose of insulin, or both. The treatment for dawn phenomenon is an increase in insulin or an adjustment in administration time. Your assessment must include insulin dose, injection sites, and variability in the time of meals or insulin administration. Ask the patient to measure and document bedtime, nighttime

TABLE 53.7 Assessing the Patient Treated With Glucose-Lowering Agents

Category	Assessment
For Patient With Newly Diagnosed DM or for Reevaluation of Drug Plan	
Affective	• What emotions and attitudes are patient and caregiver displaying concerning DM diagnosis and insulin or other treatment?
Cognitive	• Is patient or caregiver able to understand why insulin or other drugs are part of DM management? • Is patient or caregiver able to understand concepts of asepsis, combining insulins, and drug side effects? • Is patient able to remember to take >1 dose/day? • Does patient take medications at right times in relation to meals?
Psychomotor	• Is patient or caregiver physically able to prepare and give accurate drug doses?
For Patient Follow-up	
Effectiveness of therapy	• Is patient having symptoms of hyperglycemia? • Does glucose record show glucose levels in or out of the target range? • Is A1C in a safe range and consistent with glucose records?
Self-management behaviors	• If patient is having hyperglycemia or hypoglycemia, how do they manage the episodes? • Has patient determined reason for hyperglycemia or hypoglycemia? • How much insulin or other drug is patient taking and at what time of day? Is patient adjusting insulin dose? Under what circumstances and by how much? • Has the exercise pattern changed? • Is patient making healthy food choices? Are meals taken at times corresponding to peak insulin action?
Side effects of therapy	• Is atrophy or hypertrophy present at injection sites? • Has patient had hypoglycemia? If so, how often? What time of day? What were the symptoms of hypoglycemia? • Are there reports of nightmares, night sweats, or early morning headaches? • Has patient had a skin rash or GI upset since taking DM drugs? • Has patient gained or lost weight?

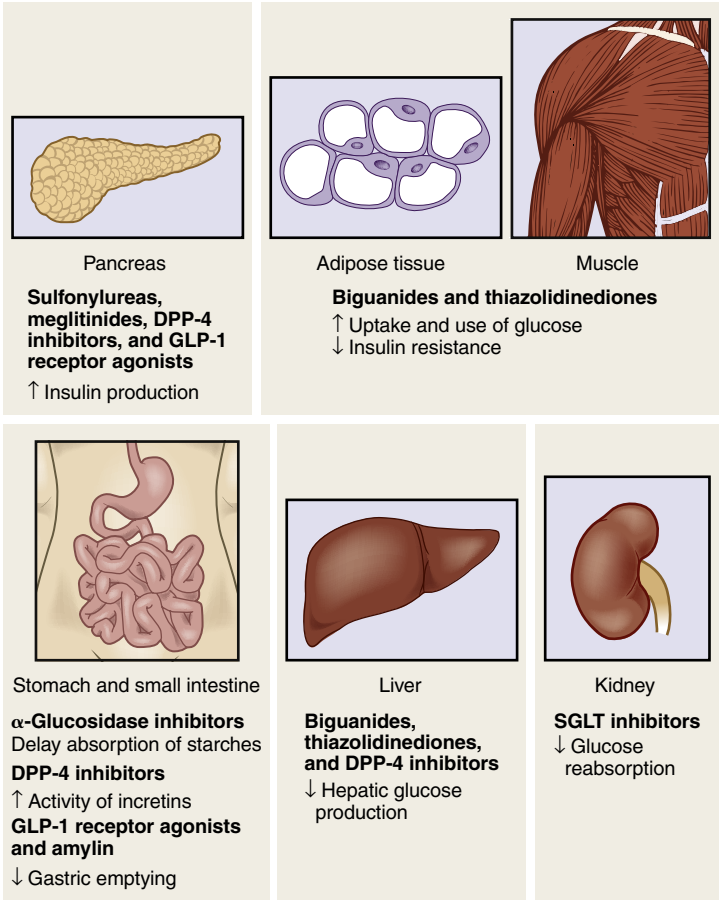

Fig. 53.8 Sites and mechanisms of action of type 2 DM drugs. *DDP-4*, Dipeptidyl peptidase; *GLP-1*, glucagon-like peptide-1; *SGLT*, sodium-glucose co-transporter.

(between 2:00 and 4:00 AM), and morning fasting glucose levels on several occasions. If the predawn levels are less than 60 mg/dL (3.3 mmol/L) and signs and symptoms of hypoglycemia are present, the insulin dosage should be reduced. If the 2:00 to 4:00 AM glucose is high, the insulin dosage should be increased. Counsel the patient on appropriate bedtime snacks.

Inhaled Insulin

Afrezza is a rapid-acting inhaled insulin. It is given at the beginning of each meal or within 20 minutes after starting a meal. Afrezza must be used in combination with long-acting insulin in those with type 1 DM. It should not be used to treat DKA. People with chronic lung disease, such as asthma or COPD, or who smoke should not use Afrezza because bronchospasm can occur. Other side effects include hypoglycemia, cough, and throat pain or irritation.

Drug Therapy: Oral and Noninsulin Injectable Agents

OAs and noninsulin injectable agents work to improve the mechanisms by which the body makes and uses insulin and glucose. These drugs primarily work on 3 defects of type 2 DM: (1) insulin resistance, (2) decreased insulin production, and (3) increased liver glucose production (Fig. 53.8). They may be used in combination with drugs from other classes or with insulin to achieve glucose goals. Table 53.8 lists OAs and noninsulin injectable agents.

Biguanides

The most widely used OA is metformin. It is the only drug in the biguanide class available in the United States. Metformin is the most effective first-line treatment for type 2 DM. Forms of metformin include Glucophage (immediate-release), Glucophage XR (extended-release), Fortamet (extended-release), and Riomet (liquid). The primary action of metformin is to reduce glucose production by the liver. It enhances insulin sensitivity at the tissue level and improves glucose transport into the cells. It has beneficial effects on lipid levels.

Because it may cause moderate weight loss, metformin may be useful for people with type 2 DM and prediabetes who are overweight or obese. It may prevent type 2 DM in those with prediabetes who are younger than age 60 and have risk factors, such as hypertension or a history of gestational DM.

Patients who are having surgery or radiologic procedures that involve the use of a contrast medium need to temporarily discontinue metformin before surgery or the procedure. This reduces the risk of contrast-induced kidney injury (CIN) (see Chapter 49). They should not resume the metformin until 48 hours afterward once their serum creatinine has been checked and is normal.

TABLE 53.8 Drug Therapy

Oral Agents and Noninsulin Injectable Agents

Type	Mechanism of Action	Side Effects	Considerations
Oral Agents			
α-Glucosidase Inhibitors			
acarbose (Precose) miglitol (Glyset)	Delays absorption of complex carbohydrates (starches) from GI tract	Gas, abdominal pain, diarrhea	Take with the first bite of each main meal.
Biguanides			
metformin (Fortamet Glucophage, Glucophage XR, Glumetza, Riomet)	↓ Liver glucose production. ↑ Insulin sensitivity. Improves glucose uptake by tissues, especially muscles	Diarrhea, lactic acidosis	Must be held 1–2 days before IV contrast media given and for 48 hr after. Take with food to minimize GI side effects.
Dipeptidyl Peptidase-4 (DPP-4) Inhibitors			
alogliptin (Nesina) linagliptin (Tradjenta) saxagliptin (Onglyza) sitagliptin (Januvia)	↑ Activity of incretins. ↑ Insulin release from pancreatic β-cells. ↓ Liver glucose production	Pancreatitis, allergic reactions	Take with or without food.
Dopamine Receptor Agonists			
bromocriptine (Cycloset)	Activates dopamine receptors in central nervous system. Unknown how it improves glucose levels	Orthostatic hypotension, nausea, headache, fatigue	Take with food at the same time each day. Teach the patient to change positions slowly.
Meglitinides			
nateglinide repaglinide	Stimulates a rapid and short-lived release of insulin from the pancreas	Weight gain, hypoglycemia	Take any time from 30 min before each meal right up to the time of the meal. They should not be taken if a meal is skipped.
Sodium-Glucose Co-Transporter 2 (SGLT2) Inhibitors			
canagliflozin (Invokana) dapagliflozin (Farxiga) empagliflozin (Jardiance) ertugliflozin (Steglatro)	↓ Renal glucose reabsorption. ↑ Urinary glucose excretion	Increased risk of genital and urinary tract infections. Hypoglycemia	Take in the morning before the first meal of the day. Teach the patient to drink 1–2 glasses of water each day above their normal intake.
Sulfonylureas			
glimepiride (Amaryl) glipizide (Glucotrol, Glucotrol XL) glyburide (DiaBeta, Glynase)	↑ Insulin release from pancreatic islets. ↓ Glycogenolysis and gluconeogenesis. Enhances cellular sensitivity to insulin	Weight gain, hypoglycemia	Take 30 min before meals. Avoid alcohol use.
Thiazolidinediones			
pioglitazone (Actos) rosiglitazone (Avandia)	↑ Glucose uptake in muscle. ↓ Endogenous glucose production	Weight gain, edema. *Pioglitazone:* ↑ Risk for bladder cancer and worsen heart failure. *rosiglitazone:* ↑ Risk for cardiovascular events (e.g., myocardial infarction, stroke)	Taken with or without food.
Combination Oral Therapy			
Actoplus Met, Actoplus Met XR	Same as for metformin and pioglitazone	See side effects for individual drugs	
Duetact	Same as for pioglitazone and glimepiride	Same as above	
Glucovance	Same as for metformin and glyburide	Same as above	
Glyxambi	Same as for empagliflozin and linagliptin	Same as above	
Invokamet, Invokamet XR	Same as for canagliflozin and metformin	Same as above	
Janumet, Janumet XR	Same as for metformin and sitagliptin	Same as above	
Jentadueto, Jentadueto XR	Same as for linagliptin and metformin	Same as above	
Kazano	Same as for alogliptin and metformin	Same as above	
Kombiglyze	Same as for saxagliptin and metformin	Same as above	
Oseni	Same as for alogliptin and pioglitazone	Same as above	
PrandiMet	Same as for metformin and repaglinide	Same as above	

Continued

TABLE 53.8 Drug Therapy—cont'd

Oral Agents and Noninsulin Injectable Agents

Type	Mechanism of Action	Side Effects	Considerations
Qtern	Same as for dapagliflozin and saxagliptin	Same as above	
Qternmet XR	Same as for dapagliflozin, saxagliptin, and metformin XR	Same as above	
Segluromet	Same as for metformin and ertugliflozin	Same as above	
Steglujan	Same as for sitagliptin and ertugliflozin	Same as above	
Synjardy, Synjardy XR	Same as metformin and empagliflozin	Same as above	
Trijardy	Same as for empagliflozin, linagliptin, and metformin XR	Same as above	
Xigduo	Same as for dapagliflozin and metformin	Same as above	
Noninsulin Injectable Agents			
Amylin Analogs			
pramlintide (Symlin)	Slows gastric emptying. ↓ Glucagon secretion and endogenous glucose output from liver. ↑ Satiety	Hypoglycemia, nausea, vomiting, decreased appetite, headache	Inject subcutaneously into the thigh or abdomen before meals. Do not inject into the arm because absorption from the arm is too variable.
Glucagon-Like Peptide-1 (GLP-1) Receptor Agonists			
albiglutide (Tanzeum) dulaglutide (Trulicity) exenatide (Byetta) exenatide extended-release (Bydureon) liraglutide (Victoza) lixisenatide (Adlyxin) semaglutide (Ozempic)	↑ Insulin release. ↓ Glucagon secretion and slow gastric emptying. ↑ Satiety	Nausea, vomiting, hypoglycemia, diarrhea, headache	The delayed gastric emptying may affect the absorption of other oral drugs. Tell patients to take fast-acting oral agents at least 1 hr before injecting a GLP-1 agonist drug.

DRUG ALERT

Metformin

- Do not use in patients with kidney disease, liver disease, or heart failure. Lactic acidosis is a rare complication of metformin accumulation.
- IV contrast media that contain iodine pose a risk for CIN, which could worsen metformin-induced lactic acidosis.
- To reduce risk for CIN, discontinue metformin 2 days before the procedure.
- May be resumed 48 hours after the procedure, assuming kidney function is normal.
- Do not use in people who drink excess amounts of alcohol.

Sulfonylureas

Sulfonylureas include glimepiride (Amaryl), glipizide (Glucotrol, Glucotrol XL), and glyburide (DiaBeta, Glynase). Their primary action is to increase insulin production by the pancreas. This makes hypoglycemia the major side effect.

Meglitinides

Like sulfonylureas, nateglinide and repaglinide increase insulin production by the pancreas. However, because they are more rapidly absorbed and eliminated than sulfonylureas, they are less likely to cause hypoglycemia. When taken just before meals, pancreatic insulin production increases during and after the meal, mimicking the normal response to eating.

α-Glucosidase Inhibitors

These drugs, also known as "starch blockers," work by slowing down carbohydrate absorption in the small intestine. Acarbose and miglitol (Glyset) are the available drugs in this class. They are most effective in lowering postprandial glucose. Their effectiveness is measured by checking 2-hour postprandial glucose levels.

Thiazolidinediones

Thiazolidinediones, sometimes called "insulin sensitizers," include pioglitazone (Actos) and rosiglitazone (Avandia). They are most effective for people who have insulin resistance. These drugs improve insulin sensitivity, transport, and use at target tissues. Because they do not increase insulin production, they do not cause hypoglycemia when used alone. These drugs are rarely used because of their adverse effects. Rosiglitazone can cause cardiovascular events (e.g., myocardial infarction [MI]). It can be obtained only through restricted access programs. Pioglitazone can worsen heart failure (HF). Use is associated with an increased risk for bladder cancer.

Dipeptidyl Peptidase-4 Inhibitors

Normally, the intestines release incretin hormones throughout the day. When glucose levels are normal or high, incretins increase insulin synthesis and release from the pancreas and decrease liver glucose production. Incretin levels increase

after a meal. The 2 main incretin hormones are gastric inhibitory peptide [GIP] and glucagon-like peptide-1 [GLP-1]). They are quickly inactivated by the enzyme dipeptidyl peptidase-4 (DPP-4).

DPP-4 inhibitors (also called *gliptins*) come in pill form. They include alogliptin (Nesina), linagliptin (Tradjenta), saxagliptin (Onglyza), and sitagliptin (Januvia). DPP-4 inhibitors block the action of DPP-4, which inactivates incretin hormones. The result is an increase in insulin release, a decrease in glucagon secretion, and a decrease in liver glucose production. Since the DPP-4 inhibitors are glucose-dependent, they have a lower potential for hypoglycemia. Their main benefit over other drugs with similar effects is the absence of weight gain as a side effect.

Sodium-Glucose Co-Transporter 2 (SGLT2) Inhibitors

Normally, sodium-glucose transporters reabsorb glucose from the kidneys back into the bloodstream. SGLT2 inhibitors work by blocking glucose reabsorption by the kidney, increasing urinary glucose excretion. Drugs in this class include canagliflozin (Invokana), dapagliflozin (Farxiga), and empagliflozin (Jardiance).

Dopamine Receptor Agonist

Bromocriptine (Cycloset) is a dopamine receptor agonist that improves glucose levels. The mechanism of action is unknown. We think people with type 2 DM have low dopamine levels in the morning. These low dopamine levels may interfere with the body's ability to control glucose. Bromocriptine increases dopamine receptor activity. It can be used alone or with another type 2 DM treatment.

Combination Oral Therapy

Many combination drugs are currently available (Table 53.8). These drugs combine different classes of DM medications in 1 pill. An advantage of combination therapy is that the patient takes fewer pills, thus making it easier to take medication.

Glucagon-Like Peptide-1 Receptor Agonists

GLP-1 receptor agonists stimulate GLP-1 (an incretin hormone). It is decreased in people with type 2 DM. These drugs increase insulin synthesis and release from the pancreas, inhibit glucagon secretion, slow gastric emptying, and reduce food intake by increasing satiety. They may be used alone or with another type 2 DM treatment when OAs have not achieved optimal glucose levels.

Except for semaglutide (Rybelsus), which is given orally, they are all given using a subcutaneous injection in a prefilled pen. Exenatide (Byetta) is given twice daily. Liraglutide (Victoza) is given once daily. Albiglutide (Tanzeum), dulaglutide (Trulicity), and exenatide extended-release (Bydureon) are given once every 7 days.

DRUG ALERT

Exenatide (Byetta)

- Acute pancreatitis and kidney problems may occur.

DRUG ALERT

Liraglutide (Victoza) and Dulaglutide (Trulicity)

- Do not use in patients with a personal or family history of medullary thyroid cancer.
- Acute pancreatitis may occur.

Amylin Analogs

Pramlintide (Symlin) is the only available amylin analog. Amylin is a hormone secreted by the β cells of the pancreas in response to food intake. It slows gastric emptying, reduces glucagon secretion, and increases satiety. People with type 1 or type 2 DM with high glucose levels on insulin therapy take pramlintide with their mealtime insulin. It is only used concurrently with insulin and is not a replacement for insulin. The drug cannot be mixed in the same syringe with insulin.

The concurrent use of pramlintide and insulin increases the risk for severe hypoglycemia during the 3 hours after injection, especially in those with type 1 DM. Teach patients to eat a meal with at least 250 calories and fast-acting glucose on hand in case hypoglycemia develops. When using pramlintide, the bolus insulin dose should be reduced.

DRUG ALERT

Pramlintide (Symlin)

- Can cause severe hypoglycemia when used with insulin.

Other Drugs Affecting Glucose Levels

Both the patient and the HCP must be aware of drug interactions that can potentiate hypoglycemia and hyperglycemia effects. For example, β-adrenergic blockers can mask symptoms of hypoglycemia and prolong the hypoglycemic effects of insulin. Loop diuretics can worsen hyperglycemia by inducing potassium loss.

Nutrition Therapy

Patient-centered nutrition therapy, consisting of counseling, education, and ongoing monitoring, is a cornerstone of care for people with DM and prediabetes. Changing eating habits can be challenging for many people.[15] Achieving nutrition goals requires a coordinated team effort that considers the person's behavioral, cognitive, socioeconomic, cultural, and religious backgrounds and preferences. Because of these complexities, a dietitian with expertise in DM management should work with the person with DM. The dietitian starts with a nutrition assessment and develops a patient-centered food plan. Other team members may include nurses, certified diabetes care and education specialists (CDCESs), clinical nurse specialists, social workers, and other HCPs.

ADA guidelines state that, within the context of an overall healthy eating plan, a person with DM can eat the same foods as a person without DM. This means that the same principles of healthy nutrition that apply to the general population apply to the person with DM. Table 53.9 describes nutrition guidelines

TABLE 53.9 NUTRITION THERAPY

DM

Component	Recommendations
Total carbohydrate	• Include carbohydrate from fruits, vegetables, grains, legumes, and low-fat milk • Monitor by carbohydrate counting, exchange lists, or use of appropriate proportions • Fiber intake at 14 g/1000 kcal/day • Nonnutritive sweeteners are safe when consumed within FDA daily intake levels
Protein	Individualize goals
Fat	• Individualize goals • ≥2 servings of fish per week to provide polyunsaturated fatty acids • Consume fats from plant products
Alcohol	• Limit to moderate amount (maximum 1 drink per day for women, 2 drinks per day for men) • Consume alcohol with food to reduce risk for nocturnal hypoglycemia in those using insulin or drugs that promote insulin secretion • Moderate alcohol consumption has no acute effect on glucose and insulin concentrations • Carbohydrate taken with alcohol (mixed drink) may raise glucose

Source: ADA: Lifestyle management: standards of medical care in diabetes, *Diabetes Care* 43:S50, 2020.

for people with DM. According to the ADA, the overall goal of nutrition therapy is to help people with DM make healthy food choices that will lead to achieving and/or maintaining safe and healthy glucose levels.[16] Additional goals include:

- Maintain glucose levels as close to normal as safely possible to prevent or reduce the risk for DM-related complications.
- Achieve lipid profiles and BP levels that reduce the risk for CVD.
- Prevent or slow the rate of development of chronic complications by modifying nutrient intake and lifestyle.
- Address nutrition needs while considering personal and cultural preferences and respecting the person's willingness or ability to change eating and dietary habits.
- Maintain the pleasure of eating by encouraging a variety of healthy food choices.

Type 1 Diabetes

People with type 1 DM base their meal planning on usual food intake and preferences balanced with insulin and exercise patterns. The patient coordinates insulin dosing with eating habits and activity in mind. Day-to-day consistency in timing and amount of food eaten makes it much easier to manage glucose levels, especially for those using conventional, fixed insulin plans. Those using rapid-acting insulin can adjust the dose before each meal based on the current glucose level and the carbohydrate content of the meal. Intensified insulin therapy, such as multiple daily injections or the use of an insulin pump, allows considerable flexibility in food selection and can be adjusted for changes from usual eating and exercise habits. This does not diminish or replace the need for healthy food choices and a well-balanced diet.

Type 2 Diabetes

Nutrition therapy in type 2 DM emphasizes achieving glucose, lipid, and BP goals.[17] Modest weight loss may improve insulin sensitivity. Therefore, weight loss is recommended for all persons with DM who are overweight or obese.

There is no one proven strategy or method. A nutritionally adequate meal plan with appropriate serving sizes, a reduction of saturated and *trans* fats, and lower carbohydrates can decrease calorie consumption. Spacing meals is another strategy that spreads nutrient intake throughout the day. A weight loss of 5% to 7% of body weight often improves glucose levels, even if desirable weight is not achieved. Weight loss is best achieved by a moderate decrease in calories and regular exercise. Adopting new behaviors and attitudes can promote long-term health behavior changes. Monitoring glucose levels, A1C, lipids, and BP gives feedback on how well the goals of nutrition management are being met.

Food Composition

A healthy balance of nutrients is essential to maintain glucose levels and overall health. Energy from food intake can be balanced with the patient's energy output. Teach patients to outline their meal plan with their lifestyle and health goals in mind. There is no special eating plan for people with DM. The person can work with their HCP to determine which plan works best for them, keeping in mind portions and effects on glucose, lipids, and BP. The following are general recommendations for nutrient balance.

Carbohydrate. Carbohydrates are an important source of energy, fiber, vitamins, and minerals. They are needed by all people, including those with DM. Foods containing carbohydrate from whole grains, fruits, vegetables, and low-fat dairy are part of a healthy meal plan. The ADA recommends individualizing carbohydrate intake as there is no ideal amount for all people with DM.

All persons benefit from including dietary fiber as part of a healthy meal plan. The current recommendation for people with DM is to consume a minimum of 14 grams of fiber per 1000 kcal. At least half of any grain intake should come from whole intact grains.

Nutritive and nonnutritive sweeteners may be included in a healthy meal plan in moderation. Nonnutritive sweeteners include the sugar substitutes saccharine, aspartame, sucralose, stevia, neotame, and acesulfame-K.

Fat. Fat provides energy, transports fat-soluble vitamins, and provides essential fatty acids. The ADA recommends 20% to 35% of total calorie intake from fat. People with DM benefit from eating fewer carbohydrate foods that are higher in total fat. Healthy fats are those that come from plants, such as olives, nuts, and avocados.

Protein. The amount of daily protein in the diet for people with DM and normal kidney function is the same as the general population. The ADA recommends individualizing protein intake. Teach patients to choose lean protein whenever possible.

Alcohol. Alcohol inhibits gluconeogenesis by the liver. This can cause severe hypoglycemia in people who take insulin or OAs that increase insulin secretion. Alcohol use can make DM

harder to manage. Create a trusting environment in which patients feel comfortable talking openly about their alcohol use.

Moderate alcohol use can be safely included in the meal plan if the person monitors glucose levels and is not at risk for other alcohol-related problems. Moderate use is defined as 1 drink per day for women and 2 drinks per day for men. A person can reduce the risk for alcohol-induced hypoglycemia by eating carbohydrates when drinking alcohol. Mixed drinks often contain sweetened mixers and can increase glucose levels. To decrease the carbohydrate content, recommend using sugar-free mixes and drinking dry, light wines.

Patient Teaching Related to Nutrition Therapy

Most often, the dietitian initially teaches the principles of nutrition management. Whenever possible, work with dietitians as part of the DM care team. Some patients who have limited insurance coverage or live in remote areas do not have access to a dietitian. In these cases, you may need to assume responsibility for teaching basic nutrition principles to patients with DM.

Carbohydrate counting is a meal planning technique used to keep track of the amount of carbohydrate eaten at each meal and per day. Teach patients to keep carbohydrate intake within a healthy range. The amount of total carbohydrate per day depends on glucose levels, age, weight, activity level, patient preference, and drug plan. A serving size of carbohydrate is 15 g. A typical adult might start with 45 to 60 g of carbohydrate per meal. Some patients tailor insulin doses to the amount of carbohydrate foods that they will consume at the meal, with a set number of units of insulin given per gram of carbohydrate (e.g., 1 U/15 g carbohydrate, 2 U/25 g carbohydrate). Teach the patient about the foods that contain carbohydrate, how to read food labels, and appropriate serving sizes.

Diabetes exchange lists are another method for meal planning. Instead of counting carbohydrates, the person uses a meal plan with specific numbers of helpings from a list of exchanges for each meal and snack. The exchanges are starches, fruits, milk, meats, vegetables, fats, and free foods. The person chooses foods from the various exchanges based on the prescribed meal plan. This method may be easier for some people than carbohydrate counting. It also encourages a well-balanced meal plan. Another advantage is that this approach helps the person limit portion sizes and overall food intake, an important part of weight management.

The MyPlate method can help the person see how much vegetables, starch, and meat should fill a 9-in plate.[18] The recommendation is that each meal has half of the plate filled with nonstarchy vegetables, one-fourth filled with a starch, and one-fourth filled with a protein. An 8-oz glass of nonfat milk and a small piece of fresh fruit complete the meal.

Whenever possible, include family members and caregivers in nutrition education and counseling, especially the person who cooks for the household. However, the responsibility for maintaining a healthy eating plan still belongs to the person with DM. Reliance on another person to make health decisions interferes with the patient's ability to develop self-care skills, which are essential in managing DM. Foster independence, even in patients with visual or cognitive problems.

TABLE 53.10 Activities That Affect Caloric Expenditure

Light Activity (100–200 kcal/hr)	Moderate Activity (200–350 kcal/hr)	Vigorous Activity (400–900 kcal/hr)
• Fishing	• Active housework	• Aerobic exercise
• Light housework	• Bicycling (light)	• Bicycling (vigorous)
• Secretarial work	• Bowling	• Hard labor
• Teaching	• Dancing	• Ice skating
• Walking casually	• Gardening	• Outdoor sports
	• Golf	• Running
	• Roller skating	• Soccer
	• Walking briskly	• Tennis
		• Wood chopping

Discuss traditional and favorite foods with the patient. Explore the influences of culture on food choices and meal planning with the patient. Individualize food choices considering the patient's preferences and culturally appropriate foods. Nutrition resources designed for members of different cultural groups are available from the ADA.

Exercise

Regular, consistent exercise is an essential part of DM and prediabetes management. The ADA recommends that people with DM engage in at least 150 minutes/week (30 minutes, 5 days/week) of a moderate-intensity aerobic activity (Table 53.10). The ADA encourages people with DM to perform resistance training 2 to 3 times a week unless contraindicated.

Exercise decreases insulin resistance and can have a direct effect on lowering glucose levels. It contributes to weight loss, which further decreases insulin resistance. The therapeutic benefits of regular activity may result in a decreased need for DM drugs to reach target glucose goals in people with type 2 DM. Regular exercise may help reduce triglyceride and low-density lipoprotein (LDL) cholesterol levels, increase HDL, reduce BP, and improve circulation.

Encourage patients to be active every day and decrease the amount of time sitting. Medical clearance may be needed for new, intensive exercise programs. Teach patients to start slowly and gradually progress toward the desired goal. Patients who use insulin, sulfonylureas, or meglitinides are at increased risk for hypoglycemia when they increase physical activity, especially if they exercise at the time of peak drug action or eat too little to maintain adequate glucose levels. This can also occur if a normally sedentary patient with DM has an unusually active day.

The glucose-lowering effects of exercise can last up to 48 hours after the activity, so it is possible for hypoglycemia to occur long after the activity. People who use drugs that can cause hypoglycemia should exercise about 1 hour after a meal or have a 10- to 15-g carbohydrate snack and check their glucose before exercising. It is preferable not to increase caloric intake for exercise. If needed, they can eat small carbohydrate snacks every 30 minutes during exercise to prevent hypoglycemia. Patients using drugs that place them at risk for hypoglycemia should always carry a fast-acting source of carbohydrate, such

TABLE 53.11 PATIENT & CAREGIVER TEACHING

Exercise for Patients With DM

Include the following information in the exercise teaching plan for the patient and caregiver:

1. Exercise does not have to be vigorous to be effective. The glucose-reducing effects of exercise can be reached with activity such as brisk walking.
2. Choose activities that are enjoyable to foster regularity.
3. Use properly fitting footwear to avoid rubbing or injury.
4. The exercise session includes a warm-up period and a cool-down period. Start the exercise program gradually and increase slowly.
5. Exercise is best done after meals when the glucose level is rising.
6. Exercise plans are patient-specific and monitored by the HCP.
7. Monitor glucose levels before, during, and after exercise to determine the effect exercise has on glucose levels at specific times of the day.
8. Before exercise, if glucose ≤100 mg/dL, eat a 15-g carbohydrate snack. After 15–30 min, recheck glucose levels. Delay exercise if <100 mg/dL. Talk to HCP about lowering drug dose(s) if hypoglycemia occurs consistently.
9. Before exercise, if glucose ≥250 mg/dL in a person with type 1 DM and ketones are present, delay vigorous activity until ketones are gone. Drink fluids.
10. Exercise-induced hypoglycemia may occur several hours after completing exercise.
11. Planned or spontaneous exercise is still important when taking a glucose-lowering medication.
12. Compensate for extensive planned and spontaneous activity by monitoring glucose levels and adjusting the insulin dose (if taken) and food intake.

Fig. 53.9 Blood glucose meters are used to measure glucose levels. (© iStock.com/kolesnikovserg.)

Fig. 53.10 Continuous blood glucose meter showing a reading after scanning the sensor of the glucose monitoring system placed on the arm. (Click_and_Photo/iStock.com.)

as glucose tablets or hard candies, when exercising. If they have frequent lows from exercise, the dose may need to be lowered. Table 53.11 describes exercise guidelines for people with DM.

The body can perceive strenuous activity as stress, causing a release of counterregulatory hormones and a temporary increase in glucose. In a person with type 1 DM who has hyperglycemia and ketones, exercise can worsen these conditions. Teach these patients to delay activity if the glucose level is over 250 mg/dL and ketones are present in the urine. If hyperglycemia is present without ketosis, it is not necessary to postpone exercise.

Blood Glucose Monitoring

Blood glucose monitoring (BGM) is a critical part of DM management. By providing a current glucose reading, BGM lets the patient make decisions about food intake, activity patterns, and drug dosages. It produces accurate records of daily glucose fluctuations and trends and alerts the patient to acute episodes of hyperglycemia and hypoglycemia. BGM provides patients with a tool for achieving and maintaining specific glycemic goals. It is recommended for all people who use insulin to manage their DM. Other patients with DM use BGM to help achieve and maintain glycemic goals and monitor for acute fluctuations in glucose related to drugs, food, and exercise.

The frequency of BGM depends on several factors. These include the patient's glycemic goals, type of DM, drug plan, patient's ability to check glucose independently, access to supplies and equipment, and patient's willingness and ability to do so. The recommendation for patients who use multiple insulin injections or insulin pumps is to monitor their glucose 4 to 8 times each day. Patients using less frequent insulin injections, noninsulin therapy, or nutrition management may use BGM as often as needed to achieve their glycemic goals.

People who perform BGM use portable blood glucose meters. A wide variety of blood glucose meters are available (Fig. 53.9). Disposable lancets are used to get a small drop of capillary blood (usually from a finger stick) that is placed in a reagent strip. After a specified time, the meter displays a reading of the capillary glucose value. Technology is rapidly changing. More convenient systems are introduced on an ongoing basis.

CGM systems are another route for monitoring glucose (Fig. 53.10).[19] More people with type 1 DM are using CGMs. These systems are slowly being used by more people with type 2 DM. Insurance coverage and cost are the most common limiting factors. Some insulin pumps have CGM integrated as part of the system.

Using a sensor inserted subcutaneously, the CGM systems display new glucose values every 1 to 5 minutes. CGM assesses interstitial glucose, which lags behind blood glucose by 5 to 10 minutes. The person inserts the sensor using an automatic insertion device. Data are sent from the sensor to a transmitter, which displays the glucose value on either an insulin pump or a pager-like receiver. The CGM can be used with or without an insulin pump. Newer CGMs can "share" data with a smartphone.

CGMs help the patient and HCP identify trends and patterns in glucose levels. The goal is to increase "time in range" (70 to 180 mg/dL) and have fewer highs and lows. They are useful for managing insulin therapy or when continuous glucose readings are important. They alert the person to episodes of hypoglycemia and hyperglycemia. This allows them to take corrective action quickly.

Blood glucose meters are reliable when used consistently and correctly. It is not necessary to compare their readings to laboratory readings. If the A1C result does not correspond to the glucose readings on the home meter, troubleshoot any problems with the meter, technique, strips, and hand washing.

Because errors in BGM technique can cause errors in management strategies, patient teaching is essential. Follow the initial instruction with regular reassessment. Review the instructions that come with each product. If a product has a control solution, teach patients to use and interpret control solutions. A control should be done when first using a blood glucose meter or when there is a reason to believe that the readings are not correct. Table 53.12 lists the steps to include when teaching the patient how to perform BGM.

People with type 1 DM often check their glucose before meals. This is because many people use insulin pumps or multiple daily injections and base the insulin dose on the amount of carbohydrate in a meal or the preprandial glucose value. Checking glucose 2 hours after the first bite of food helps a person determine if the bolus insulin dose was adequate for that meal.

Teach patients to check glucose whenever they suspect hypoglycemia and then take immediate action. During times of illness, check glucose levels at 4-hour intervals (or more) to determine the effects of the illness on glucose levels. Teach the patient to check glucose before and after exercise to determine the effects of exercise on glucose levels. This is especially important for the patient with type 1 DM.

A patient with impaired vision, cognitive impairment, or limited dexterity needs careful assessment to see if BGM can be done independently. Nurses preparing patients for discharge from the hospital and nurses working in home health and outpatient settings may need to identify caregivers who can assume this responsibility. Adaptive devices are available to help patients with certain limitations. These include talking monitors and other equipment for the visually impaired.

TABLE 53.12 PATIENT & CAREGIVER TEACHING

Blood Glucose Monitoring (BGM)

Include the following instructions when teaching the patient and caregiver about BGM:

1. Wash and dry hands completely. It is not necessary to clean the site with alcohol, and it may interfere with results.
2. If it is hard to get an adequate drop of blood for monitoring, warm the hands in warm water or let the arms hang dependently for a few minutes before making the finger puncture.
3. A lancing device is often used. Place the lancet in the device, following the instructions that come with it. If the puncture is made on the finger, use the side of the finger pad rather than near the center. There are fewer nerve endings along the side of the finger pad.
4. Set lancing device to make a puncture just deep enough to get a sufficiently large drop of blood. Unnecessarily deep punctures may cause pain and bruising. Current meters need very small amounts of blood.
5. Follow instructions on meter for checking the glucose level.
6. Record results. Compare with personal glucose goals.

Pancreas Transplantation

Pancreas transplantation is an option for select persons with type 1 DM. Candidates include patients who have ESRD and have had or plan to have a kidney transplant. Kidney and pancreas transplants are often done together, or a pancreas may be transplanted after a kidney transplant. If renal failure is not present, the ADA recommends that pancreas transplantation be considered only for people who meet 3 criteria: (1) a history of frequent, acute, and severe metabolic complications (e.g., hypoglycemia, hyperglycemia, DKA) requiring medical attention; (2) clinical and emotional problems with the use of insulin therapy that are so severe as to be incapacitating; and (3) consistent failure of insulin-based management to prevent acute complications.

Successful pancreas transplantation can improve quality of life, primarily by eliminating the need for insulin therapy and frequent BGM. Transplantation can eliminate acute complications experienced by people with type 1 DM (e.g., hypoglycemia, hyperglycemia). However, transplantation is only partially successful in reversing the renal and neurologic complications of DM. The patient will need lifelong immunosuppression to prevent rejection of the organ. Complications can result from immunosuppressive therapy. Immunosuppressive therapy is discussed in Chapter 14.

Pancreatic islet cell transplantation is another potential treatment measure. During this procedure, the islets are harvested from the pancreas of a deceased organ donor. Most recipients need islets from 2 or more pancreases. The islets are infused via a catheter through the upper abdomen into the portal vein of the liver. With only the islets transplanted, pain and recovery time are less than with whole pancreas transplants. Currently, this procedure is experimental in the United States. Research is continuing to explore the best ways to implant the islet cells and prevent their rejection.

❖ NURSING MANAGEMENT: DIABETES

◆ Assessment

Table 53.13 provides initial subjective and objective data you should obtain from a person with DM. After the initial assessment, perform periodic patient assessments on a regular basis.

◆ Clinical Problems

Clinical problems for the patient with DM may include:

- Altered blood glucose level
- Deficient knowledge
- Risk for injury
- Impaired endocrine function
- Neurologic problem

TABLE 53.13 NURSING ASSESSMENT

DM

Subjective Data

Important Health Information

Health history: Mumps, rubella, coxsackievirus, or other viral infections. Recent trauma, infection, or stress. Pregnancy, gave birth to infant >9 lb. Pancreatitis, Cushing syndrome, acromegaly, family history of type 1 or type 2 DM

Medications: Use of insulin, OAs, noninsulin injectables, corticosteroids, diuretics, phenytoin

Surgery or other treatments: Any recent surgery

Functional Health Patterns

Health perception–health management: Positive family history, malaise

Nutrition-metabolic: Obesity, weight loss (type 1), weight gain (type 2). Thirst, hunger, nausea, and vomiting. Poor healing (especially involving the feet), eating habits

Elimination: Constipation or diarrhea, frequent urination, frequent bladder infections, nocturia, urinary incontinence

Activity-exercise: Muscle weakness, fatigue

Cognitive-perceptual: Abdominal pain, headache, blurred vision, numbness or tingling of extremities, pruritus

Sexuality-reproductive: ED, frequent vaginal infections, vaginal dryness, or pain, ↓ libido

Adaptation: Depression, irritability, apathy

Value-belief: Health beliefs, commitment to lifestyle changes involving food, medication, and activity patterns

Objective Data

Cardiovascular

Hypotension.[a] Weak, rapid pulse[a]

Eyes

Soft, sunken eyeballs.[a] History of vitreal hemorrhages, cataracts

GI

Dry mouth, vomiting.[a] Fruity breath[a]

Musculoskeletal

Muscle wasting[a]

Neurologic

Altered reflexes, restlessness, confusion, stupor, coma[a]

Respiratory

Rapid, deep respirations (Kussmaul respirations)[a]

Skin

Dry, warm, inelastic skin. Pigmented lesions (on legs), ulcers (especially on feet), loss of hair on toes, acanthosis nigricans

Possible Findings

Serum electrolyte abnormalities. Fasting glucose level ≥126 mg/dL. OGTT >200 mg/dL, random glucose ≥200 mg/dL. Leukocytosis. ↑ BUN, creatinine, triglycerides, cholesterol, LDL, VLDL. ↓ HDL. A1C >6.0% (A1C >7.0% in those with diagnosed DM), glycosuria, ketonuria, albuminuria. Acidosis

[a]Indicates manifestations of DKA.

Additional information on clinical problems and interventions for the patient with DM is presented in eNursing Care Plan 53.1, available on the website.

Planning

The overall goals are for the patient with DM to (1) engage in self-care behaviors to actively manage DM, (2) have few or no hyperglycemia or hypoglycemia emergencies, (3) maintain safe and healthy glucose levels, (4) reduce the risk for chronic complications, and (5) adjust lifestyle to accommodate the DM plan with minimal stress. The goal is for the patient with DM to safely and effectively fit DM into life rather than living life around DM.

Implementation

Health Promotion

Your role in health promotion is to identify, monitor, and teach the patient at risk for DM. Obesity is a key risk factor for type 2 DM. The ADA recommends routine screening for type 2 DM for all adults who are overweight or obese (BMI 25 kg/m^2 or greater) or have 1 or more risk factors. A DM risk test is available at www.diabetes.org/risk-test. The DM risk test determines if the person is at risk for prediabetes or DM based on the number of risk factors present. For people who do not have risk factors for DM, begin screening at age 45. Table 53.14 provides criteria to screen for prediabetes and DM. If results are normal, repeat screening at 3-year intervals.

Primary prevention is a cost-effective approach (Box 53.3). Current recommendations for primary prevention include lifestyle modifications for at-risk people. A modest weight loss of 5% to 7% of body weight and 150 minutes of physical activity a week lowers the risk for developing type 2 DM by 34% to 58%.

TABLE 53.14 Screening for DM in Asymptomatic, Undiagnosed Persons

Who to Screen

1. Consider screening all adults who are overweight (BMI >25 kg/m^2) and have risk factors for DM:
   - First-degree relative with DM
   - Physically inactive
   - Members of a high-risk ethnic population (e.g., Black, Hispanic, Native American, Asian American,[a] Pacific Islander)
   - Women who delivered a baby weighing >9 lb or were diagnosed with gestational DM
   - Hypertensive (≥140/90 mm Hg) or on therapy for hypertension
   - HDL cholesterol level ≤35 mg/dL (0.90 mmol/L) and/or a triglyceride level ≥250 mg/dL (2.82 mmol/L)
   - Women with polycystic ovary syndrome
   - A1C ≥5.7%, IGT, or IFG on previous screening
   - Other conditions associated with insulin resistance (e.g., acanthosis nigricans)
2. In the absence of the above criteria, screening for DM should begin at age 45 years.
3. If results are normal, repeat screening at least every 3 years, with more frequent screening depending on initial results and risk status.

What Measurements to Use

To screen for DM or to assess risk of future DM, A1C, FPG, or 2-hr OGTT is appropriate (Table 53.2).

Reprinted with permission from American Diabetes Association. © 2022 by American Diabetes Association.

[a]Consider screening Asian Americans with a BMI of 23 kg/m^2 or higher.

BOX 53.3 PROMOTING POPULATION HEALTH

Preventing DM

- Aim for 150 min of moderate activity each week.
- Maintain a healthy weight through a nutritionally balanced diet.
- Follow a diet low in saturated and *trans* fat, total calories, and processed foods and high in whole grains, fruits, and vegetables.
- If overweight and over age 45, have yearly screening for DM.
- Avoid cigarette smoking or tobacco products.
- Limit alcohol use to moderate levels.
- Follow the prescribed treatment plan for hypertension.

Acute Care

Acute situations involving the patient with DM include hypoglycemia, DKA, and hyperosmolar hyperglycemic syndrome (HHS). Management for these situations is discussed in more detail later in this chapter. Other areas of acute care relate to management during acute illness and surgery (Table 53.15).

Acute illness and surgery. Emotional and physical stress can increase the glucose level and cause hyperglycemia. Because stress is unavoidable, certain situations may require more intense treatment, such as extra insulin and more frequent BGM, to maintain glycemic goals and avoid hyperglycemia.

Acute illness, injury, and surgery may evoke a counterregulatory hormone response, causing hyperglycemia. Even common illnesses, such as an upper respiratory tract infection or the flu, can cause this response. Encourage patients to check glucose at least every 4 hours when they are ill. Teach acutely ill patients with type 1 DM and glucose greater than 240 mg/dL (13.3 mmol/L) to check urine for ketones every 3 to 4 hours.

Teach patients to contact the HCP when glucose levels are over 300 mg/dL twice in a row, or urine ketone levels are moderate to high. A patient with type 1 DM may need an increase in insulin to prevent DKA. High glucose levels can lead to poor healing and infection. A patient with type 2 DM may need insulin therapy to prevent or treat hyperglycemia symptoms and avoid an acute hyperglycemia emergency. In critically ill patients, insulin therapy may be started if the glucose is persistently greater than 180 mg/dL. These patients have a higher targeted glucose goal, which is usually 140 to 180 mg/dL. Food intake is important during times of stress and illness when the body needs extra energy. If patients can eat normally, they can continue with their regular meal plan while increasing the intake of noncaloric fluids, such as water, sugar-free gelatin, and other decaffeinated beverages, and continue taking OAs, noninsulin injectable agents, and insulin as prescribed. When illness causes patients to eat less than normal, they can continue to take OAs, noninsulin injectable agents, and/or insulin as prescribed while supplementing food intake with carbohydrate-containing fluids. Examples include low-sodium soups, juices, and regular, sugar-sweetened decaffeinated soft drinks. It is important to tell the patient to contact an HCP if they are unable to keep down food or fluid.

During the intraoperative period, we often adjust the DM plan to ensure safe and healthy glucose levels. The patient receives IV fluids and insulin (if needed) just before, during, and after surgery when there is no oral intake. Explain to the patient with type 2 DM who has been taking OAs that this is a temporary measure, not a sign of worsening DM.

When caring for an unconscious surgical patient receiving insulin, be alert for signs of hypoglycemia, such as sweating, tachycardia, and tremors. Frequent glucose monitoring can prevent episodes of hypoglycemia.

TABLE 53.15 NURSING MANAGEMENT

Caring for the Patient With DM

- Assess for risk factors for prediabetes and type 1 and type 2 DM.
- Teach the patient and caregiver about DM management, including BGM, drug therapy, nutrition, activity, and managing hypoglycemia.
- Develop a plan to avoid hypoglycemia or hyperglycemia in a patient with DM who is acutely ill or having surgery.
- Assess for acute complications and implement appropriate actions for hypoglycemia, DKA, and HHS.
- In patients with acute complications, perform or directly supervise actions, including IV fluid and insulin administration.
- Assess for chronic complications, including CVD, retinopathy, nephropathy, neuropathy, and foot complications.
- Teach the patient and caregiver about prevention and management of chronic complications.
- Supervise LPN/VNs, and in some states and settings APs, administer insulin, noninsulin injectable agents, and OAs to stable patients.

Collaborate With Other Team Members

Dietitian

- Obtain a diet history from the patient.
- Work with patient and caregiver to create a patient-centered meal plan.
- Provide instructions for meal plan as needed.

Physical Therapist

- Assess patient's current level of fitness.
- Develop an exercise plan with the patient.

Occupational Therapist

- Teach patients with impaired vision how to use devices to draw up and measure insulin.
- Provide teaching on how to use a talking glucose meter or any glucose meter one-handed.
- Develop protective techniques for activities that involve exposure to heat, cold, and sharp objects.

Social Worker

- Aid the patient in finding resources to meet medical and financial needs.
- Help with coping with DM, including managing problems within the family or workplace.

Ambulatory Care

Successful DM management involves ongoing interaction among the patient, caregiver, and health care team. Because DM is a complex chronic condition, a great deal of patient contact takes place in outpatient and home settings. The major goal of patient care in these settings is to enable the patient (with the help of a caregiver as needed) to reach an optimal level of independence in self-management.

Many patients face challenges in reaching these goals. DM increases the risk for other chronic conditions that can affect self-management. These include impaired vision, lower extremity problems that affect mobility, and other functional limitations related to a stroke. Other barriers may include feelings of inadequacy about their abilities, unwillingness to make behavior changes, ineffective coping strategies, and cognitive problems. If the patient is not able to manage DM, a family member may be able to assume part of this role. If the patient or caregiver cannot make decisions related to DM management, consider a referral to a CDCES, social worker, or other resources within the community. These resources can help the patient and family in outlining a feasible treatment program that meets their capabilities.

Assess the ability of patients and caregivers in performing activities such as BGM and insulin injection. Assistive devices for self-administration of insulin include syringe magnifiers, vial stabilizers, and dosing aids for the visually impaired. In some cases, referrals can help the patient achieve their self-care goal. These may include an occupational therapist, a social worker, a home care nurse, a home health aide, or a dietitian.

A diagnosis of DM affects each person in many profound ways. Self-management of DM is demanding. People with DM continually face lifestyle choices that affect the foods they eat, their activities, and demands on their time and energy. The requirements of scheduled meals, BGM, medication, and insulin management may interfere with the patient's other responsibilities. Any change in the daily routine can be hard. In addition, they face the challenge of preventing or dealing with the complications of DM.

Assess the patient's knowledge of DM and lifestyle preferences when planning a teaching program (Box 53.4). What does it mean to the person to have DM? Assess the patient's knowledge frequently so that you can help with gaps in knowledge or correct misinformation.

Identify the patient's support system. Include them in planning, teaching, and counseling. When we include family members and other persons close to the patient, they can support the patient's self-management. They can also provide care if self-care is not possible. Encourage the family and caregivers to provide emotional support and encouragement as the patient deals with the reality of living with a chronic disease.

The goals of DM education are to match the level of self-management to the patient's ability so that they can become the most active participant possible. Patients who actively manage their DM care have better outcomes than those who do not. For this reason, advocate for an educational approach that facilitates informed decision-making by the patient. We call this the *empowerment approach* to education. People with DM trust their HCPs more if they make them feel like a partner in their care.[20]

Tables 53.16 and 53.17 present guidelines to use for patient and caregiver teaching. The ADA offers resources for patients in the form of pamphlets, booklets, books, and their website. The ADA publishes materials and sponsors conferences for health care professionals concerned with DM care, education, and research. The ADA website (www.diabetes.org) has extensive information for the public and health care professionals. Most drug companies that make DM-related products have free education materials for patients and HCPs. You need to stay current in your DM knowledge so that you can effectively teach and support patients with DM.

BOX 53.4 EVIDENCE-BASED PRACTICE

Interactive Self-Management and DM

You are a member of a nurse-led diabetes care team that interacts with adult patients throughout the hospital. You have a referral to meet with A.Y., a 62-year-old woman with type 2 DM. Quarterly A1C results over the past year ranged from 6.9% to 9.4%. She knows that keeping glucose levels close to normal can help prevent long-term complications. A.Y. tells you she wants to be more involved in her care and make changes to her eating habits. You see that she is motivated and wants to learn how to better manage her DM.

Making Clinical Decisions

Best Available Evidence

The delivery of education and skills related to DM self-management is person-centered. These include guiding patients to make food choices that lead to stabilizing glucose levels as measured by A1C levels or TIR, increased knowledge and self-efficacy, and reduced DM-related distress.

Clinician Expertise

You know interactive self-management strategies are effective in helping patients stabilize glucose levels. There are several options for eating approaches in patients with DM who manage their own care. You discuss the multiple influences on success in glucose management and tell her that team members will help her identify any barriers to self-care.

Patient Preferences and Values

A.Y. shows a strong interest in taking more control of her DM and wishes to receive information on exercise, BGM, and diet.

Implications for Nursing Practice

1. What options for interactive self-management will you offer A.Y.?
2. As you empower A.Y. to manage her care, why is it important to assess her knowledge and skills?
3. What parameters will you use to assess if she is able to manage her own care?

Reference for Evidence

Kloss KA, Funnell MM, Piatt GA, Nwankwo R: One size does not fit all: nutrition strategies for people with diabetes, *Nursing* 50:32–38, 2020.

Insulin therapy. Nursing responsibilities for the patient receiving insulin include proper administration, assessing the patient's response to insulin therapy, and teaching the patient about administration, storage, and side effects of insulin (Table 53.6). Table 53.7 lists guidelines for assessing a patient using GLAs, including insulin and OAs.

Assess the new user of insulin for their ability to safely manage therapy. This includes the ability to understand the interaction of insulin, food, and activity and to recognize and treat the symptoms of hypoglycemia appropriately. If the patient does not have the cognitive skills to do these things, identify and teach another responsible person. The patient or caregiver must have the cognitive and manual skills needed to prepare and inject insulin. Otherwise, additional resources will be needed to assist the patient. For patients with cognitive, physical, and other barriers, consider referral to a CDCES. A CDCES has the

TABLE 53.16 PATIENT & CAREGIVER TEACHING

DM Management

Include the following instructions when teaching the patient and caregiver how to manage DM:

Component	What to Teach
Disease process	• Introduce the pancreas and the islets of Langerhans. • Describe how insulin is made and what affects its production. • Discuss the relationship between insulin and glucose. • Explain the difference between type 1 and type 2 DM.
Drug therapy	• Ensure that the patient understands the drug plan • Account for a patient's physical or other limitations or inabilities for self-medication. If necessary, involve the family or caregiver in proper use of medication. • Discuss all side effects and safety issues.
Exercise	• Discuss the effect of regular exercise on managing glucose and improving cardiovascular function and general health.
Meal planning	• Stress the importance of a well-balanced diet as part of a DM management plan. • Explain the impact of carbohydrates on glucose levels.
Monitoring glucose	• Teach correct BGM. • Include when to check glucose levels, how to record them, and how to adjust insulin levels, if necessary.
Risk reduction	• Ensure that the patient understands and appropriately responds to the signs and symptoms of hypoglycemia and hyperglycemia (Table 53.18). • Stress the importance of proper foot care (Table 53.23), regular eye examinations, and consistent BGM. • Teach the patient about the effect that stress can have on glucose.
Psychosocial	• Help the patient identify resources that are available to help with the adjustment and answer questions about living with a chronic condition such as DM.

TABLE 53.17 PATIENT & CAREGIVER TEACHING

Instructions for the Patient With DM

Include the following essential instructions for DM management for the patient and caregiver:

Glucose Levels

- Monitor your glucose at home and record results in a log.
- Take your insulin, OA, and/or noninsulin injectable agent as prescribed.
- Take insulin consistently, especially when you are sick.
- Keep an adequate supply of insulin on hand at all times.
- Obtain A1C blood test every 3–6 months as an indicator of your long-term glucose levels.
- Be aware of symptoms of hypoglycemia and hyperglycemia.
- Always carry a form of rapid-acting glucose so that you can treat hypoglycemia quickly.
- Teach family members how and when to use glucagon if you are unresponsive because of hypoglycemia.

Exercise

- Learn how exercise and food affect your glucose levels.
- Remember that exercise will usually lower your glucose level.
- Begin an exercise program after approval from HCP.

Food

- Work with a dietitian to create a patient-specific meal plan.
- Make healthy food choices and eat regular meals at regular times.
- Choose foods low in saturated and *trans* fat. Know your cholesterol level.
- Limit the amount of alcohol you drink.
- Be aware that excess alcohol use may lead to unpredictable low glucose events.
- Avoid fad diets.
- Limit regular soda and fruit juice.

Other Guidelines

- Have an annual eye examination by an ophthalmologist.
- Obtain annual urine monitoring for protein.
- Examine your feet at home.
- Wear comfortable, well-fitting shoes to help prevent foot injury. Break-in new shoes gradually.
- Always carry identification that says you have DM.
- Have other medical problems treated, especially high BP and high cholesterol.
- Have a yearly influenza vaccination.
- Quit or never start smoking cigarettes or using nicotine products.
- Avoid applying heat or cold directly to your feet.
- Do not go barefoot.
- Keep skin moisturized by applying cream to surfaces of feet, but not between toes.

specialized knowledge and skills to promote self-care behaviors for these patients.

Many people are fearful when they first begin using insulin. Some find it hard to self-inject because they are afraid of needles or the pain associated with an injection. Others may think that they do not need insulin or that they will have hypoglycemia after an injection. Explore the patient's underlying fears before beginning the teaching. Assessing the patient's beliefs and concerns about starting insulin will guide the teaching, counseling, and plan of care. Having open discussion with patients, providing educational materials and programs, and working with a CDCES are all beneficial for patients starting insulin.

Follow-up assessment of the patient who has been using insulin therapy includes inspecting injection sites for signs of lipodystrophy and other reactions, reviewing insulin preparation and injection technique, taking a history of the occurrence of hypoglycemia, and assessing how they managed hypoglycemia. Reviewing the recorded glucose readings is vital in assessing how the patient is doing and making any needed adjustments.

Oral and noninsulin injectable agents. Your responsibilities for the patient taking OAs and noninsulin injectable agents are similar to those for the patient taking insulin. Proper storage

and administration, assessing the patient's use of and response to these drugs, and teaching the patient and family are all essential nursing actions.

Your assessment is valuable in determining the most appropriate drug for a patient. Factors such as the patient's mental status, eating habits, home environment, learning ability, resources, attitude toward DM, and medication history all play a significant role in determining the most appropriate drug. For example, frail older adults who live alone are at high risk for severe hypoglycemia because low glucose is often undetected or untreated. This is especially true for patients with cognitive impairment. In these cases, an OA that does not cause hypoglycemia, or a shorter-acting OA, would be most appropriate.

Patient teaching is essential. Some patients may assume that their DM is not a serious condition if they are only taking a pill to treat it. Teach the patient that OAs help manage glucose and prevent serious long- and short-term complications. Discuss how OAs and noninsulin injectable agents are part of the DM plan with food choices and activity. Stress the importance of following their meal and activity plans. Teach patients not to take extra pills if they have overeaten. If the patient uses sulfonylureas and metformin, teach the patient how to prevent, recognize, and manage hypoglycemia.

Personal hygiene. The potential for infection requires diligent skin and dental hygiene practices. Because of the susceptibility to periodontal disease, encourage daily brushing and flossing and regular dental visits. When having dental work done, teach the patient to tell the dentist they have DM.

Routine care includes regular bathing, with an emphasis on foot care.[21] Teach patients to inspect their feet daily, avoid going barefoot, and wear shoes that are supportive and comfortable. If cuts, scrapes, or burns occur, treat them promptly and monitor them carefully. Wash the area and apply a nonabrasive or nonirritating antiseptic ointment. Cover the area with a dry, sterile pad. Teach patients to notify the HCP at once if the injury does not begin to heal within 24 hours or if signs of infection develop.

Medical identification and travel. Teach the patient to always carry medical identification indicating that they have DM. Police, paramedics, and many private citizens know to look for this identification when working with sick or unconscious persons. An identification card (Fig. 53.11) can supply valuable information, such as the name of the HCP; the type of DM; and the type and dosage of insulin, noninsulin injectable agents, or OAs.

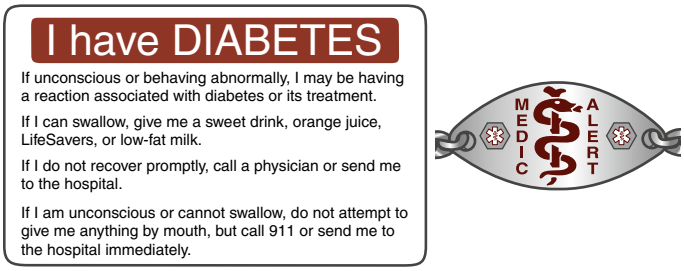

Fig. 53.11 Medical alerts. A patient with DM should carry a card and wear a bracelet or necklace that indicates DM. If the patient with DM is unconscious, these measures will ensure prompt and appropriate attention.

Travel for a person with DM requires planning. Being sedentary for long periods may raise the person's glucose level. Encourage the patient to get up and walk at least every 2 hours to lower the risk for deep vein thrombosis and prevent high glucose levels. Teach the patient to have a full set of DM care supplies in their carry-on luggage when traveling by plane, train, or bus. This includes BGM equipment, insulin, noninsulin injectable agents, OAs, syringes, insulin pens, and pen needles.

Best practices for traveling with DM supplies change frequently. Encourage patients to check TSA guidelines before traveling at https://www.diabetes.org/resources/know-your-rights/what-can-i-bring-with-me. Notify screeners if an insulin pump is used so that they can inspect it while it is on the body, rather than removing it.

For patients who use insulin or OAs that can cause hypoglycemia, keep snack items and a quick-acting carbohydrate source for treating hypoglycemia in the carry-on luggage. Keep extra insulin available in case a bottle breaks or is lost. For longer trips, carry a full day's supply of food in case of canceled flights, delayed meals, or closed restaurants. If the patient is planning a trip out of the country, it is wise to have a letter from the HCP explaining that the patient has DM and requires all the materials, especially syringes, for ongoing health care.

When travel involves time zone changes, the patient can contact the HCP to plan an appropriate insulin schedule. During travel, most patients find it helpful to keep watches set to the time of the city of origin until they reach their destination. The key to travel when taking insulin is to know the type of insulin being taken, its onset of action, the anticipated peak time, and mealtimes.

◆ Evaluation

The expected outcomes are that the patient with DM will

- State key elements of the treatment plan
- Describe measures that may prevent or slow progression of chronic complications
- Maintain a balance of nutrition, activity, and insulin availability that results in stable, safe, and healthy glucose levels
- Have no injury from decreased sensation in the feet

ACUTE COMPLICATIONS OF DIABETES

The acute complications of DM arise from events associated with hyperglycemia and hypoglycemia. Hyperglycemia (high glucose) occurs when there is not enough insulin working. Hypoglycemia (low glucose) occurs when there is too much insulin working. Many signs and symptoms of hyperglycemia and hypoglycemia overlap. It is important to distinguish between them because hypoglycemia worsens rapidly and is a serious threat if action is not immediately taken. Table 53.18 compares the manifestations, causes, management, and prevention of hyperglycemia and hypoglycemia.

DIABETES-RELATED KETOACIDOSIS (DKA)

Etiology and Pathophysiology

DKA is caused by a profound deficiency of insulin. It is characterized by hyperglycemia, ketosis, acidosis, and dehydration.

TABLE 53.18 Comparison of Hyperglycemia and Hypoglycemia

Hyperglycemia	Hypoglycemia
Manifestations	
• High glucose • ↑ Urination • ↑ Appetite followed by anorexia • Weakness, fatigue • Blurred vision • Headache • Glycosuria • Nausea and vomiting • Abdominal cramps • Progression to DKA or HHS • Mood swings	• Glucose <70 mg/dL (3.9 mmol/L) • Cold, clammy skin • Numbness of fingers, toes, mouth • Tachycardia • Emotional changes • Headache • Nervousness, tremors • Faintness, dizziness • Unsteady gait, slurred speech • Hunger • Changes in vision • Seizures, coma
Causes	
• Illness, infection • Corticosteroids • Too much food • Too little or no DM medication • Inactivity • Emotional, physical stress • Poor absorption of insulin	• Alcohol intake without food • Too little food—delayed, omitted, inadequate intake • Too much DM medication • Too much exercise without adequate food intake • DM medication or food taken at wrong time • Loss of weight without change in medication • Use of β-adrenergic blockers interfering with recognition of symptoms
Clinical Course	
• More gradual onset • Definition of high glucose varies by person, based on personal glucose targets	• More rapid onset • Pattern of manifestations changes over time
Treatment	
• Get medical care • Continue DM medication as prescribed • Check glucose frequently and check urine for ketones. Record results • Drink fluids at least on an hourly basis • Contact HCP about ketonuria	• Follow the Rule of 15. • See Table 53.19 for emergency treatment of hypoglycemia.
Preventive Measures	
• Take prescribed dose of medication at proper time • Accurately give insulin, noninsulin injectables, OA • Make healthy food choices • Follow sick-day rules when ill • Check glucose routinely • Wear or carry DM identification	• Take prescribed dose of medication at proper time • Accurately give insulin, noninsulin injectables, OA • Coordinate eating with medications • Eat adequate food intake needed for calories for exercise • Be able to recognize symptoms and treat them immediately • Carry simple carbohydrates • Teach family and caregiver about symptoms and treatment • Check glucose routinely • Wear or carry DM identification

PATHOPHYSIOLOGY MAP

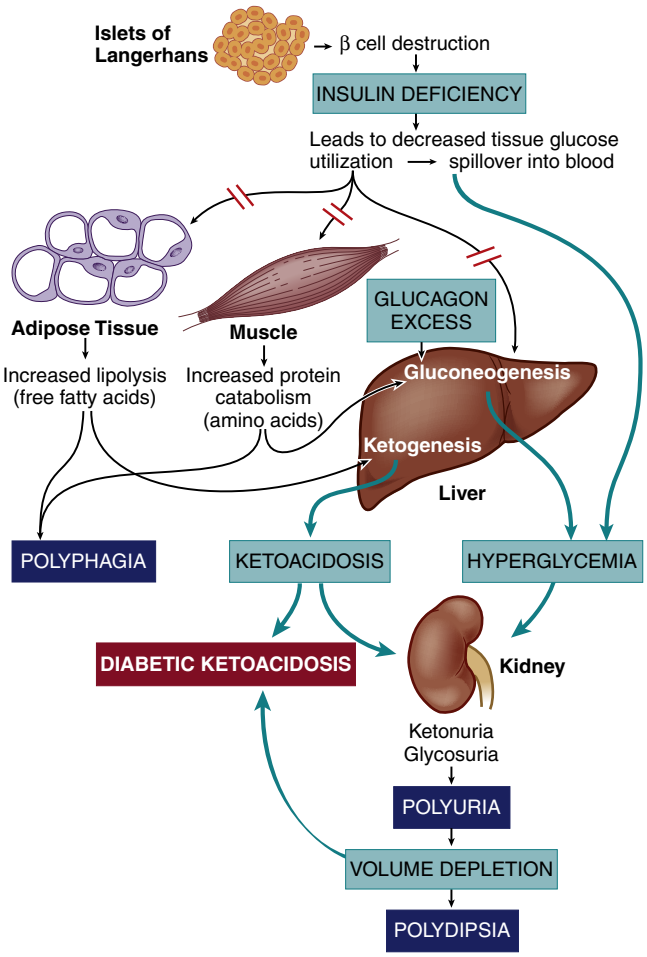

Fig. 53.12 Metabolic events leading to DKA. (Modified from Kumar V, Abbas AK, Aster JC, et al.: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders.)

It is most likely to occur in people with type 1 DM. DKA may occur in people with type 2 DM in conditions of severe illness or stress in which the pancreas cannot meet the extra demand for insulin. Precipitating factors include illness; infection; inadequate insulin dosage; undiagnosed type 1 DM; lack of education, understanding, or resources; and neglect.

When the circulating supply of insulin is insufficient, glucose cannot be properly used for energy. The body compensates by breaking down fat stores as a secondary source of fuel (Fig. 53.12). Ketones are acidic by-products of fat metabolism that can cause serious problems when they become excessive in the blood. Ketosis alters the pH balance, causing metabolic acidosis to develop. Ketonuria occurs when ketone bodies are excreted in the urine. During this process, the kidney excretes cation electrolytes with the anionic ketones to try to maintain balance.

Insulin deficiency impairs protein synthesis and causes excessive protein degradation. This results in nitrogen losses from the tissues. Insulin deficiency stimulates glucose production from amino acids (from proteins) in the liver and leads to further hyperglycemia. Because of insulin deficiency, the body

cannot use the additional glucose, and the glucose level rises further. This adds to the osmotic diuresis.

If not treated, the patient will develop severe depletion of sodium, potassium, chloride, magnesium, and phosphate. Vomiting caused by acidosis results in more fluid and electrolyte losses. Eventually, hypovolemia, followed by shock, will ensue. Renal failure, which may eventually occur from hypovolemic shock, causes the retention of ketones and glucose. The acidosis progresses. Untreated, the patient becomes comatose from dehydration, electrolyte imbalance, and acidosis. If the condition is not treated, death is inevitable.

Clinical Manifestations

Dehydration occurs in DKA with dry mucous membranes, tachycardia, and orthostatic hypotension. Early symptoms may include lethargy and weakness. As the patient becomes severely dehydrated, the skin becomes dry and loose. The eyes become soft and sunken. Abdominal pain may be present and accompanied by anorexia, nausea, and vomiting. Acetone is noted on the breath as a sweet, fruity odor.

Kussmaul respirations (rapid, deep breathing associated with dyspnea) are the body's attempt to reverse metabolic acidosis through exhaling excess CO_2. (See Chapter 17 for a discussion of respiratory compensation of metabolic acidosis.) Laboratory findings include a glucose level of 250 mg/dL (13.9 mmol/L) or greater, arterial blood pH less than 7.30, and serum bicarbonate level less than 16 mEq/L (16 mmol/L). Moderate to large ketones are present in the urine or serum.

Interprofessional Care

DKA is a serious condition that proceeds rapidly and must be treated promptly. Hospitalization may not be needed to treat the patient with DKA. If fluid and electrolyte imbalances are not severe and glucose levels can be safely monitored at home, DKA can be managed on an outpatient basis (Table 53.19). Other factors to consider when deciding where we manage the patient include the presence of fever, nausea, vomiting, and diarrhea; altered mental status; the cause of the DKA; and availability of communication with the HCP (every few hours). Patients with DKA who have an illness such as pneumonia or a urinary tract infection (UTI) usually need admitted to the hospital.

Refer to Table 53.20 for the emergency management of a patient with DKA. Because fluid imbalance is potentially life-threatening, the first goal of therapy is to establish IV access and begin fluid and electrolyte replacement. Typically, the initial fluid therapy involves an IV infusion of 0.45% or 0.9% NaCl at a rate to raise BP and restore urine output to 30 to 60 mL/h. When glucose levels approach 250 mg/dL (13.9 mmol/L), 5% to 10% dextrose is added to prevent hypoglycemia and a sudden drop in glucose that can cause cerebral edema. Rapid rehydration, especially with hypotonic IV solutions, can cause cerebral edema.

The aim of fluid and electrolyte therapy is to replace extracellular and intracellular water and to correct deficits of sodium, chloride, bicarbonate, potassium, phosphate, and magnesium. Monitor patients with kidney or heart problems for fluid overload. Obtain a serum potassium level before starting insulin. If the patient is hypokalemic, giving insulin will further decrease potassium levels, making early potassium replacement essential. Although initial serum potassium may be normal or high, levels can rapidly decrease once therapy starts as insulin drives potassium into the cells, leading to life-threatening hypokalemia.

IV insulin therapy is given to correct hyperglycemia and hyperketonemia. It is important to prevent rapid drops in serum glucose to avoid cerebral edema. A glucose reduction of 36 to 54 mg/dL/hr (2 to 3 mmol/L/hr) will avoid complications. Insulin allows water and potassium to enter the cell along with glucose and can lead to a depletion of vascular volume and hypokalemia. Monitor the patient's fluid balance and potassium levels.

TABLE 53.19 Interprofessional Care

DKA and HHS

Diagnostic Assessment
- History and physical assessment
- Blood studies, including glucose, CBC, pH, ketones, electrolytes, BUN, arterial or venous blood gases
- Urinalysis, including specific gravity, glucose, acetone

Management
- IV fluid administration
- IV administration of short-acting insulin
- Electrolyte replacement
- Assess mental status
- Record of intake and output
- Central venous pressure monitoring (if indicated)
- Monitoring glucose levels
- Assess blood and urine for ketones
- ECG monitoring
- Assess cardiovascular and respiratory status

CHECK YOUR PRACTICE

A 22-year-old female with DKA has a glucose level of 554 mg/dL. You are trying to regulate her IV rate. You know that giving IV fluids too rapidly and quickly, lowering the serum glucose, can lead to cerebral edema. You also know that incorrect fluid replacement, especially with hypotonic fluids, can cause a sudden fall in serum sodium that can cause cerebral edema.
- What are the best clinical indicators of successful treatment of DKA?
- What is your role as a nurse in caring for this patient?

HYPEROSMOLAR HYPERGLYCEMIA SYNDROME

Hyperosmolar hyperglycemia syndrome (HHS) is a life-threatening syndrome that can occur in patients with DM who are able to make enough insulin to prevent DKA but not enough to prevent severe hyperglycemia, osmotic diuresis, and extracellular fluid depletion (Fig. 53.13). HHS is less common than DKA (Table 53.19). It often occurs in patients over 60 years of age with type 2 DM.

Common causes include UTIs, pneumonia, sepsis, an acute illness, and newly diagnosed type 2 DM. HHS is often related to impaired thirst sensation and/or a functional inability to replace fluids. There is usually a history of inadequate fluid intake, increasing mental depression or impaired cognition, and polyuria.

TABLE 53.20 EMERGENCY MANAGEMENT

DKA

Etiology	Assessment Findings	Interventions
• Undiagnosed DM • Inadequate treatment of existing DM • Insulin not taken as prescribed • Illness, infection • Change in eating, insulin, or exercise plan • Malfunction of insulin pump/non-delivery of insulin	• Abdominal pain • Breath odor of ketones (fruity) • Dry mouth • Eyes appearing sunken • Fever • Flushed, dry skin • Glucosuria and ketonuria • Increasing restlessness, confusion, lethargy • Labored breathing (Kussmaul respirations) • Nausea and vomiting • Rapid, weak pulse • Serum glucose >250 mg/dL (13.9 mmol/L) • Thirst • Urinary frequency	**Initial** • Ensure patent airway. • Give O_2 via nasal cannula or nonrebreather mask. • Establish IV access with large-bore catheter. • Begin fluid resuscitation with 0.9% NaCl solution 1 L/h until BP stabilized and urine output 30–60 mL/h. • Begin continuous regular insulin drip 0.1 U/kg/h. • Identify history of DM, time of last food, and time and amount of last insulin injection. **Ongoing Monitoring** • Monitor vital signs, level of consciousness, ECG, O_2 saturation, and urine output. • Assess breath sounds for fluid overload. • Monitor serum glucose and serum potassium. • Give potassium to correct hypokalemia. • Give sodium bicarbonate if severe acidosis (pH <7.0). • Add dextrose to IV fluid for glucose <250 mg/dL.

The main difference between HHS and DKA is that the patient with HHS usually has enough circulating insulin so that ketoacidosis does not occur. Because HHS has fewer symptoms in the earlier stages, glucose levels can climb quite high before the problem is recognized. The higher glucose levels increase serum osmolality and cause more severe neurologic manifestations, such as somnolence, coma, seizures, hemiparesis, and aphasia. Since these manifestations resemble a stroke, immediate determination of the glucose level is critical for correct diagnosis and treatment.

Laboratory values in HHS include a glucose level greater than 600 mg/dL (33.33 mmol/L) and a marked increase in serum osmolality. Ketone bodies are absent or minimal in both blood and urine.

Interprofessional Care

HHS is a medical emergency. It has a high mortality rate. The management of HHS is similar to DKA. It includes immediate IV administration of insulin and either 0.9% or 0.45% NaCl. HHS usually requires large volumes of fluid replacement. This should be done slowly and carefully. Patients with HHS are often older and may have heart or kidney problems, requiring hemodynamic monitoring to avoid fluid overload during fluid replacement. When glucose levels fall to about 250 mg/dL (13.9 mmol/L), IV fluids containing dextrose are given to prevent hypoglycemia.

Electrolytes are monitored and replaced as needed. Hypokalemia is not as significant in HHS as it is in DKA, although fluid losses may result in milder potassium deficits that require replacement. Assess vital signs, intake and output, laboratory values, and cardiac monitoring to check the efficacy of fluid and electrolyte replacement. This includes monitoring serum osmolality and frequently assessing cardiac, renal, and mental status. Once the patient is stable, begin attempts to detect and correct the underlying cause.

❖ NURSING MANAGEMENT: DIABETES-RELATED KETOACIDOSIS AND HYPEROSMOLAR HYPERGLYCEMIA SYNDROME

Closely monitor the hospitalized patient with appropriate blood and urine tests. You must monitor glucose and urine for output and ketones and use laboratory data to determine appropriate patient care.

Monitor the administration of (1) IV fluids to correct dehydration, (2) insulin therapy to reduce glucose and serum ketone levels, and (3) electrolytes given to correct electrolyte imbalance. Assess renal status and cardiopulmonary status related to hydration and electrolyte levels. Monitor level of consciousness.

Assess for signs of potassium imbalance resulting from low levels of insulin and osmotic diuresis (see Chapter 17). When insulin treatment is started, potassium levels may rapidly decrease as potassium moves into the cells once insulin is available. This movement of potassium into and out of extracellular fluid influences cardiac function. ECG monitoring is useful in detecting changes in potassium levels (see Fig. 17.14). Assess vital signs often to identify fever, hypovolemic shock, tachycardia, and Kussmaul respirations.

HYPOGLYCEMIA

Hypoglycemia, or low glucose, occurs when there is too much insulin in proportion to available glucose in the blood. This causes the glucose level to drop to less than 70 mg/dL (3.9 mmol/L). When glucose drops below 70 mg/dL, the body

PATHOPHYSIOLOGY MAP

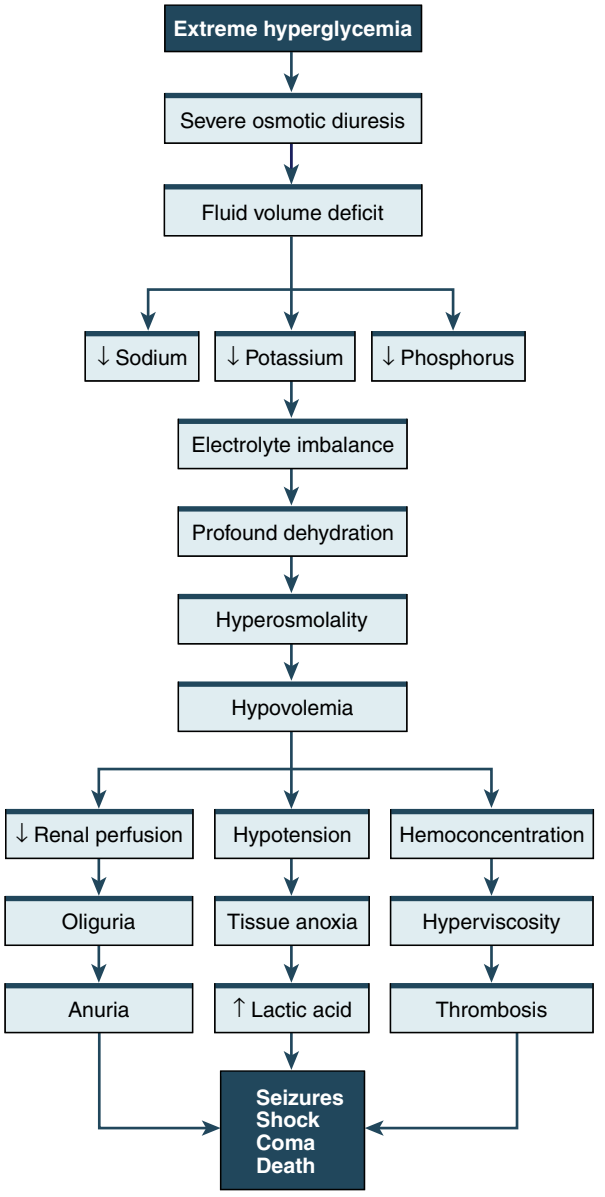

Fig. 53.13 Pathophysiology of hyperosmolar hyperglycemic syndrome. (Modified from Urden LD, Stacy KM, Lough ME: *Critical care nursing: diagnosis and management*, ed 6, St Louis, 2010, Mosby.)

releases counterregulatory hormones and activates the autonomic nervous system. Suppressing insulin secretion and producing glucagon and epinephrine provide a defense against hypoglycemia. Epinephrine release causes manifestations that include shakiness, palpitations, nervousness, diaphoresis, anxiety, hunger, and pallor. Because the brain needs a constant supply of glucose in sufficient quantities to function properly, hypoglycemia can affect mental functioning. These "neuroglycopenia" manifestations are difficulty speaking, visual changes, stupor, confusion, and coma. Manifestations of hypoglycemia can mimic alcohol intoxication. Untreated hypoglycemia can progress to loss of consciousness, seizures, coma, and death.

Hypoglycemia unawareness is a condition in which a person does not have the warning signs and symptoms of hypoglycemia until the glucose level reaches a critical point. Then the person may become incoherent and combative or lose consciousness. This is often a result of DM-related autonomic neuropathy that interferes with the secretion of counterregulatory hormones that cause these symptoms. Patients at risk for hypoglycemia unawareness include those who have had repeated episodes of hypoglycemia, older adults, and patients who use β-adrenergic blockers. Using intensive treatment to lower glucose levels in patients who have or are at risk for hypoglycemia unawareness may not be an appropriate goal. These patients usually keep glucose levels somewhat higher than those who can detect and manage the onset of hypoglycemia.

Causes of hypoglycemia are often related to a mismatch in the timing of food intake and the peak action of insulin or OAs that increase insulin secretion. Common causes include receiving too much insulin or medication, ingesting too little food, delaying the time of eating, and performing unusual or unexpected exercise. Hypoglycemia can occur at any time. It most often occurs when the OA or insulin is at its peak of action or when the patient's daily routine is disrupted without adequate adjustments in diet, drugs, and activity. Hypoglycemia is most common with insulin therapy. It can occur with noninsulin injectable agents and OAs and may persist for an extended time because of the longer duration of action of these drugs.

Symptoms of hypoglycemia may occur when a very high glucose level falls too rapidly (e.g., a glucose level of 300 mg/dL [16.7 mmol/L] falling quickly to 150 mg/dL [10 mmol/L]). Although the glucose level is above normal by definition and measurement, the sudden metabolic shift can cause hypoglycemia symptoms. Aggressively managing glucose levels, lowering high glucose levels for the first time, or lowering glucose with insulin after a long period of hyperglycemia can cause this situation.

❖ NURSING AND INTERPROFESSIONAL MANAGEMENT: HYPOGLYCEMIA

Hypoglycemia can usually be quickly reversed with effective treatment. At the first sign of hypoglycemia, check the glucose, if possible. If it is less than 70 mg/dL (3.9 mmol/L), immediately begin treatment for hypoglycemia. If the glucose is greater than 70 mg/dL, look for other possible causes of the signs and symptoms. If the patient has manifestations of hypoglycemia and monitoring equipment is not available, or the patient has a history of fluctuating glucose levels, assume hypoglycemia, and start treatment.

Follow the "Rule of 15" to treat hypoglycemia (Table 53.21). A glucose value less than 70 mg/dL is treated by ingesting 15 to 20 g of a simple (fast-acting) carbohydrate, such as 4 to 6 oz of fruit juice or a regular soft drink. Encourage the patient to carry or have available glucose tablets, gels, and powders for use in such situations. Recheck the glucose 15 minutes later. If the value is still less than 70 mg/dL, ingest 15 to 20 g more of carbohydrate and recheck the glucose in 15 minutes. If no significant improvement occurs after 2 or 3 doses, contact the HCP. After an acute episode of hypoglycemia, the patient may need a snack with carbohydrate and protein if the next meal is more than an hour away or if they are being active.

TABLE 53.21 EMERGENCY MANAGEMENT

Hypoglycemia

Etiology	Assessment Findings	Interventions
• Too little food—delayed, omitted, inadequate intake • Too much DM medication • Too much exercise without adequate food intake • DM medication or food taken at wrong time • Alcohol use without food intake	• Glucose <70 mg/dL (3.9 mmol/L) • Cold, clammy skin • Numbness of fingers, toes, mouth • Tachycardia • Emotional changes • Headache • Nervousness, tremors • Faintness, dizziness • Unsteady gait, slurred speech • Hunger • Changes in vision • Seizures, coma	**Initial** • Check glucose. • Determine cause of hypoglycemia (after correcting condition). **Management** ***Conscious Patient*** • Have patient eat or drink 15–20 g of quick-acting carbohydrate (4–6 oz of regular soda, 5–8 LifeSavers, 1 Tbsp syrup or honey, 4 tsp jelly, 4–6 oz orange juice, commercial dextrose products [per label instructions]). • Wait 15 min. Check glucose level. • If glucose is still <70 mg/dL, have patient eat or drink another 15–20 g of carbohydrate. • Once the glucose level is stable, give patient additional food of carbohydrate plus protein or fat (e.g., crackers with peanut butter or cheese) if the next meal is more than 1 h away or patient is engaged in physical activity. • Immediately notify HCP or emergency service (if patient outside hospital) if symptoms do not subside after 2 or 3 doses of quick-acting carbohydrate. ***Worsening Symptoms or Unconscious Patient*** • 1 mg glucagon subcutaneous or IM or IV administration of 20–50 mL of 50% glucose. • Turn the patient on the side to prevent aspiration.

Avoid treatment with carbohydrates that contain fat, such as candy bars, cookies, whole milk, and ice cream. The fat in those foods will slow glucose absorption and delay the response to treatment. Do not overtreat with large quantities of quick-acting carbohydrates because a rapid fluctuation to hyperglycemia can occur.

In an acute care setting, patients with hypoglycemia may receive 20 to 50 mL of 50% dextrose IV. If the patient is not alert enough to swallow and no IV access is available, another option is to give 1 mg of glucagon by IM or subcutaneous injection. An IM injection in a site such as the deltoid muscle will result in a quicker response. Glucagon stimulates the liver to convert glycogen to glucose and makes glucose rapidly available. Nausea is a common reaction after glucagon injection. To prevent aspiration if vomiting occurs, turn the patient on the side until they are alert. Patients with minimal glycogen stores will not respond to glucagon. This includes patients with alcohol-related liver disease, starvation, and adrenal insufficiency. Teach family members and others likely to be present if severe hypoglycemia occurs when and how to inject glucagon.

Once the episode is resolved, explore with the patient the reasons why the situation developed. This assessment may indicate the need for further patient teaching to avoid future episodes of hypoglycemia.

CHRONIC COMPLICATIONS ASSOCIATED WITH DIABETES

ANGIOPATHY

Chronic complications associated with DM are primarily those of end-organ disease from damage to blood vessels *(angiopathy)* from chronic hyperglycemia (Fig. 53.14). Angiopathy is a leading cause of DM-related deaths, with about 68% of deaths caused by CVD and 16% caused by strokes for those ages 65 or older.[22] These chronic blood vessel dysfunctions are divided into 2 categories: macrovascular and microvascular complications.

Several theories exist as to how and why chronic hyperglycemia damages cells and tissues. Possible causes include (1) the accumulation of damaging by-products of glucose metabolism, such as sorbitol, which damage nerve cells; (2) the formation of abnormal glucose molecules in the basement membrane of small blood vessels, such as those that circulate to the eyes and kidneys; and (3) a problem with RBC function that leads to a decrease in tissue oxygenation.

The Diabetes Control and Complications Trial (DCCT), a landmark study in DM management, showed the risk for microvascular complications is reduced in people with type 1 DM by keeping glucose levels as near to normal as possible for as much of the time as possible *(tight or intensive therapy)*.[23] Those who maintained tight glucose levels reduced their risk for developing eye and kidney problems, common microvascular complications. Intensive treatment of type 2 DM greatly lowers the risk of developing DM-related eye and kidney problems.[24] Based on these findings, the ADA issued treatment goals to maintain glucose levels as near to normal as possible. Specific targets for each patient must consider their risk for severe or undetected hypoglycemia as a side effect of intensive management.

Because of the devastating effects of long-term complications, people with DM need scheduled and ongoing monitoring for the detection and prevention of chronic complications. The ADA recommendations for ongoing evaluation are shown in Table 53.22. It is essential that patients understand the importance of regular follow-up visits.

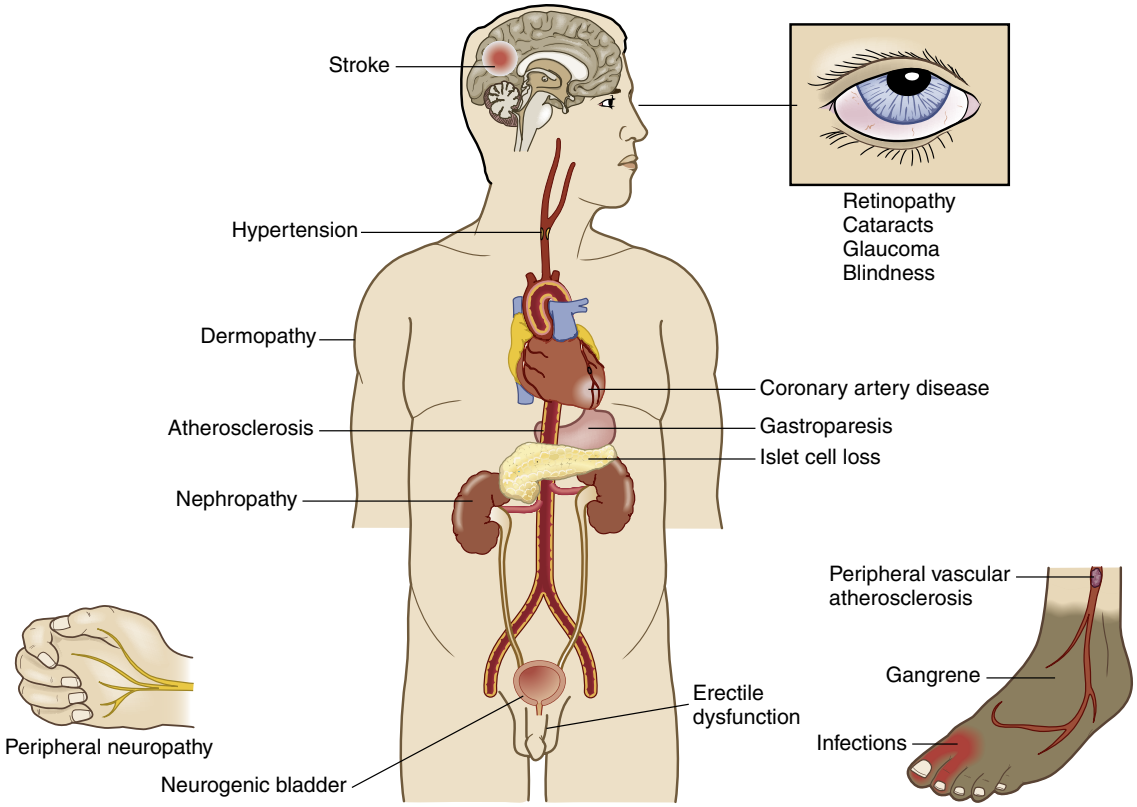

Fig. 53.14 Long-term complications of DM. (From Kumar V, Abbas AK, Aster JC, et al.: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders.)

TABLE 53.22 Monitoring for Long-Term Complications Related to DM

Complication	Type of Examination	Frequency
Retinopathy	• Funduscopic: dilated eye examination • Fundus photography	• Annually
Nephropathy	• Urine for albuminuria • Serum creatinine	• Annually
Neuropathy (foot and lower extremities)	Visual examination of foot • Comprehensive foot • Vision examination • Sensory testing with monofilament and tuning fork • Palpation (pulses, temperature, callus formation)	• Daily by patient • Every visit to HCP • Annually[a]
CVD	• Risk factor assessment: hypertension, dyslipidemia, smoking, family history of premature coronary artery disease, and presence of albuminuria	• Every visit • At least annually
	• Exercise stress testing (may include stress ECG, stress echocardiogram, stress nuclear imaging)	• As needed, based on risk factors

[a]If patients have a history of foot ulcers, loss of sensation in their feet, or other foot abnormalities, the recommendation is to have a foot examination at every visit.

Source: ADA: Standards of medical care in diabetes, *Diabetes Care* 43:S135, 2020.

Macrovascular Complications

Macrovascular complications are diseases of the large- and medium-size blood vessels that occur with greater frequency and with an earlier onset in people with DM. Macrovascular diseases include cerebrovascular, cardiovascular, and peripheral vascular disease. Women with DM have a 4 to 6 times increased risk for CVD. Men with DM have a 2 to 3 times increased risk for CVD compared with those without DM.

There are several modifiable risk factors associated with macrovascular complications. These include obesity, smoking, hypertension, high fat intake, and sedentary lifestyle. The ADA recognizes that DM alone is a CVD risk factor. The ADA recommends yearly screening for CVD risk factors in people with DM.[25]

Insulin resistance is important in developing CVD and implicated in the pathogenesis of essential hypertension and dyslipidemia. We do not completely understand the role of insulin resistance in the pathogenesis of CVD. It seems to combine with dyslipidemia in contributing to greater risk for CVD in people with DM.

Optimizing BP in patients with DM is significant in preventing CVD and kidney disease. Treating hypertension in those with DM results in a decrease in macrovascular and microvascular complications. Hypertension in people with DM causes an increase in mortality greater than for those with hypertension without DM. The ADA recommends BP screening at every visit for people with DM. They recommend lifestyle counseling for BP greater than 130/80 mm Hg and treatment to achieve a

target BP of less than 140/90 mm Hg for most patients with DM. Hypertension is discussed in Chapter 36, and coronary artery disease is discussed in Chapter 37.

People with DM have an increase in lipid abnormalities that contribute to their increased risk for CVD. The ADA recommends screening all adults for dyslipidemia when they are diagnosed with DM and starting statin therapy as needed. Dosing is based on the presence of age and other CVD risk factors. The ADA advocates treating hyperlipidemia with lifestyle interventions, including nutrition therapy, exercise, weight loss, and smoking cessation.

Smoking is especially dangerous for people with DM. It significantly increases the risk for blood vessel and CVD, stroke, and lower extremity amputation.

Microvascular Complications

Microvascular complications result from thickening of the vessel membranes in the capillaries and arterioles (small vessels) in response to chronic hyperglycemia. Although microangiopathy can be found throughout the body, the areas most noticeably affected are the eyes (retinopathy), kidneys (nephropathy), and nerves (neuropathy). Microvascular changes are present in some people with type 2 DM at the time of diagnosis.

RETINOPATHY

Etiology and Pathophysiology

Diabetes-related retinopathy refers to the microvascular damage to the retina because of chronic hyperglycemia, nephropathy, and hypertension in people with DM. DM-related retinopathy is the leading cause of new cases of adult blindness.

We classify retinopathy as nonproliferative or proliferative. In *nonproliferative retinopathy,* the most common form, partial occlusion of the small blood vessels in the retina, causes microaneurysms to develop in the capillary walls. The walls of these microaneurysms are so weak that capillary fluid leaks out, causing retinal edema and eventually hard exudates or intraretinal hemorrhages. This may cause mild to severe vision loss, depending on which parts of the retina are affected. If the center of the retina (macula) is affected, vision loss can be severe.

Proliferative retinopathy, the most severe form, involves the retina and vitreous. When retinal capillaries become occluded, the body compensates by forming new blood vessels to supply the retina with blood, a process called *neovascularization.* These new vessels are very fragile and bleed easily, causing vitreous contraction. Eventually, light cannot reach the retina as the vessels break and bleed into the vitreous cavity. The patient sees black or red spots or lines. If these new blood vessels pull the retina while the vitreous contracts, causing a tear, partial or complete retinal detachment will occur. If the macula is involved, vision is lost. Without treatment, more than half of people with proliferative diabetic retinopathy will be blind.

Persons with DM are prone to other visual problems. Glaucoma occurs because of the occlusion of the outflow channels from neovascularization. This type of glaucoma is hard to treat and often results in blindness. Cataracts develop at an earlier age and progress more rapidly in people with DM.

Interprofessional Care

The earliest and most treatable stages of DM-related retinopathy often cause no changes in the vision. Teach patients with type 2 DM to have a dilated eye examination by an ophthalmologist or a specially trained optometrist at the time of diagnosis and annually thereafter for early detection and treatment. Those with type 1 DM need to have a dilated eye examination within 5 years after the onset of DM and then annually.

The best approach to managing DM-related eye disease is to prevent it by maintaining healthy glucose levels and managing hypertension. Laser photocoagulation therapy can reduce the risk for vision loss in patients with proliferative retinopathy or macular edema and, sometimes, nonproliferative retinopathy. Laser photocoagulation destroys the ischemic areas of the retina that make growth factors that encourage neovascularization. A patient who develops vitreous hemorrhage and retinal detachment may need to undergo vitrectomy. *Vitrectomy* is the aspiration of blood, membrane, and fibers from the inside of the eye through a small incision just behind the cornea. (Photocoagulation and vitrectomy are discussed in Chapter 22.)

A fluocinolone acetonide intravitreal implant (Iluvien) is used to treat retinopathy. It is an injectable microinsert that provides sustained treatment through continuous delivery of corticosteroid fluocinolone acetonide for 36 months. Iluvien is injected in the back of the eye with an applicator that uses a 25-gauge needle, which allows for a self-sealing wound.

Vascular endothelial growth factor (VEGF) plays a key role in developing DM-related retinopathy. We are currently studying drugs injected into the eye that block the action of VEGF and reduce inflammation for their effectiveness in treating retinopathy.[26]

NEPHROPATHY

Diabetes-related nephropathy is associated with damage to the small blood vessels that supply the glomeruli of the kidney. It is the leading cause of ESRD in the United States and is seen in 20% to 40% of people with DM. Risk factors include hypertension, genetic predisposition, smoking, and chronic hyperglycemia. Keeping glucose levels in a healthy range is critical in preventing DM-related nephropathy.

Patients are screened for nephropathy annually with a random spot urine collection to assess for albuminuria and measure the albumin-to-creatinine ratio. Serum creatinine is measured to give an estimate of the glomerular filtration rate and the degree of kidney function.

Patients with albuminuria receive either ACE inhibitor drugs (e.g., lisinopril) or angiotensin II receptor blockers (e.g., losartan). Both these drug classes are used to treat hypertension and delay the progression of nephropathy in patients with DM. Hypertension significantly accelerates the progression of nephropathy. Aggressive BP management is indicated for Patients with DM and hypertension. Patients with DM and hypertension need aggressive BP management (see Chapter 36). See Chapter 51 for a discussion of renal failure.

NEUROPATHY

Diabetes-related neuropathy is nerve damage that occurs from the metabolic imbalances associated with DM. About 60% to 70% of patients with DM have some degree of neuropathy. The most common type affecting persons with DM is sensory neuropathy. This can lead to the loss of sensation in the lower extremities. Coupled with other factors, it significantly increases the risk for complications that result in lower limb amputation. More than 60% of nontraumatic amputations in the United States occur in people with DM. Neuropathy can precede, accompany, or follow the diagnosis of DM. Screening for neuropathy begins at the time of diagnosis in patients with type 2 DM and 5 years after diagnosis in patients with type 1 DM.[27]

Fig. 53.15 Neuropathy: neurotrophic ulceration.

Etiology and Pathophysiology

We do not completely understand the pathophysiology of DM-related neuropathy. Theories include metabolic, vascular, and autoimmune factors. The prevailing theory is that persistent hyperglycemia leads to an accumulation of sorbitol and fructose in the nerves that causes damage. How they cause damage is unknown. The result is reduced nerve conduction and demyelination. Ischemic damage by chronic hyperglycemia in blood vessels that supply the peripheral nerves is implicated in developing DM-related neuropathy.

Classification

The 2 major categories of DM-related neuropathy are *sensory neuropathy,* which affects the peripheral nervous system, and *autonomic neuropathy.* Each type has several forms.

Sensory Neuropathy

The most common form of sensory neuropathy is distal symmetric polyneuropathy. It affects the hands and/or feet bilaterally. We sometimes call this *stocking-glove neuropathy.* Characteristics include loss of sensation, abnormal sensations, pain, and paresthesias. Patients describe the pain as burning, cramping, crushing, or tearing. It is usually worse at night and may occur only at that time. The paresthesias may be associated with tingling, burning, and itching sensations. The patient may report a feeling of walking on pillows or numb feet. The skin can become so sensitive (hyperesthesia) that the patient cannot tolerate even light pressure from bed sheets. Complete or partial loss of sensitivity to touch and temperature is common. Foot injury and ulcerations can occur without the patient ever having pain (Fig. 53.15). Neuropathy can cause atrophy of the small muscles of the hands and feet, causing deformity and limiting fine movement.

Managing glucose is the only treatment for DM-related neuropathy. It is effective in many, but not all, cases. Drug therapy may be used to treat neuropathic symptoms, especially pain. At the start of therapy, symptoms usually increase, followed by relief of pain in 2 to 3 weeks.

Common drugs used include topical creams (e.g., capsaicin), tricyclic antidepressants (e.g., amitriptyline), selective serotonin and norepinephrine reuptake inhibitors (e.g., duloxetine), and antiseizure drugs (e.g., gabapentin). Capsaicin is a moderately effective topical cream made from chili peppers. It depletes the accumulation of pain-mediating chemicals in the peripheral sensory neurons. The cream is applied 3 or 4 times a day.

Tricyclic antidepressants are moderately effective in treating DM-related neuropathy. They inhibit the reuptake of norepinephrine and serotonin, which are neurotransmitters thought to play a role in pain transmission. We think duloxetine relieves pain by increasing the levels of serotonin and norepinephrine, which improves the body's ability to regulate pain. Antiseizure drugs decrease the release of neurotransmitters that transmit pain.

Autonomic Neuropathy

Autonomic neuropathy can affect nearly all body systems and lead to hypoglycemia unawareness, bowel incontinence and diarrhea, and urinary retention. *Gastroparesis* (delayed gastric emptying) is a complication of autonomic neuropathy that can cause anorexia, nausea, vomiting, gastroesophageal reflux, and persistent feelings of fullness. Gastroparesis can trigger hypoglycemia by delaying food absorption. Cardiovascular problems from autonomic neuropathy include postural hypotension, resting tachycardia, and painless MI. Assess for postural hypotension to determine if the patient is at risk for falls. Teach the patient with postural hypotension to change from a lying or sitting position slowly.

DM can affect sexual function. Erectile dysfunction (ED) in men with DM is common. It is often the first manifestation of autonomic neuropathy. ED is associated with other factors, including vascular disease, high glucose levels, endocrine problems, psychogenic factors, and other drugs. Decreased libido is a problem for some women with DM. Candida and nonspecific vaginitis are common. ED and sexual problems require sensitive counseling for both the patient and the patient's partner. See Chapter 59 for more about ED.

A neurogenic bladder may develop as the sensation in the inner bladder wall decreases, causing urinary retention. A patient with retention has infrequent voiding, difficulty voiding, and a weak stream of urine. Emptying the bladder every 3 hours in a sitting position helps prevent stasis and infection. Tightening the abdominal muscles during voiding and using the Credé maneuver (mild massage downward over the lower abdomen and bladder) may help with complete bladder emptying.

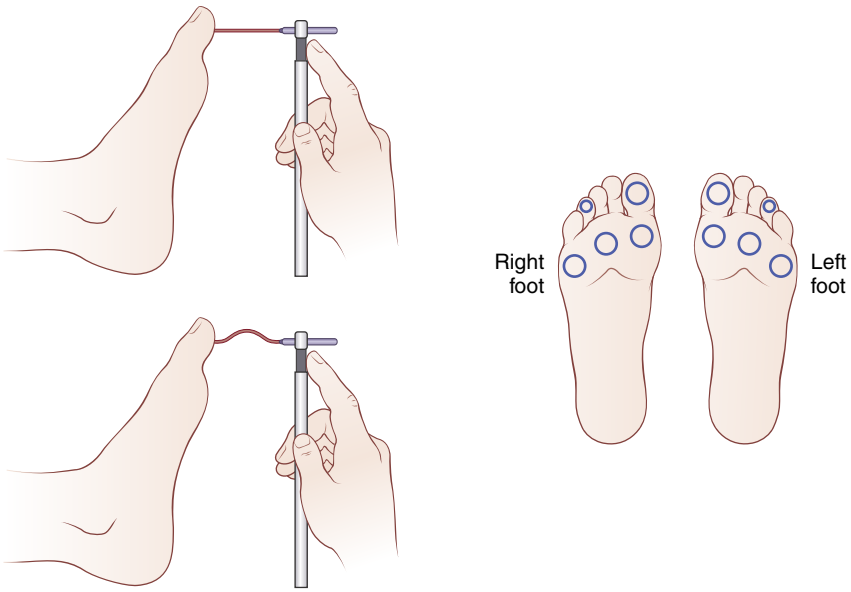

Fig. 53.16 Monofilament testing. Press the monofilament lightly until it bows in each area of the foot that should be tested. Record the presence of sensation in that area. (From Dehn R: *Essential clinical procedures,* St. Louis, 2021, Elsevier.)

Cholinergic agonist drugs, such as bethanechol (Urecholine), may be used. The patient may need to learn self-catheterization (see Chapter 50).

COMPLICATIONS OF FEET AND LOWER EXTREMITIES

People with DM are at high risk for foot ulcerations and lower extremity amputations. The development of DM-related foot complications can be the result of a combination of microvascular and macrovascular diseases that place the patient at risk for injury and serious infection. Sensory neuropathy and peripheral artery disease (PAD) are risk factors for foot complications. Clotting abnormalities, impaired immune function, and autonomic neuropathy have a role. Smoking has a negative effect on lower extremity blood vessels and increases the risk for amputation.

Sensory neuropathy is a major risk factor for lower-extremity amputation in people with DM. *Loss of protective sensation* (LOPS) often prevents the patient from being aware that a foot injury has occurred. Improper footwear and injury from stepping on foreign objects while barefoot are common causes of undetected foot injury in the person with LOPS. Because the primary risk factor for lower extremity amputation is LOPS, annual screening with monofilament testing is important (Fig. 53.16).

PAD increases the risk for amputation by reducing blood flow to the lower extremities. With decreased blood flow, oxygen, white blood cells (WBCs), and vital nutrients are not available to the tissues. Wounds take longer to heal, and the risk for infection increases. Signs of PAD include intermittent claudication, pain at rest, cold feet, loss of hair, delayed capillary refill, and dependent rubor. PAD is diagnosed by history, ankle-brachial index (ABI), and angiography. Management includes reducing risk factors, especially smoking, and managing cholesterol and hypertension. Bypass or graft surgery is needed in some patients. PAD is discussed in Chapter 41.

If the patient has LOPS or PAD, aggressive measures must be taken to teach the patient how to prevent foot ulcers. These measures include choosing proper footwear, including protective shoes. Teach the patient to carefully avoid injury to the foot, practice diligent skin and nail care, inspect the foot thoroughly each day, and treat small problems promptly. Guidelines for patient teaching are listed in Table 53.23.

Proper care of a foot ulcer is critical for wound healing. Several forms of treatment can be used. Casting can redistribute the weight on the plantar surface of the foot. Wound care for the ulcer can include debridement, dressings, advanced wound healing products, vacuum-assisted closure, ultrasound, hyperbaric O_2, and skin grafting.

Neuropathic arthropathy, or *Charcot's foot,* results in ankle and foot changes that lead to joint problems and footdrop. These changes occur gradually. They promote an abnormal distribution of weight over the foot. This increases the chances of developing a foot ulcer as new pressure points appear. Foot deformity should be recognized early, and proper footwear fitted before ulceration occurs.

SKIN COMPLICATIONS

Up to two-thirds of persons with DM develop skin problems. DM-related dermopathy, the most common skin lesion, is characterized by reddish-brown, round or oval patches. They initially are scaly, then they flatten out and become indented. The lesions appear most often on the shins but can occur on the front of the thighs, forearm, side of the foot, scalp, and trunk.

Acanthosis nigricans is a manifestation of insulin resistance. It can appear as a velvety light brown to black skin thickening,

TABLE 53.23 PATIENT & CAREGIVER TEACHING

Foot Care

Include the following instructions when teaching the patient and caregiver about foot care:

1. Wash feet daily with mild soap and warm water. First, test water temperature with elbow.
2. Pat feet dry gently, especially between toes.
3. Examine feet daily for cuts, blisters, swelling, and red, tender areas. Do not depend on feeling sores. If eyesight is poor, have others inspect feet.
4. Use lanolin on feet to prevent skin from drying and cracking. Do not apply between toes.
5. Use mild foot powder on sweaty feet.
6. Do not use commercial remedies to remove calluses or corns.
7. Cleanse cuts with warm water and mild soap, covering with clean dressing. Do not use iodine, rubbing alcohol, or strong adhesives.
8. Report skin infections or nonhealing sores to HCP at once.
9. Cut toenails evenly with rounded contour of toes. Do not cut down corners. The best time to trim nails is after a shower or bath.
10. Separate overlapping toes with cotton or lamb's wool.
11. Avoid open-toe, open-heel, and high-heel shoes. Leather shoes are preferred to plastic ones. Wear slippers with soles. Do not go barefoot. Inspect feet, socks, and shoes for foreign objects before putting on.
12. Wear clean, absorbent (cotton or wool) socks or stockings that have not been mended. Colored socks must be colorfast.
13. Do not wear clothing that leaves impressions, hindering circulation.
14. Do not use hot water bottles or heating pads to warm feet. Wear socks for warmth.
15. Guard against frostbite.
16. Exercise feet daily either by walking or by flexing and extending feet in suspended position. Avoid prolonged sitting, standing, and crossing of legs.

mainly on flexures, axillae, and the neck (Fig. 53.17). *Necrobiosis lipoidica diabeticorum* usually appears as red-yellow lesions, with atrophic skin that becomes shiny and transparent, revealing tiny blood vessels under the surface. This condition is uncommon. It occurs more often in young women. It may appear before other signs and symptoms of DM. Because the thin skin is prone to injury, special care must be taken to protect affected areas from injury and ulceration.

INFECTION

A person with DM is more susceptible to infections because of a defect in the mobilization of WBCs and impaired phagocytosis by neutrophils and monocytes. Recurring or persistent infections, such as *Candida albicans,* boils, and furuncles in the undiagnosed patient often lead the HCP to suspect DM. Loss of sensation (neuropathy) may delay the detection of an infection.

Persistent glycosuria may predispose people to bladder infections, especially those with a neurogenic bladder. Decreased circulation resulting from angiopathy can prevent or delay the immune response. Antibiotic therapy has prevented infection from being a major cause of death in patients with DM. The treatment of infections must be prompt and vigorous. Teach patients to prevent infection by practicing good hand hygiene, avoiding exposure to persons who have a communicable illness, and getting an annual influenza vaccine and pneumococcal vaccine.

Fig. 53.17 Acanthosis nigricans of the neck. (From Strauss J: *Yen and Jaffe's reproductive endocrinology*, St Louis, 2019, Elsevier.)

PSYCHOLOGIC CONSIDERATIONS

People with DM have high rates of distress, anxiety, and eating disorders. Depression and distress contribute to diminished DM self-care, feelings of helplessness related to chronic illness, and poor outcomes. DM distress encompasses the stress, fear, and burden of living with and managing a demanding chronic disease. Assess patients for manifestations of depression and/or DM distress.

Disordered eating behaviors (DEBs) can occur in people with both type 1 and type 2 DM. DEBs include anorexia, bulimia, binge eating, excessive calorie restriction, and intense exercise. Adolescent girls with DM are more than twice as likely to develop DEB than those who do not have DM.[28] Patients may intentionally decrease their dose of insulin or omit the dose. This is called "diabulimia." It leads to weight loss, hyperglycemia, and glycosuria because the food ingested cannot be used for energy without adequate insulin. Insulin omission and DEBs can have serious consequences, including retinopathy, neuropathy, lipid abnormalities, DKA, and death.

Open communication is critical to identify these behaviors early. Refer patients with DEB to a mental health professional with expertise in DEB and an understanding of DM management.

Gerontologic Considerations: DM

DM is present in more than 25% of persons over 65 years of age. This age group is the fastest-growing segment of the population developing DM. Older people with DM have higher rates of premature death, functional disability, and coexisting illnesses, such as hypertension and stroke, than those without DM. The prevalence of DM increases with age. A major reason for this is that the aging process is associated with a reduction in β-cell function, decreased insulin sensitivity, and altered carbohydrate metabolism. Aging is associated with conditions

that are more likely to be treated with drugs that impair insulin action (e.g., corticosteroids, antihypertensives, phenothiazines). Undiagnosed and untreated DM is more common in older adults. This in part occurs because manifestations of DM, such as low energy levels, dizziness, confusion, and chronic UTIs, are wrongly attributed to normal age-related changes.

Several factors affect setting glycemic goals for an older adult. One is that hypoglycemia unawareness is more common in older adults, making them more likely to have adverse consequences from glucose-lowering therapy. They may have problems that could interfere with the ability to treat hypoglycemia. Other factors include the patient's desire for treatment and coexisting medical problems, such as cognitive impairment. Compounding the challenge, DM increases the rate of cognitive decline. Although treatment is needed to prevent complications, intensive DM management may be hard and dangerous to achieve, especially in older adults.

Meal planning and exercise are recommended therapy for older adults with DM. Consider functional limitations that may interfere with physical activity and the ability to prepare meals. Because of the physiologic changes that occur with aging, the therapeutic outcome for the older adult who receives OAs may be altered. Assess renal function and creatinine clearance in those over 80 years of age taking metformin. Monitor those taking sulfonylurea drugs (e.g., glipizide) for hypoglycemia and kidney and liver problems. Insulin therapy may be started if OAs are not effective. However, older adults are more likely to have limitations in the dexterity and visual acuity needed for accurate insulin administration. Insulin pens may be a safer alternative.

Patient education issues include those related to altered vision, mobility, cognitive status, and functional ability. Plan patient teaching based on individual needs. Use a slower pace with simple printed or audio materials in patients with cognitive and functional limitations. Include the family or caregivers in the teaching. Consider the patient's financial and social situation and the effect of multiple drugs, eating habits, and quality-of-life issues.

Case Study

DKA

(© katrinaelena/iStock/Thinkstock.)

Patient Profile

N.B., a 48-year-old farmer, is in the emergency department after his wife found him unconscious in the barn. They live 40 miles from the nearest hospital. He has a medical history of type 1 DM, hypertension, and DM-related neuropathy.

Subjective Data (Provided by Wife)

- Diagnosed with type 1 DM 15 years ago
- Takes 40 U/day of insulin via insulin pump: 5 U of lispro insulin bolus with breakfast, 5 U bolus with lunch, and 10 U bolus with dinner plus 20 U of basal insulin
- Has history of gastroenteritis for 1 week with vomiting and anorexia
- Stopped taking mealtime boluses 2 days ago when he was unable to eat
- Has not changed his infusion set in 5 days

Objective Data

Physical Assessment

- Respirations deep with rate 36 breaths/min
- Fruity acetone smell on breath
- Skin flushed and dry
- Heart rate 118 beats/min; BP 98/60 mm Hg

Diagnostic Studies

- Glucose level 730 mg/dL (40.5 mmol/L)
- Blood pH 7.26

Discussion Questions

1. ***Recognize***: Briefly explain the pathophysiology behind N.B.'s DKA.
2. ***Recognize***: What factors precipitated his developing DKA?
3. ***Analyze***: What clinical manifestations of DKA does this patient exhibit?
4. ***Analyze***: What distinguishes this case history from one of HHS or hypoglycemia?
5. ***Prioritize:*** Based on the assessment data presented, what are the priority clinical problems?
6. ***Prioritize:*** What is the priority nursing intervention for N.B.?
7. ***Act:*** What teaching do you need to provide for N.B. and his family?
8. ***Act:*** N.B.'s wife asks you if she should have given her husband insulin when he got sick. How would you respond?
9. ***Act:*** How can the health care team be most effective in caring for N.B?
10. ***Evaluate:*** What outcomes would indicate that the health care team was effective in caring for N.B.?
11. Develop a conceptual care map for N.B.

Answers and a corresponding concept map available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. The nurse is assessing a patient newly diagnosed with type 1 diabetes. Which symptom reported by the patient correlates with the diagnosis?
   - **a.** Excessive thirst
   - **b.** Gradual weight gain
   - **c.** Overwhelming fatigue
   - **d.** Recurrent blurred vision
2. When distinguishing between persons with type 1 diabetes from type 2 diabetes, the nurse is aware that
   - **a.** persons with type 1 diabetes require insulin therapy.
   - **b.** autoantibodies to pancreatic β-cells are found in type 2 diabetes.
   - **c.** persons with type 1 diabetes may be managed with metformin alone.
   - **d.** hyperosmolar hyperglycemia syndrome is more common in type 1 diabetes.

BRIDGE TO NCLEX EXAMINATION—cont'd

3. Goals of managing the patient with diabetes include *(select all that apply)*
   - **a.** keeping the target A1C greater than 9%.
   - **b.** teaching self-monitoring of glucose levels.
   - **c.** preventing complications of hypoglycemia.
   - **d.** monitoring for ophthalmologic complications.
   - **e.** maintaining the LDL cholesterol greater than 100 mg/dL (2.6 mmol/L).
4. Which patient statement demonstrates an understanding of the role of exercise in managing diabetes?
   - **a.** "I cannot exercise if I am taking insulin and metformin."
   - **b.** "Exercise increases insulin resistance, so I will need a higher dose of insulin."
   - **c.** "It is better to exercise before a meal if I take medication that causes hypoglycemia."
   - **d.** "My insulin dose may need to be changed if I have low glucose levels after exercising."
5. You are caring for a patient with newly diagnosed type 2 diabetes who was started on metformin. What information should you include in discharge teaching? (*Select all that apply.*)
   - **a.** Need to reduce physical activity
   - **b.** Eliminate all forms of sugar from diet
   - **c.** Use of a portable blood glucose meter
   - **d.** Hypoglycemia prevention, symptoms, and treatment
   - **e.** Procedures that require IV contrast media are contraindicated
6. What is the *priority* action for the nurse to take if the patient with type 2 diabetes reports headache, nervousness, and dizziness?
   - **a.** Administer glucagon.
   - **b.** Give insulin as ordered.
   - **c.** Check the patient's glucose level.
   - **d.** Assess for other signs of neurologic stroke.
7. A patient with diabetes has a serum glucose level of 824 mg/dL (45.7 mmol/L) and is unresponsive. After assessing the patient, the nurse suspects diabetes-related ketoacidosis rather than hyperosmolar hyperglycemia syndrome based on the finding of
   - **a.** polyuria.
   - **b.** severe dehydration.
   - **c.** rapid, deep respirations.
   - **d.** decreased serum potassium.
8. Which are appropriate therapies for patients with diabetes? *(Select all that apply.)*
   - **a.** Use of statins to reduce CVD risk
   - **b.** Use of diuretics to treat nephropathy
   - **c.** Use of β-blockers to treat retinopathy
   - **d.** Use of serotonin agonists to decrease appetite
   - **e.** Use of ACE or ARB inhibitors to treat nephropathy

1. a; 2. a; 3. b, c, d; 4. d; 5. c, d; 6. c; 7. c; 8. a, e.

LEARNING OUTCOMES

1. Explain the pathophysiology, clinical manifestations, and interprofessional and nursing management of the patient with an anterior pituitary gland problem.
2. Describe the pathophysiology, clinical manifestations, and interprofessional and nursing management of the patient with a posterior pituitary gland problem.
3. Explain the pathophysiology, clinical manifestations, and interprofessional and nursing management of the patient with a thyroid problem.
4. Describe the pathophysiology, clinical manifestations, and interprofessional and nursing management of the patient with a parathyroid problem.
5. Identify the pathophysiology, clinical manifestations, and interprofessional and nursing management of the patient with an adrenal cortex problem.
6. Describe the pathophysiology, clinical manifestations, and interprofessional and nursing management of the patient with an adrenal medulla problem.
7. Outline the side effects of corticosteroid therapy.

KEY TERMS

acromegaly
Addison disease
Cushing syndrome
diabetes insipidus (DI)
goiter
Graves disease
hyperaldosteronism
hyperparathyroidism
hyperthyroidism
hypoparathyroidism
hypopituitarism
hypothyroidism
myxedema
pheochromocytoma
syndrome of inappropriate antidiuretic hormone (SIADH)
thyroid cancer
thyroiditis
thyrotoxicosis

The endocrine system is made up of several organs and glands involved in the synthesis and secretion of hormones which affect every body system. Because hormones have a wide range of action, problems with their regulation may cause homeostatic changes that can affect many aspects of a person's life. The severity varies widely. There may be adverse effects on perfusion, metabolism, skin integrity, and nutrition. Regulating fluid and electrolyte balance and temperature may be difficult. The patient may have problems with growth and fertility and reproductive processes because these are hormone dependent. There may be a wide range of psychologic responses, including anxiety and depression.

ANTERIOR PITUITARY GLAND PROBLEMS

The pituitary gland is considered the master gland of the endocrine system. The anterior pituitary gland secretes growth hormone (GH), prolactin, and 4 tropic hormones—adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH).

Fig. 54.1 Progressive development of facial changes from acromegaly. (Courtesy Linda Haas, Seattle, WA.)

These hormones affect growth, sexual maturation, reproduction, metabolism, stress response, and fluid balance. As a result, pituitary gland disorders manifest in a variety of ways.

Pituitary gland tumors account for 5% to 20% of primary intracranial tumors.[1] The most common, a pituitary adenoma, is a slow-growing, benign tumor. It often occurs in adults between 40 and 60 years of age. Hypersecretory pituitary adenomas secrete an excess of a specific hormone causing manifestations related to the action of that hormone. The most common are prolactinomas and GH- and ACTH-secreting adenomas.[1]

ACROMEGALY

Acromegaly is a rare condition characterized by an overproduction of GH. Around 3 cases per 1 million people in the United States are diagnosed annually.[2] It affects both genders equally. The mean age at the time of diagnosis is 40 to 45 years old.

Etiology and Pathophysiology

Acromegaly most often occurs because of a benign GH-secreting pituitary adenoma. The excess GH results in an overgrowth of soft tissues and bones in the hands, feet, and face. Because the problem develops after epiphyseal closure, the bones of the arms and legs do not grow longer.

Clinical Manifestations

The changes resulting from excess GH in adults can occur slowly, over many years. They may go unnoticed by the person, family, and friends. Thickening and enlargement of the bony and soft tissues on the face, feet, and head occur (Fig. 54.1). Patients may have proximal muscle weakness and joint pain that can range from mild to crippling. Carpal tunnel syndrome and peripheral neuropathy may be present.

Tongue enlargement causes dental and speech problems. The voice deepens because of hypertrophy of the vocal cords. Sleep apnea may occur because of upper airway narrowing and obstruction from increased amounts of pharyngeal soft tissues. The skin becomes thick, leathery, and oily with acne outbreaks.

Vision changes may occur from pressure on the optic nerve from a pituitary adenoma. Headaches are common. Since GH antagonizes the action of insulin, glucose intolerance and manifestations of diabetes may occur, including increased thirst and *polyuria* (increased urination).

The life expectancy of those with acromegaly is reduced by 5 to 10 years. They are prone to cardiovascular disease (CVD), diabetes, and colorectal cancer.[3] Even if patients are cured or the disease is well controlled, manifestations such as joint pain and deformities often remain.

Diagnostic Studies

In addition to the history and physical assessment, a diagnosis requires evaluating plasma insulin-like growth factor-1 (IGF-1) levels and GH response to an oral glucose tolerance test (OGTT). IGF-1 mediates the peripheral actions of GH. As GH levels rise, so do IGF-1 levels. Since GH is released in a pulsatile fashion, we need several samples to obtain an accurate assessment. Serum IGF-1 levels are more constant, giving a reliable diagnostic measure of acromegaly. During an OGTT, GH concentration normally falls because glucose inhibits GH secretion. In acromegaly, GH levels do not fall and in some cases GH levels rise.

MRI or high-resolution CT scan with contrast can detect pituitary adenomas. A complete eye examination, including visual fields, is done because a tumor may cause pressure on the optic chiasm or optic nerves.

Interprofessional and Nursing Care

The patient's prognosis depends on the age at onset, age when treatment started, and tumor size. The overall goal is to return the patient's GH levels to normal. Treatment consists of surgery, radiation therapy, drug therapy, or a combination of these. Treatment can stop bone growth and reverse tissue hypertrophy. However, sleep apnea, diabetes, and cardiac problems may persist.

Surgery (hypophysectomy) is the treatment of choice. It offers the best chance for a cure and optimal symptom management, especially for smaller pituitary tumors.[4] Surgery results in an immediate reduction in GH levels. IGF-1 levels fall within a few weeks. Patients with larger tumors or those with GH levels greater than 45 ng/mL may need adjuvant radiation or drug therapy. Surgery and radiation therapy for pituitary tumors are discussed later in this chapter.

Drug therapy is an option for patients whose surgery did not result in a cure and/or in combination with radiation therapy. The main drug used is octreotide (Sandostatin), a somatostatin analog. It reduces GH levels to normal in many patients. Octreotide is given by subcutaneous injection 3 times a week. Long-acting somatostatin analogs, octreotide (Sandostatin LAR), pasireotide (Signifor), and lanreotide SR (Somatuline Depot), are available as IM injections given every 4 weeks. GH levels are measured every 2 weeks to guide drug dosing and then every 6 months until the desired response is achieved.

Dopamine agonists (e.g., bromocriptine, cabergoline) may be given alone or with somatostatin analogs if surgery does not result in a complete remission. These drugs reduce GH secretion from the tumor.

GH antagonists (e.g., pegvisomant [Somavert]) reduce the effect of GH in the body by blocking liver production of IGF-1. Most patients taking this drug achieve normal IGF-1 levels with symptom improvement.[3]

Serial photographs showing improvement in appearance may be helpful to the patient's recovery. Psychosocial effects of acromegaly include body image problems, sexual problems, and depression. Fatigue and sleep problems may persist after surgery. Patients will need strategies for dealing with these symptoms. Referral to a support group may be helpful.

EXCESSES OF OTHER TROPIC HORMONES

Excess prolactin or tropic hormone (e.g., ACTH, TSH) secretion by the anterior pituitary gland will cause other endocrine glands to overproduce certain hormones. An excess of these hormones (discussed later in the chapter) can cause significant problems in metabolism and general health.

A prolactin-secreting adenoma is known as a *prolactinoma*. They account for about 40% of pituitary tumors.[5] Women with prolactinomas may have galactorrhea, anovulation, infertility, infrequent or absent menses, decreased libido, and hirsutism. In men, impotence, decreased sperm density, and libido may result. Compression of the optic chiasm can cause vision changes and signs of increased intracranial pressure, including headache, nausea, and vomiting.

Because prolactinomas do not typically grow, drug therapy is usually the first-line treatment. The dopamine agonists cabergoline and bromocriptine are given to block prolactin release. Surgery may be an option, depending on the extent and size of the tumor. Radiation therapy can reduce the risk for tumor recurrence for patients with large tumors.

PITUITARY GLAND HYPOFUNCTION

Hypopituitarism is a rare disorder that involves a decrease in 1 or more of the pituitary hormones. A deficiency of only 1 pituitary hormone is called *selective hypopituitarism*. Total failure of the pituitary gland results in deficiency of all pituitary hormones—a condition called *panhypopituitarism*. The most common hormone deficiencies from hypopituitarism involve GH and gonadotropins (e.g., LH, FSH).

Etiology and Pathophysiology

The usual cause of pituitary hypofunction is a pituitary tumor. Autoimmune disorders, infections, pituitary infarction (Sheehan syndrome), or destruction of the pituitary gland (from trauma, radiation, surgery) can also cause hypopituitarism. The incidence varies among populations, with a higher mortality in women.

Anterior pituitary hormone deficiencies can lead to end-organ failure. TSH and ACTH deficiencies are life threatening. ACTH deficiency can lead to acute adrenal insufficiency and hypovolemic shock from sodium and water depletion.

Clinical Manifestations and Diagnostic Studies

The manifestations vary with the type and degree of dysfunction. Early manifestations of a space-occupying lesion include headaches, vision changes (decreased visual acuity, decreased peripheral vision), loss of smell, nausea and vomiting, and seizures. Manifestations associated with hyposecretion of the target glands vary widely (Table 54.1).

TABLE 54.1 Manifestations of Hypopituitarism

Hormone Deficiency	Manifestations
Adrenocorticotropic hormone (ACTH)	Involves cortisol deficiency: weakness, fatigue, headache, dry and pale skin, ↓axillary and pubic hair, ↓ resistance to infection, fasting hypoglycemia
Follicle-stimulating hormone (FSH) and luteinizing hormone (LH)	*Women:* Menstrual irregularities, loss of libido, changes in secondary sex characteristics (e.g., ↓ breast size) *Men:* Testicular atrophy, ↓ spermatogenesis, loss of libido, impotence, ↓ facial hair and muscle mass
Growth hormone (GH)	Subtle, nonspecific findings: truncal obesity, osteoporosis, ↓ muscle mass and strength, weakness, fatigue, depression, or flat affect
Thyroid-stimulating hormone (TSH)	Mild form of primary hypothyroidism: fatigue, cold intolerance, constipation, lethargy, weight gain

In addition to a history and physical assessment, diagnostic studies such as MRI and CT can identify a pituitary tumor. Laboratory tests generally involve the direct measurement of pituitary hormones (e.g., TSH) or an indirect determination of the target organ hormones (e.g., triiodothyronine [T_3], thyroxine [T_4]). See Chapter 52 for more information about diagnostic studies.

Interprofessional and Nursing Care

The treatment for hypopituitarism often consists of surgery or radiation therapy followed by lifelong hormone therapy. Surgery and radiation therapy for pituitary tumors are discussed in the next section. Appropriate hormone therapy is used (e.g., corticosteroids, thyroid hormone). Hormone therapies for thyroid hormone and corticosteroids are discussed later in this chapter.

Somatropin (Genotropin, Humatrope, Omnitrope) is recombinant human GH. It is used for long-term hormone therapy in adults with GH deficiency. These patients respond well to GH replacement. They have increased energy, increased lean body mass, a feeling of well-being, and improved body image. Side effects include fluid retention with swelling in the feet and hands, muscle and joint pain, and headache. GH is given daily as a subcutaneous injection, preferably in the evening. The dosing is variable and adjusted based on symptoms, IGF-1 levels, and side effects.

Although gonadal deficiency is not life threatening, hormone therapy will improve sexual function and general well-being. It is contraindicated in those with certain medical conditions, such as phlebitis, pulmonary embolism, breast cancer, and prostate cancer. Estrogen and progesterone replacement therapy may be given to hypogonadal women to treat hot flashes, vaginal dryness, and decreased libido (see Chapter 58). Testosterone is used to treat men with gonadotropin deficiency. The benefits of testosterone therapy include a return of male secondary sex characteristics, improved libido, and increased muscle mass, bone mass, and bone density. Hormone therapy for men is discussed in Chapter 59.

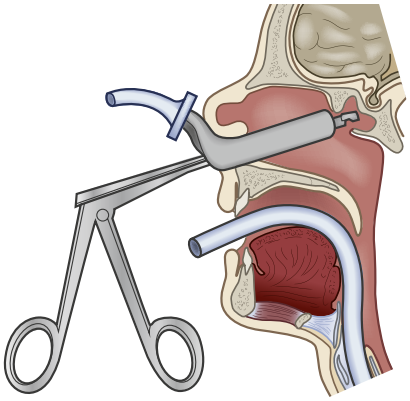

Fig. 54.2 Surgery on the pituitary gland is most often done by a transsphenoidal approach. An incision is made in the inner aspect of the upper lip and gingiva. The sella turcica is entered through the floor of the nose and sphenoid sinuses.

PITUITARY SURGERY

A *hypophysectomy* is the surgical removal of the pituitary gland. It is the treatment of choice for tumors in the pituitary area, especially smaller pituitary adenomas. Most surgeries are done by an endoscopic *transsphenoidal* approach (Fig. 54.2). When the entire pituitary gland is removed, there is permanent loss of all pituitary hormones. The patient will need lifelong replacement therapy of thyroid hormone, sex hormones, and glucocorticoids.[6]

Radiation therapy can reduce the size of a tumor before surgery. It is also used when surgery does not produce a cure or when patients are not candidates for surgery. The full effects may take months to years. Radiation therapy may lead to hypopituitarism, which then requires lifelong hormone replacement therapy. Stereotactic radiosurgery (Gamma Knife surgery, proton beam, linear accelerator) is an option for small, surgically inaccessible pituitary tumors or in place of conventional radiation.

❖ NURSING MANAGEMENT: PITUITARY SURGERY

After surgery, assess the patient for the presence of a hematoma compressing the optic nerve or optic chiasma. Monitor peripheral vision, visual acuity, extraocular movements, and pupillary response. Report changes at once. Prompt intervention may prevent vision changes from becoming permanent (Table 54.2).

Cerebrospinal fluid (CSF) leaks and nosebleeds are other common complications after surgery. The HCP may place a petroleum jelly–coated ribbon of gauze or a balloon-tipped catheter (like an indwelling urinary catheter) in the sphenoid sinus. It is usually removed after 24 hours. It can be left in for 2 to 3 days if there is concern for bleeding or CSF leak. The patient must not blow the nose for at least 48 hours after surgery. They need to avoid vigorous coughing, sneezing, and straining at stool.

Monitor the "moustache" dressing regularly for any drainage. Check any clear drainage with a urine dipstick for glucose and protein. If present, notify the HCP of a possible CSF leak. A sample can be sent to the laboratory. A glucose level greater than 30 mg/dL (1.67 mmol/L) indicates CSF leakage from an open connection with the brain. If this happens, the patient is at increased risk for meningitis.

A persistent and severe generalized or supraorbital headache may indicate CSF leakage into the sinuses. A CSF leak usually resolves within 72 hours when treated with head elevation and bed rest. If the leak persists, daily spinal taps can reduce pressure to below-normal levels.

Keep the head of the bed elevated at a 30-degree angle. This avoids pressure on the sella turcica and decreases headaches. Monitor pupillary response, speech patterns, and extremity strength to detect neurologic complications. Gentle mouth care every 4 hours keeps the surgical site clean and free of debris. Have the patient avoid brushing their teeth for at least 10 days to protect the suture line.

Fluid and electrolyte problems can occur if diabetes insipidus (DI) develops.[7] Transient DI may occur because of the loss of antidiuretic hormone (ADH), which is stored in the posterior lobe of the pituitary gland, or cerebral edema from manipulation of the pituitary during surgery. DI may be permanent after surgery. To assess for DI, monitor urine output and measure specific gravity. Report a urine output of more than 200 mL/hr for more than 3 consecutive hours or a specific gravity level of less than 1.005. Patients with DI will have a high serum sodium and extreme thirst. We treat DI by giving desmopressin acetate (DDAVP). Fluid replacement may be needed to avoid hypovolemia from high urine output.

Syndrome of inappropriate antidiuretic hormone secretion (SIADH) can occur after any intracranial surgery. SIADH typically occurs later than DI, usually around the 4th postoperative day. It may occur due to manipulation of the pituitary and other structures causing release of ADH. The fluid retention caused

TABLE 54.2 NURSING MANAGEMENT

Care of the Patient After Pituitary Surgery

- Monitor vital signs. Assess peripheral pulses and watch for orthostatic hypotension.
- Monitor neurologic and cognitive status (e.g., level of consciousness, orientation, speech) hourly for the first 24 h and then every 4 h.
- Assess extremity strength and reflexes.
- Monitor field of vision, visual acuity, extraocular movements, and pupillary response. Notify HCP of any changes.
- Assess dressing for type and amount of drainage. Notify HCP for excessive bleeding or CSF drainage.
- Maintain strict intake and output and monitor fluid balance. Assess for DI or SIADH.
- Keep head of bed elevated at least 30 degrees.
- Encourage deep-breathing exercises and incentive spirometer use.
- Monitor for pain and give analgesic medications as prescribed.
- Encourage high-fiber diet to decrease risk for constipation.
- Perform oral care every 4 hr.
- Teach the patient to:
  - Avoid vigorous coughing, sneezing, and blowing the nose
  - Avoid bending over at the waist or straining at stool (Valsalva maneuver) due to risk for increased intracranial pressure
  - Avoid use of toothbrushes until incision heals
  - Follow replacement hormone therapy plan

PATHOPHYSIOLOGY MAP

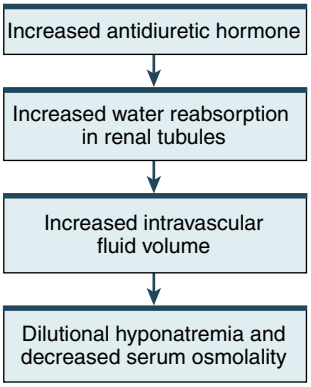

Fig. 54.3 Pathophysiology of SIADH. (Modified from Urden LD, Stacy KM, Lough ME: *Critical care nursing: diagnosis and management,* ed 6, St Louis, 2010, Mosby.)

by circulating ADH leads to dilutional hyponatremia. Sodium levels of less than 125 mEq/L will present as headache, vomiting, and decreased level of consciousness. DI and SIADH are discussed in the next section.

The patient needs lifelong ADH, cortisol, and thyroid hormone replacement after a hypophysectomy. Surgery may result in permanent loss or deficiencies in FSH and LH. This can lead to decreased fertility. Assist the patient in working through the grieving process associated with these losses.

POSTERIOR PITUITARY GLAND PROBLEMS

The hormones secreted by the posterior pituitary are ADH and oxytocin. ADH, also called *arginine vasopressin* (AVP) or vasopressin, has a key role in regulating water balance and serum osmolarity (see Chapter 52). The main problems result from either overproduction or underproduction of ADH.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE

Etiology and Pathophysiology

Syndrome of inappropriate antidiuretic hormone (SIADH) results from an overproduction of ADH or the release of ADH despite normal or low plasma osmolarity (Fig. 54.3). ADH increases the permeability of the renal distal tubule and collecting duct, which leads to the reabsorption of water into the circulation. Extracellular fluid volume expands, plasma osmolality declines, glomerular filtration rate increases, and sodium levels decline (dilutional hyponatremia). Thus features of SIADH are fluid retention, serum hypoosmolality, dilutional hyponatremia, hypochloremia, and concentrated urine in the presence of normal or increased intravascular volume.

SIADH occurs more often in older adults. The most common cause is cancer, especially small cell lung cancer (Table 54.3). SIADH tends to be self-limiting when caused by head trauma or drugs. It can be chronic when caused by tumors or metabolic diseases.

TABLE 54.3 Causes of SIADH

Cancer
- Colorectal cancer
- Lymphoid cancers (Hodgkin lymphoma, non-Hodgkin lymphoma, lymphocytic leukemia)
- Pancreatic cancer
- Prostate cancer
- Small cell lung cancer
- Thymus cancer

CNS Disorders
- Brain tumors
- Cerebral atrophy
- Guillain-Barré syndrome
- Head injury (skull fracture, subdural hematoma, subarachnoid hemorrhage)
- Infection (encephalitis, meningitis)
- Stroke
- Systemic lupus erythematosus

Drug Therapy
- Carbamazepine (Tegretol)
- Chemotherapy agents (vincristine, vinblastine, cyclophosphamide)
- General anesthesia agents
- Opioids
- Oxytocin
- Thiazide diuretics
- Selective serotonin reuptake inhibitor (SSRI) antidepressants
- Tricyclic antidepressants

Miscellaneous Conditions
- Adrenal insufficiency
- COPD
- HIV
- Hypothyroidism
- Lung infection (pneumonia, tuberculosis, lung abscess)
- Positive pressure mechanical ventilation

Clinical Manifestations and Diagnostic Studies

The patient with SIADH has low urine output and increased body weight. At first, the patient has thirst, dyspnea on exertion, and fatigue. Mild hyponatremia causes muscle cramping, irritability, and headache. As the serum sodium level falls (usually below 120 mEq/L [120 mmol/L]), manifestations become more severe and include vomiting, abdominal cramps, and muscle twitching. As plasma osmolality and serum sodium levels continue to decline, cerebral edema may occur, leading to lethargy, confusion, seizures, and coma.

The diagnosis is made by simultaneous measurements of urine and serum osmolality. Dilutional hyponatremia is indicated by a serum sodium less than 135 mEq/L, serum osmolality less than 280 mOsm/kg (280 mmol/kg), and urine specific gravity greater than 1.030. A serum osmolality much lower than the urine osmolality shows the body is inappropriately excreting concentrated urine in the presence of dilute serum.

Interprofessional and Nursing Care

When assessing patients at risk and those who have confirmed SIADH, be alert for low urine output with a high specific gravity, a sudden weight gain without edema, or a decreased serum

sodium level. Monitor intake and output, vital signs, and heart and lung sounds. Obtain daily weights. Observe for signs of hyponatremia, including seizures, headache, vomiting, and decreased neurologic function.

Treatment is directed at the underlying cause.[8] Medications that stimulate ADH release should be avoided or discontinued (Table 54.3). If symptoms are mild and serum sodium is greater than 125 mEq/L (125 mmol/L), the only treatment may be a fluid restriction of 800 to 1000 mL/day. This restriction should result in weight loss and a gradual rise in serum sodium concentration and osmolality. An improvement in symptoms should accompany normalization of serum sodium and osmolality. Provide the patient with frequent oral care and distractions to decrease discomfort related to thirst from the fluid restriction.

A loop diuretic, such as furosemide (Lasix), may be used to promote diuresis. Since loop diuretics cause sodium loss, the serum sodium must be at least 125 mEq/L (125 mmol/L). Because furosemide increases potassium, calcium, and magnesium loss, the patient may need supplements. Demeclocycline also may be given. It blocks the effect of ADH on the renal tubules, resulting in more dilute urine.

Initiate seizure and fall precautions if the patient has an altered sensorium or is having seizures. Keep the head of the bed flat or elevated no more than 10 degrees. This promotes venous return to the heart and increases left atrial filling pressure, thus reducing ADH release. Frequent turning, positioning, and range-of-motion exercises are important to maintain skin integrity and joint mobility.

In cases of severe hyponatremia (less than 120 mEq/L), especially in the presence of neurologic manifestations, such as seizures, small amounts of IV hypertonic saline solution (3% sodium chloride) may be given. We must correct hyponatremia slowly. The level should not increase by more than 8 to 12 mEq/L in the first 24 hours. Quickly increasing levels can cause osmotic demyelination syndrome with permanent damage to nerve cells in the brain. A fluid restriction of 500 mL/day may be needed for those with severe hyponatremia.

Vasopressor receptor antagonists block the activity of ADH. They are used to treat euvolemic hyponatremia in hospitalized patients. Two drugs are approved for use in the United States: conivaptan (Vaprisol) and tolvaptan (Samsca). Conivaptan is given IV; tolvaptan is given orally. Neither should be given to patients with liver disease because they worsen liver function.

Help the patient with chronic SIADH to self-manage their treatment. In chronic SIADH, a fluid restriction of 800 to 1000 mL/day is recommended. Ice chips or sugarless chewing gum help decrease thirst. Teach them to supplement the diet with sodium and potassium, especially if taking loop diuretics. Have the patient obtain a daily weight to monitor changes in fluid balance. Teach the patient the symptoms of fluid and electrolyte imbalances, especially those involving sodium and potassium (see Chapter 17).

DIABETES INSIPIDUS

Etiology and Pathophysiology

Diabetes insipidus (DI) is caused by deficient production or secretion of ADH or a decreased renal response to ADH.[9] The decrease in ADH results in fluid and electrolyte imbalances caused by increased urine output and increased plasma osmolality (Fig. 54.4). Depending on the cause, DI may be transient or a chronic, lifelong condition. There are several types of DI (Table 54.4). Central DI is the most common form.

PATHOPHYSIOLOGY MAP

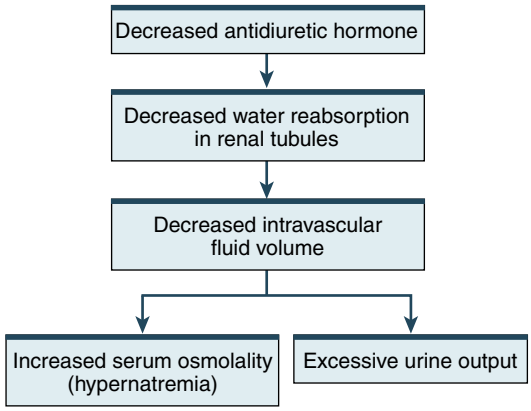

Fig. 54.4 Pathophysiology of diabetes insipidus.

TABLE 54.4 Types of Diabetes Insipidus

Type	Cause
Central (neurogenic) DI	Interference with ADH synthesis, transport, or release *Examples:* Brain tumor, head injury, brain surgery, CNS infections
Nephrogenic DI	Inadequate renal response to ADH despite presence of adequate ADH *Examples:* Drug therapy (especially lithium), renal damage, hereditary renal disease
Primary DI	Excess water intake *Examples:* Structural lesion in thirst center, psychologic disorder

Clinical Manifestations

Key features of DI are polydipsia and polyuria. The patient excretes large quantities of urine (2 to 20 L/day) with a very low specific gravity (less than 1.005) and urine osmolality of less than 100 mOsm/kg (100 mmol/kg). Serum osmolality is increased (usually greater than 295 mOsm/kg [295 mmol/kg]) because of hypernatremia (serum sodium greater than 145 mg/dL) from pure water loss in the kidneys. Most patients compensate for fluid loss by drinking large amounts of water so that serum osmolality stays normal or is somewhat increased. The patient may be tired from nocturia and have generalized weakness. Uncorrected hypernatremia can cause brain shrinkage and intracranial bleeding.

The onset of central DI is usually acute and accompanied by excess fluid loss. After intracranial surgery, central DI has a triphasic pattern: (1) an acute phase with an abrupt onset of polyuria, (2) an interphase in which urine volume normalizes, and (3) a third phase in which central DI may become permanent. The third phase occurs 10 to 14 days after surgery. Central DI

from head trauma is often self-limiting. It improves with treatment of the underlying problem. Although the manifestations of nephrogenic DI are like those of central DI, the onset and amount of fluid loss are less dramatic.

Severe dehydration can result if oral intake cannot keep up with urinary losses. The patient will have hypotension, tachycardia, and hypovolemic shock. Increasing serum osmolality and hypernatremia can cause central nervous system (CNS) manifestations, ranging from irritability and mental dullness to coma.

Diagnostic Studies

Patients with DI excrete dilute urine at a rate greater than 200 mL/h with a specific gravity of less than 1.005. We diagnose central DI with a water deprivation test. Before the test, we measure body weight, and urine osmolality, volume, and specific gravity. The patient is deprived of water for 8 to 12 hours and then given DDAVP subcutaneously or nasally. Patients with central DI have a dramatic increase in urine osmolality (from 100 to 600 mOsm/kg) and a significant decrease in urine volume. The patient with nephrogenic DI will not be able to increase urine osmolality to greater than 300 mOsm/kg.

Another test to distinguish central DI from nephrogenic DI is to measure the ADH level after giving an analog of ADH (e.g., desmopressin). If the cause is central DI, the kidneys will respond to the hormone by concentrating urine. If the kidneys do not respond in this way, the cause is nephrogenic.

Interprofessional and Nursing Care

Management of DI includes early detection, maintaining adequate hydration, and patient teaching for self-management. A clinical goal is maintaining fluid and electrolyte balance.

For central DI, fluid and hormone therapy are the cornerstone of treatment. We replace fluids orally or IV, depending on the patient's condition and ability to drink copious amounts. In acute DI, IV hypotonic saline or dextrose 5% in water (D_5W) is given and titrated to replace urine output. If IV glucose solutions are used, monitor serum glucose levels. Hyperglycemia and glycosuria can lead to osmotic diuresis, which increases the fluid volume deficit. Monitor BP, heart rate, urine output, level of consciousness, and specific gravity. They may be done hourly in the acutely ill patient. Assess for signs of acute dehydration. Maintain an accurate record of intake and output and daily weights to determine fluid volume status. Adjustments in fluid replacement should be made accordingly.

DDAVP, an analog of ADH, is the hormone replacement of choice for central DI. Another ADH replacement drug is aqueous vasopressin. DDAVP can be given orally, IV, subcutaneously, or as a nasal spray. Assess the response to DDAVP by monitoring pulse, BP, level of consciousness, intake and output, and specific gravity. Medications such as carbamazepine (Tegretol) can help decrease thirst associated with central DI.

Because the kidney is unable to respond to ADH in nephrogenic DI, hormone therapy has little effect. Instead, the treatment includes a low-sodium diet and thiazide diuretics (e.g., chlorothiazide), which may reduce flow to the ADH-sensitive distal nephrons. Limiting sodium intake to no more than 3 g/day often helps decrease urine output. If a low-sodium diet and thiazide drugs are not effective, indomethacin may be prescribed. It is a nonsteroidal antiinflammatory drug (NSAID) that helps increase renal responsiveness to ADH.

THYROID GLAND PROBLEMS

Thyroid gland problems are among the most common endocrine disorders. The thyroid hormones T_4 and T_3 regulate energy metabolism and growth and development. Thyroid gland problems include goiter, benign and malignant nodules, inflammatory conditions leading to hyperthyroidism, and hypothyroidism (Fig. 54.5).

GOITER

A **goiter** is an enlarged thyroid gland. The person may have an overactive thyroid (hyperthyroidism) or an underactive thyroid (hypothyroidism). The most common cause of goiter worldwide is a lack of diet iodine. In the United States, where most people use iodized salt, goiter is more often due to the overproduction or underproduction of thyroid hormones or to nodules that develop in the thyroid gland. *Goitrogens* (foods or drugs that contain thyroid-inhibiting substances) can cause a goiter (Table 54.5).

A nontoxic goiter is a diffuse enlargement of the thyroid gland that does not result from cancer or inflammation. The thyroid hormone levels are normal. *Nodular goiters* are thyroid hormone–secreting nodules. They function independently of TSH stimulation. There may be multiple nodules (multinodular goiter) or a single nodule (solitary autonomous nodule). The nodules are usually benign follicular adenomas. If these nodules cause hyperthyroidism, they are called *toxic nodular goiters.*[10] This type of goiter is often found in patients with Graves disease

Fig. 54.6 Goiter. (From Iyomasa RM, Tagliarini JV, Rodrigues SA, et al.: Laryngeal and vocal alterations after thyroidectomy, *Braz J Otorhinolaryngol* 85:3, 2019.)

(Fig. 54.6). Toxic nodular goiters occur equally in men and women. Although they can appear at any age, they most often occur in people over 40 years of age.

We measure TSH and T_4 levels to determine whether a goiter is associated with normal thyroid function, hyperthyroidism, or hypothyroidism. Thyroid antibodies (e.g., thyroid peroxidase [TPO] antibody) show the presence of *thyroiditis* (inflammation of the thyroid). Treatment with thyroid hormone may prevent further thyroid enlargement. Surgery can remove large goiters. Goiter as a manifestation of thyroid disorders is discussed in the next sections.

THYROIDITIS

Thyroiditis, an inflammation of the thyroid gland, encompasses several clinical disorders. It is a frequent cause of goiter. We think that *subacute granulomatous thyroiditis* is caused by a viral infection. *Acute thyroiditis* is due to bacterial or fungal infection. Subacute and acute forms of thyroiditis have an abrupt onset. The patient reports pain in the thyroid area or radiating to the throat, ears, or jaw. Systemic manifestations include fever, chills, sweats, and fatigue.

Hashimoto thyroiditis (chronic autoimmune thyroiditis) is caused by the destruction of thyroid tissue by antibodies.[11] It is the most common cause of hypothyroid goiters in the United States. Risk factors include female gender, a family history, older age, and White ethnicity. The goiter, which is the hallmark of Hashimoto thyroiditis, may develop gradually or rapidly. If it enlarges rapidly, it may compress structures in the neck (e.g., trachea, laryngeal nerves), changing the voice and affecting breathing. As antibodies destroy thyroid tissue, there may be a transient phase of hyperthyroidism due to leaking thyroid hormone from the damaged tissues.

Silent, painless thyroiditis, which may be early Hashimoto thyroiditis, can occur in postpartum women. This condition is usually seen in the first 6 months after delivery. It may be due to an autoimmune reaction to fetal cells in the mother's thyroid gland.

At first, T_4 and T_3 levels increase in subacute, acute, and silent thyroiditis. They decrease with time. Suppressed radioactive iodine uptake (RAIU) occurs in subacute and silent thyroiditis. In Hashimoto thyroiditis, T_4 and T_3 levels are usually low and the TSH level is high. Antithyroid antibodies are present in Hashimoto thyroiditis.

Recovery from acute or subacute thyroiditis may be complete in weeks or months without any treatment. If the cause is bacterial, treatment may include antibiotics or surgical drainage. In the subacute and acute forms, NSAIDs (e.g., aspirin, naproxen) can relieve symptoms. With more severe pain, corticosteroids (e.g., prednisone up to 40 mg/day) can relieve discomfort. Propranolol (Inderal) or atenolol (Tenormin) may relieve cardiovascular symptoms related to a hyperthyroid state. The patient who is hypothyroid needs thyroid hormone therapy.

Nursing care includes patient teaching about the disease process and treatment. Teach the patient not to stop medications abruptly. Tell the patient to remain under close health care supervision so that progress can be monitored. Teach the patient to report to the HCP any change in symptoms, such as trouble breathing or swallowing, swelling to face and extremities, or rapid weight gain or loss. Those receiving thyroid hormone need to know the expected side effects and ways to manage them.

The patient with Hashimoto thyroiditis is at risk for other autoimmune diseases, such as Addison disease, pernicious anemia, or Graves disease. Teach the patient the signs and symptoms of these disorders, especially Addison disease.

HYPERTHYROIDISM

Hyperthyroidism is hyperactivity of the thyroid gland with sustained increase in synthesis and release of thyroid hormones.[12] It occurs in women more than men, with the highest frequency in persons 20 to 40 years old (Box 54.1). The most common form is Graves disease. Other causes include toxic nodular goiter, thyroiditis, excess iodine intake, pituitary tumors, and thyroid cancer. Since hyperthyroidism may be caused by iodinated contrast media used in CT scans and other radiologic studies, monitor those who are at risk closely after iodinated contrast media exposure.

Thyrotoxicosis refers to the physiologic effects or clinical syndrome of hypermetabolism resulting from excess circulating levels of T_4, T_3, or both. Hyperthyroidism and thyrotoxicosis usually occur together. Subclinical hyperthyroidism occurs when the patient has a serum TSH level below 0.4 mU/L but normal T_4 and T_3 levels. Overt hyperthyroidism is defined by low or undetectable TSH and increased T_4 and T_3 levels. The patient may or may not have symptoms of hyperthyroidism.

Etiology and Pathophysiology

Graves disease is an autoimmune disease characterized by thyroid enlargement and excess thyroid hormone secretion. It accounts for 75% of the cases of hyperthyroidism. We do not

BOX 54.1 BIOLOGIC SEX CONSIDERATIONS

Endocrine Problems

Men
- Ectopic ACTH production is more common.

Women
- Thyroid disorders are more common.
- Graves disease affects 5 times more women.
- Thyroid nodules and thyroid cancer affect up to 4 times as many women.
- Hyperparathyroidism affects twice as many women.
- Cushing disease and primary hyperaldosteronism are more common.

know the exact cause. Risk factors, such as a lack of iodine, smoking, infection, and stress, may interact with genetic factors to cause Graves disease.

In Graves disease, the patient develops antibodies to TSH receptors. These antibodies attach to the receptors and stimulate the thyroid gland to release T_3, T_4, or both. Excess thyroid hormones lead to the manifestations of thyrotoxicosis. Remissions and exacerbations occur, with or without treatment. It may progress to destruction of the thyroid tissue, causing hypothyroidism. Graves disease is associated with the presence of other autoimmune disorders, including rheumatoid arthritis, pernicious anemia, systemic lupus erythematosus, Addison disease, celiac disease, and vitiligo.

Clinical Manifestations

The manifestations are related to the effect of excess circulating thyroid hormones. They directly increase metabolism and tissue sensitivity to sympathetic nervous system stimulation.

Palpation of the thyroid gland may reveal a goiter. When the thyroid gland is excessively large, you may be able to see a goiter (Fig. 54.6). Auscultating the thyroid gland may reveal bruits from the increased blood supply. Another common finding is *ophthalmopathy,* a term used to describe abnormal eye appearance or function. A classic finding in Graves disease is *exophthalmos*, a protrusion of the eyeballs from the orbits (see Fig. 22.9). Exophthalmos results from increased fat deposits and fluid (edema) in the orbital tissues and ocular muscles. The increased pressure forces the eyeballs outward. The upper lids are usually retracted and elevated, with the sclera visible above the iris. When the eyelids do not close completely, the exposed corneal surfaces become dry and irritated. Corneal ulcers and loss of vision can occur. Changes in the ocular muscles result in muscle weakness, causing diplopia.

Other manifestations are outlined in Table 54.6. Abnormal laboratory findings are shown in Table 54.7. A patient in the early stages of hyperthyroidism may only have weight loss and increased nervousness. *Acropachy* (clubbing of the digits) may occur with advanced disease (Fig. 54.7). Manifestations (e.g., palpitations, tremors, weight loss) in older adults do not differ significantly from those of younger adults (Table 54.8). In older patients who are confused and agitated, we may suspect dementia and delay the diagnosis.

Complications

Acute thyrotoxicosis (thyrotoxic crisis or *thyroid storm)* is an acute, severe, rare condition that occurs when excess amounts of thyroid hormones are released into the circulation. Although considered a life-threatening emergency, death is rare when treatment is started early. We think that it results from stressors (e.g., infection, trauma, surgery) in a patient with preexisting hyperthyroidism. Patients having a thyroidectomy are at risk because manipulation of the hyperactive thyroid gland results in the increased release of hormones.

In acute thyrotoxicosis, all the symptoms of hyperthyroidism are prominent and severe. Manifestations include severe tachycardia, heart failure, shock, hyperthermia (up to 106°F [41.1°C]), agitation, delirium, seizures, abdominal pain, vomiting, diarrhea, and coma.

Diagnostic Studies

The primary laboratory findings used to confirm the diagnosis of hyperthyroidism are low or undetectable TSH levels (<0.4 mU/L) and increased free T_4 levels. Total T_3 and T_4 levels may be assessed, but they are not as definitive. Total T_3 and T_4 determine both free and bound (to protein) hormone levels. The free hormone is the only biologically active form of these hormones.

The RAIU test can distinguish Graves disease from other forms of thyroiditis. The patient with Graves disease shows a diffuse, homogeneous uptake of 35% to 95%, while the patient with thyroiditis shows an uptake of less than 2%. The person with a nodular goiter has an uptake in the high normal range.

Interprofessional Care

The goals of care are to block the adverse effects of excess thyroid hormone, suppress oversecretion of thyroid hormone, and prevent complications.[13] There are several treatment options. They include antithyroid medications, radioactive iodine (RAI) therapy, and surgery (Table 54.9). Supportive therapy is aimed at managing respiratory distress, reducing fever, replacing fluid, and eliminating or managing the initiating stressor(s).

The choice of treatment is influenced by the patient's age and preferences, coexistence of other diseases, and pregnancy status.

Drug Therapy

Drugs used to treat hyperthyroidism include antithyroid drugs, iodine, and β-adrenergic blockers. These drugs are useful in treating thyrotoxic states but are not curative. Radiation therapy or surgery may be needed.

Antithyroid drugs. The first-line antithyroid drugs are propylthiouracil and methimazole (Tapazole). These drugs inhibit thyroid hormone synthesis. Reasons for use include Graves disease in the young patient, hyperthyroidism during pregnancy, and the need to achieve a euthyroid state before surgery or radiation therapy. Propylthiouracil is generally used for patients who are in the first trimester of pregnancy, had an adverse reaction to methimazole, or need a rapid reduction in symptoms. It is the first line therapy in thyrotoxicosis since it blocks the peripheral conversion of T_4 to T_3. An advantage of propylthiouracil is that it achieves the therapeutic goal of being euthyroid more quickly.

TABLE 54.6 Manifestations of Thyroid Problems

Hyperfunction	Hypofunction
Cardiovascular System	
• ↑ BP	• ↑ Capillary fragility
• ↑ Rate and force of cardiac contractions	• ↓ Rate and force of contractions
• Bounding, rapid pulse	• Varied changes in BP
• ↑ Cardiac output	• Cardiac hypertrophy
• Systolic murmurs	• Distant heart sounds
• Dysrhythmias	• Anemia
• Palpitations	• Heart failure
• Angina	• Angina
GI System	
• ↑ Appetite, thirst	• ↓ Appetite
• Weight loss	• Weight gain
• ↑ Peristalsis	• Nausea and vomiting
• Diarrhea, frequent defecation	• Constipation
• ↑ Bowel sounds	• Distended abdomen
• Splenomegaly	• Enlarged, scaly tongue
• Hepatomegaly	• Celiac disease
Musculoskeletal System	
• Fatigue	• Fatigue
• Weakness	• Weakness
• Proximal muscle wasting	• Muscular aches and pains
• Dependent edema	• Slow movements
• Osteoporosis	• Arthralgia
Nervous System	
• Hyperactive deep-tendon reflexes	• Prolonged relaxation of deep tendon reflexes
• Depression	• Anxiety, depression
• Lack of ability to concentrate	• Slowed mental processes
• Rapid speech	• Slow, slurred speech
• Insomnia	• Sleepiness
• Difficulty focusing eyes	• Apathy
• Nervousness	• Lethargy
• Fine tremor of fingers and tongue	• Forgetfulness
• Lability of mood, delirium	• Hoarseness
• Restlessness	• Stupor, coma
• Personality changes of irritability, agitation	• Paresthesias
• Stupor, coma	

Hyperfunction	Hypofunction
Reproductive System	
• Menstrual irregularities	• Prolonged menstrual periods or amenorrhea
• Amenorrhea	• ↓ Libido
• ↓ Libido	• Infertility
• ↓ Fertility	
• Impotence and gynecomastia in men	
Respiratory	
• Dyspnea on mild exertion	• Dyspnea
• ↑ Respiratory rate	• ↓ Breathing capacity
Skin	
• Warm, smooth, moist skin	• Dry, thick, inelastic, cold skin
• Thin, brittle nails detached from nail bed (onycholysis)	• Thick, brittle nails
• Hair loss (may be patchy)	• Dry, sparse, coarse hair
• Clubbing of fingers (thyroid acropachy) (Fig. 54.7)	• Poor turgor of mucosa
• Palmar erythema	• Generalized interstitial edema
• Fine, silky hair	• Puffy face
• Premature graying (in men)	• ↓ Sweating
• Diaphoresis	• Pallor
• Vitiligo	
• Pretibial myxedema (infiltrative dermopathy)	
Other	
• Goiter (Fig. 54.6)	• Goiter
• Intolerance to heat	• Hearing problems
• Lid lag, stare	• Intolerance to cold
• Eyelid retraction	• ↑ Risk for infection
• Exophthalmos	• ↑ Sensitivity to opioids, barbiturates, anesthesia
• ↑ Temperature	

However, it must be taken 3 times per day. Methimazole is given in a single daily dose.

Improvement usually begins 1 to 2 weeks after the start of drug therapy. We usually see results within 4 to 8 weeks. Therapy is usually continued for 6 to 15 months to allow for spontaneous remission, which occurs in 20% to 40% of patients. Teach the patient the importance of adhering to the drug plan. Abruptly stopping drug therapy can result in a return of hyperthyroidism.

Iodine. Iodine is available as saturated solution of potassium iodine (SSKI) and Lugol solution. Iodine is used with other antithyroid drugs to prepare the patient for thyroidectomy or for treatment of thyrotoxicosis. Quickly giving large doses of iodine inhibits T_3 and T_4 synthesis and blocks the release of these hormones into circulation. It decreases the vascularity of the thyroid gland, making surgery safer and easier. The maximal effect usually occurs within 1 to 2 weeks. Because of a reduction in the therapeutic effect, long-term iodine therapy is not effective in controlling hyperthyroidism.

Iodine is mixed with water or juice and given after meals. Sipping it through a straw decreases the chance of it staining the teeth. Assess the patient for signs of iodine toxicity, such as swelling of the buccal mucosa and other mucous membranes, excess salivation, nausea and vomiting, and skin reactions. If toxicity occurs, stop administering iodine and notify the HCP.

β-Adrenergic blockers. β-Adrenergic blockers are used for symptomatic relief of thyrotoxicosis. They block the effects of sympathetic nervous stimulation, thereby decreasing tachycardia, nervousness, irritability, and tremors. Propranolol is usually given with antithyroid agents. Atenolol is the preferred

TABLE 54.7 Laboratory Results for Hyperthyroid and Hypothyroid Patients

Test	Hyperthyroid	HYPOTHYROID	
		Primary	Secondary
Thyroid-stimulating hormone (TSH)	↓	↑	↓
T_4 (thyroxine)	↑	↓	↓

Hyperthyroidism

Diagnostic Assessment
- History and physical assessment
- Ophthalmologic examination
- ECG
- Laboratory tests
  - TSH levels, serum free T_4
  - Thyroid antibodies (e.g., thyroid peroxidase [TPO] antibody)
  - Total serum T_3 and T_4
- Radioactive iodine uptake (RAIU)

Management

Drug Therapy
- Antithyroid drugs
  - Methimazole (Tapazole)
  - Propylthiouracil
- Iodine (SSKI)

Radiation Therapy
- Radioactive iodine

Surgical Therapy
- Subtotal thyroidectomy

Nutrition Therapy
- High-calorie, high-protein diet
- Frequent meals

β-adrenergic blocker for use in the hyperthyroid patient with asthma or heart disease.

Radioactive Iodine Therapy

RAI therapy is the treatment of choice for most nonpregnant adults. RAI damages or destroys thyroid tissue, thus limiting thyroid hormone secretion. RAI has a delayed response. The maximum effect may not be seen for up to 3 months. For this reason, the patient is usually treated with antithyroid drugs and propranolol before and for 3 months after starting RAI until the effects of radiation become apparent. Although RAI is usually effective, 80% of patients have posttreatment hypothyroidism, resulting in the need for lifelong thyroid hormone therapy. Teach the patient the symptoms of hypothyroidism and to seek medical help if these symptoms occur.

RAI therapy is usually given on an outpatient basis. A pregnancy test is done before starting therapy for all women who have menstrual cycles. Tell the patient that radiation thyroiditis and parotitis are possible and may cause dryness and irritation of the mouth and throat. Relief may be obtained with frequent sips of water, ice chips, or a salt and soda gargle 3 or 4 times per day. Make this gargle by dissolving 1 tsp of salt and 1 tsp of baking soda in 2 cups of warm water. The discomfort should subside in 3 to 4 days. A mixture of antacid (Mylanta or Maalox), diphenhydramine, and viscous lidocaine can be used to swish and spit, increasing patient comfort when eating.

To limit radiation exposure to others, teach the patient receiving RAI home precautions. These include (1) using private toilet facilities, if possible; (2) flushing 2 or 3 times after each use; (3) separately laundering towels, bed linens, and clothes daily at home; and (4) not preparing food for others that needs prolonged handling with bare hands. They should avoid being close to pregnant women and children for 7 days after therapy.

Surgical Therapy

A thyroidectomy is done for those who have (1) a large goiter causing tracheal compression, (2) a lack of response to antithyroid therapy, or (3) thyroid cancer (Fig. 54.8). Surgery may be done when a person is not a candidate for RAI. One advantage that thyroidectomy has over RAI is a more rapid reduction in

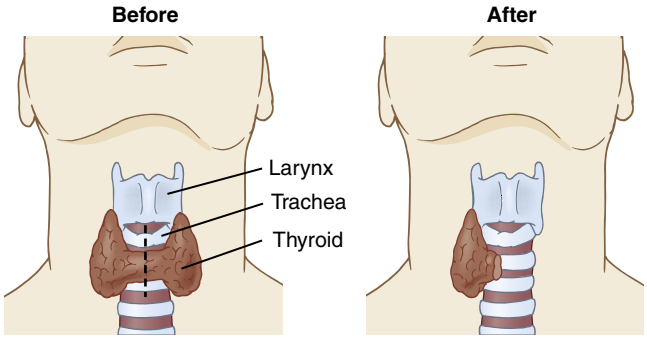

Fig. 54.8 Subtotal thyroidectomy. Part of the thyroid gland is removed.

T_3 and T_4 levels. A *subtotal thyroidectomy* is the preferred surgical procedure. It involves removing a large portion (90%) of the thyroid gland.

Some patients may have minimally invasive endoscopic or robotic thyroidectomy. Endoscopic thyroidectomy is appropriate for patients with small nodules (less than 3 cm) and no evidence of cancer. Robotic surgery is best for those who are not overweight and have small nodules on only 1 side of the gland. Advantages of these procedures include less scarring, less pain, and a faster return to normal activity.

Nutrition Therapy

With the increased metabolic rate in hyperthyroid patients, there is a high risk for nutrition problems. A high-calorie diet (4000 to 5000 cal/day) may be needed to satisfy hunger, prevent tissue breakdown, and decrease weight loss. The patient may need 6 full meals a day and snacks high in protein, carbohydrates, minerals, and vitamins. The protein content should be 1 to 2 g/kg of ideal body weight. Increase carbohydrate intake to compensate for increased metabolism. Carbohydrates provide energy and decrease the use of body-stored protein. Teach the patient to avoid highly seasoned and high-fiber foods because they can further stimulate the already hyperactive GI tract. Have the patient avoid caffeine-containing liquids, such as coffee, tea, and cola, to decrease the restlessness and sleep problems. Refer the patient to a dietitian for help in meeting their nutrient needs.

❖ NURSING MANAGEMENT: HYPERTHYROIDISM

◆ Assessment

Subjective and objective data you should obtain from a person with hyperthyroidism are outlined in Table 54.10.

◆ Clinical Problems

Clinical problems for the patient with hyperthyroidism include:

- Activity intolerance
- Nutritionally compromised

Additional information on clinical problems and interventions is presented in eNursing Care Plan 54.1 for the patient with hyperthyroidism (available on the website for this chapter).

TABLE 54.10 NURSING ASSESSMENT

Hyperthyroidism

Subjective Data

Important Health Information

Health history: Preexisting goiter. Recent infection or trauma, immigration from iodine-deficient area, autoimmune disease

Medications: Thyroid hormones, herbal therapies that may contain thyroid hormone

Functional Health Patterns

Health perception–health management: Positive family history of thyroid or autoimmune disorders

Nutritional-metabolic: Iodine intake, weight loss, ↑ appetite, thirst, nausea, vomiting

Elimination: Diarrhea, polyuria, sweating

Activity-exercise: Dyspnea on exertion, palpitations, muscle weakness, fatigue

Sleep-rest: Insomnia

Cognitive-perceptual: Chest pain, nervousness, heat intolerance, pruritus

Sexuality-reproductive: ↓ Libido, impotence, gynecomastia (in men), amenorrhea (in women)

Coping–stress tolerance: Emotional lability, irritability, restlessness, personality changes, delirium

Objective Data

Cardiovascular

↑ HR, bounding pulse, systolic murmurs, dysrhythmias, ↑ BP, bruit over the thyroid gland

Eyes

Exophthalmos, eyelid retraction, infrequent blinking

General

Agitation, rapid speech and body movements, anxiety, restlessness, fever, enlarged or nodular thyroid gland

GI

↑ Bowel sounds. ↑ Appetite, diarrhea, weight loss, liver and/or spleen enlargement

Neurologic

Hyperreflexia; diplopia. Fine tremors of hands, tongue, eyelids

Musculoskeletal

Muscle wasting

Reproductive

Menstrual irregularities, infertility, impotence, gynecomastia in men

Respiratory

Tachypnea, dyspnea on exertion

Skin

Warm, diaphoretic, velvety skin. Thin, loose nails. Fine, silky hair and hair loss. Palmar erythema, clubbing, white pigmentation of skin (vitiligo), diffuse edema of legs and feet

Possible Diagnostic Findings

↑ T_3, ↑ T_4, ↑ T_3 *resin* uptake, ↓ or undetectable TSH. Chest x-ray showing enlarged heart. ECG findings of tachycardia, atrial fibrillation

◆ Planning

The overall goals are that the patient with hyperthyroidism will (1) have relief of symptoms, (2) have no serious complications

TABLE 54.11 EMERGENCY MANAGEMENT

Acute Thyrotoxicosis

Cause	Assessment Findings	Interventions

• Infection, surgery, trauma in a patient with hyperthyroidism
• Thyroidectomy
	• Abdominal pain
	• Agitation
	• Delirium
	• Diarrhea
	• Fever (up to 106°F [41.1°C])
	• Heart failure
	• Seizures
	• Severe tachycardia
	• Shock
	• Vomiting
		• Begin fluid replacement with isotonic saline infusions containing dextrose.
		• Monitor airway, breathing, and circulation.
		• Monitor vital signs at least every 30 min.
		• Apply continuous O_2 saturation and ECG monitoring.
		• Monitor serial serum electrolytes, serum glucose, ABGs, and serum calcium levels.
		• Monitor urine output hourly.
		• Apply ice packs and cooling blankets to reduce fever. Acetaminophen as needed.
		• Provide pulmonary hygiene.
		• Assess for manifestations of heart failure or pulmonary edema (e.g., extra heart sounds, adventitious lung sounds).
		• Decrease O_2 demands by decreasing anxiety and pain.
		• Restrict visitors, if needed.
		• Give prescribed drugs and monitor effects:
		  • β-Adrenergic blockers
		  • Antithyroid agents
		  • Iodine compounds

related to the disease or treatment, (3) maintain balanced nutrition, and (4) cooperate with the therapeutic plan.

Implementation

Acute Care

Patients with hyperthyroidism are usually treated in an outpatient setting. However, those who develop acute thyrotoxicosis or undergo thyroidectomy need hospitalization and acute care.

Acute thyrotoxicosis. Acute thyrotoxicosis requires aggressive treatment, often in an intensive care unit (ICU).[14] Give medications that block thyroid hormone production and sympathetic nervous system effects. Provide supportive therapy, including monitoring for dysrhythmias and decompensation, ensuring adequate oxygenation, and giving IV fluids to replace fluid and electrolyte losses. This is important in the patient who has fluid losses from vomiting and diarrhea (Table 54.11).

Ensuring adequate rest may be a challenge because of the patient's irritability and restlessness. Provide a calm, cool, quiet room. Use light bed coverings and change the linen often if the patient is diaphoretic. Encourage and assist with exercise involving large muscle groups (tremors can interfere with small-muscle coordination) to allow the release of nervous tension and restlessness. Establish a supportive, trusting relationship to promote coping by a patient who is irritable, restless, and anxious.

If exophthalmos is present, there is a risk for corneal injury related to irritation and dryness. The patient may have orbital pain. To relieve eye discomfort and prevent corneal ulceration, apply artificial tears to soothe and moisten conjunctival membranes. Restricting salt may help reduce periorbital edema. The patient should sit upright as much as possible to promote fluid drainage from the periorbital area.

Dark glasses reduce glare and prevent irritation from smoke, air currents, dust, and dirt. If the eyelids cannot be closed, lightly tape them shut for sleep. To maintain flexibility, teach the patient to exercise the intraocular muscles several times a day by turning the eyes in the complete range of motion. Good grooming can help promote self-esteem from an altered body image. If the exophthalmos is severe, treatment options include corticosteroids, radiation of retroorbital tissues, orbital decompression, or corrective lid or muscle surgery.

Thyroid surgery. When a subtotal thyroidectomy is planned, the patient must be adequately prepared to avoid complications. Before surgery, antithyroid drugs, iodine, and β-adrenergic blockers may be given to achieve a euthyroid state. Iodine also decreases the vascularization of the thyroid gland, reducing the risk for hemorrhage.

Teach the patient about routine postoperative care and comfort and safety measures. Show the patient how to support the head manually while turning in bed, since this minimizes stress on the suture line after surgery. The patient should practice neck range-of-motion exercises. Tell the patient that talking is likely to be difficult for a short time after surgery. Review the importance of performing leg exercises.

Postoperative care. Postoperative complications include hypothyroidism, damage to or inadvertent removal of parathyroid glands (causing hypoparathyroidism and hypocalcemia), hemorrhage, injury to the recurrent or superior laryngeal nerve, thyrotoxicosis, and infection. Recurrent laryngeal nerve damage leads to vocal cord paralysis. If both cords are paralyzed, spastic airway obstruction will occur, requiring an immediate tracheostomy.

SAFETY ALERT

Airway Obstruction

- Airway obstruction after thyroid surgery is an emergency.
- Keep O_2, suction equipment, and a tracheostomy tray available in the patient's room.

TABLE 54.12 NURSING MANAGEMENT

Care of the Patient After Thyroid Surgery

- Assess vital signs every 15 min until stable and then every 30 min for the first 24 hr after surgery.
- Monitor airway and respiratory status (patency, rate, rhythm, depth, and effort).
- Assess the patient every 2 hr for 24 hr for signs of hemorrhage or tracheal compression (e.g., irregular breathing, neck swelling, frequent swallowing, choking, blood on the dressings, and sensations of fullness at the incision site).
- Assist the patient with coughing and deep breathing.
- Apply supplemental O_2 with humidification as ordered.
- Have suction equipment and a tracheostomy kit available for immediate use.
- Assess the ability to speak aloud, noting voice quality, tone, and any problems speaking. Notify the HCP of any permanent hoarseness or loss of vocal volume.
- Monitor calcium levels. Assess for signs of tetany and hypocalcemia (e.g., tingling in toes, fingers, around the mouth; muscular twitching; apprehension) and any trouble with speaking or hoarseness. Check Trousseau sign and Chvostek sign (see Fig. 17.15).
- Keep IV calcium (calcium gluconate, calcium chloride) available for immediate use.
- Assess condition of operative site and dressing. Monitor the area under the patient's neck and shoulders for drainage.
- Keep the patient in a semi-Fowler position. Support the head and neck with pillows. Avoid neck flexion to prevent tension on the suture line.
- Provide comfort measures and give analgesic medications as prescribed.

Respiration may become difficult because of excess swelling of the neck tissues, hemorrhage, and hematoma formation. *Laryngeal stridor* (harsh, vibratory sound) may occur because of edema of the laryngeal nerve. It may be related to tetany from hypocalcemia, which occurs if the parathyroid glands were removed or damaged during surgery. To treat tetany, have IV calcium salts (e.g., calcium gluconate) available.

Assess the patient frequently for signs of bleeding or tracheal compression (Table 54.12). The patient should expect some hoarseness for 3 or 4 days after surgery because of edema. Monitor vital signs. Assess for any signs of hypocalcemia from hypoparathyroidism. If recovery is uneventful, the patient ambulates within hours after surgery. Give fluids as soon as tolerated. A soft diet starts the day after surgery.

The appearance of the incision may be distressing to the patient. Reassure the patient that the scar will fade in color and eventually look like a normal neck wrinkle. A scarf, jewelry, a high collar, or other covering can effectively camouflage the scar.

Ambulatory care. Teach the patient and caregiver that thyroid hormone balance will be monitored periodically. Most patients have a period of relative hypothyroidism soon after surgery because of the substantial reduction in the size of the thyroid. The remaining tissue usually hypertrophies over time and recovers the ability to make hormones. We usually do not give thyroid hormone because the exogenous hormone inhibits pituitary production of TSH and delays or prevents the restoration of normal gland function and tissue regeneration.

To prevent weight gain, caloric intake must be greatly reduced to less than the amount that was needed before surgery. Adequate iodine is needed to promote thyroid function, but excesses can inhibit the thyroid gland. Seafood once or twice a week or normal use of iodized salt should provide enough iodine intake. Encourage regular exercise to stimulate the thyroid gland. Teach the patient to avoid high environmental temperatures because they inhibit thyroid regeneration.

Regular follow-up care is needed. The patient should see the HCP biweekly for a month and then at least semiannually to assess thyroid function. Tell the patient who had a complete thyroidectomy about the need for lifelong thyroid hormone replacement. Teach the patient the signs and symptoms of thyroid failure and to seek medical care promptly if these develop.

◆ Evaluation

The expected outcomes are that the patient with hyperthyroidism will:

- Have relief of symptoms
- Have no serious complications related to the disease or treatment
- Cooperate with the therapeutic plan
- Maintain balanced nutrition

HYPOTHYROIDISM

Hypothyroidism is a deficiency of thyroid hormone that causes a general slowing of the metabolic rate.[15] About 4% of the U.S. population has mild hypothyroidism, with about 0.3% having more severe disease. Hypothyroidism is more common in women (Box 54.1). Subclinical hypothyroidism occurs when the TSH is greater than 4.5 mU/L, but the T_4 levels are normal. Up to 10% of women older than 60 years have subclinical hypothyroidism. Patients with overt hypothyroidism have increased TSH and decreased T_4 levels. Critically ill patients may present with nonthyroidal illness syndrome (NTIS).[15] Those with NTIS have low T_3, T_4, and TSH levels.

Etiology and Pathophysiology

We classify hypothyroidism as primary or secondary. *Primary hypothyroidism* is caused by destruction of thyroid tissue or defective hormone synthesis. *Secondary hypothyroidism* is caused by pituitary disease with decreased TSH secretion or hypothalamic dysfunction with decreased thyrotropin-releasing hormone (TRH) secretion. Hypothyroidism can be brief and related to thyroiditis or stopping thyroid hormone therapy.

Iodine deficiency is the most common cause of hypothyroidism worldwide. In the United States, the most common cause of primary hypothyroidism is atrophy of the thyroid gland. This atrophy is the result of Hashimoto thyroiditis or Graves disease. These autoimmune diseases destroy the thyroid gland. Hypothyroidism can develop after treatment for hyperthyroidism, specifically thyroidectomy or RAI therapy. Drugs such as amiodarone, which contains iodine,

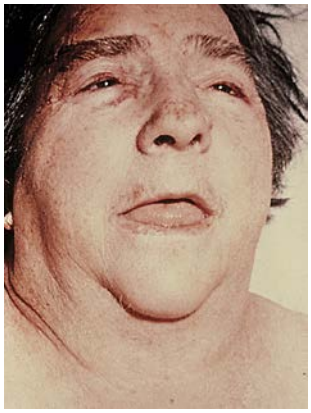

Fig. 54.9 Common features of myxedema. Dull, puffy skin; coarse, sparse hair; periorbital edema; and prominent tongue. (Courtesy Paul W. Ladenson, MD, The Johns Hopkins University and Hospital, Baltimore, MD. From Seidel HM, Ball JW, Dains JE, et al, editors: *Mosby's guide to physical examination,* ed 6, St Louis, 2006, Mosby.)

and lithium, which blocks hormone production, can cause hypothyroidism.

Hypothyroidism that develops in infancy *(cretinism)* results from thyroid hormone deficiencies during fetal or early neonatal life. In the United States, we screen all infants for decreased thyroid function at birth.

Clinical Manifestations

With hypothyroidism we see a slowing of body processes (Table 54.6). Manifestations vary depending on the severity and the duration of thyroid deficiency and the patient's age at the onset of the deficiency. Symptoms may develop over months to years, unless hypothyroidism occurs after a thyroidectomy, after thyroid ablation, or during treatment with antithyroid drugs.

The patient is often tired and lethargic. There may be personality and mental changes, including impaired memory, slowed speech, decreased initiative, and somnolence. Many appear depressed. Weight gain is a result of a decreased metabolic rate.

Hypothyroidism may cause significant cardiovascular problems, especially in a person with a history of CVD. It can cause decreased cardiac contractility and decreased cardiac output. The patient may have low exercise tolerance and shortness of breath on exertion. High serum cholesterol and triglyceride levels and the accumulation of mucopolysaccharides in the intima of small blood vessels can result in coronary atherosclerosis. Anemia is common.

Patients with severe, long-standing hypothyroidism may have **myxedema**. Myxedema results from the accumulation of hydrophilic mucopolysaccharides in the dermis and other tissues (Fig. 54.9). It alters the physical appearance of the skin and subcutaneous tissues with puffiness, facial and periorbital edema, and a mask-like affect. Patients may have an altered self-image related to their altered appearance.

In the older adult, we may attribute manifestations of hypothyroidism (fatigue, cold and dry skin, hair loss, constipation, cold intolerance) to normal aging. For this reason, the patient's symptoms may not raise suspicion of an underlying condition. Older adults who have confusion, lethargy, and depression should be screened for thyroid disease.

TABLE 54.13 Interprofessional Care

Hypothyroidism

Diagnostic Assessment	Management
• History and physical assessment • Serum TSH and free T_4 • Total serum T_3 and T_4 • Thyroid peroxidase (TPO) antibodies	• Thyroid hormone replacement (e.g., levothyroxine) • Monitor thyroid hormone levels and adjust dosage (if needed) • Nutrition therapy to promote weight loss • Patient and caregiver teaching (Table 54.14)

Complications

The mental sluggishness, drowsiness, and lethargy of hypothyroidism may progress gradually or suddenly to a notable impairment of consciousness or coma. This situation, termed *myxedema coma,* is a medical emergency. Cause of myxedema coma include infection, drugs (especially opioids, tranquilizers, and barbiturates), exposure to cold, and trauma. Manifestations include low temperature, hypotension, and hypoventilation. Cardiovascular collapse can result from hypoventilation, hyponatremia, hypoglycemia, and lactic acidosis. For the patient to survive myxedema coma, we must support vital functions and give IV thyroid hormone replacement.

Diagnostic Studies

The most reliable laboratory tests for thyroid function are TSH and free T_4. These values, correlated with findings from the history and physical assessment, confirm the diagnosis of hypothyroidism. Serum TSH levels help determine the cause. Serum TSH is high when the defect is in the thyroid and low when it is in the pituitary or the hypothalamus. The presence of thyroid antibodies suggests an autoimmune origin. Other abnormal laboratory findings are high cholesterol and triglycerides, anemia, and increased creatine kinase (Table 54.7).

Interprofessional Care

The treatment goal for a patient with hypothyroidism is to restore a euthyroid state as safely and quickly as possible with hormone therapy (Table 54.13). A low-calorie diet can promote weight loss or prevent weight gain.

Levothyroxine (Synthroid) is the drug of choice to treat hypothyroidism. In the young and otherwise healthy patient, the maintenance replacement dosage is based on the patient's response and laboratory findings. When beginning thyroid hormone therapy, the first dosages are low to avoid increases in resting heart rate and BP. In the patient with compromised cardiac status, careful monitoring is needed when starting and adjusting the dosage because the usual dose may increase myocardial O_2 demand. This may cause angina and dysrhythmias.

DRUG ALERT

Levothyroxine (Synthroid)

- Carefully monitor patients with CVD who take this drug.
- Monitor heart rate and report pulse greater than 100 beats/min or an irregular heartbeat.
- Promptly report chest pain, weight loss, nervousness, tremors, or insomnia.

In a patient without side effects, the dose is increased at 4- to 6-week intervals as needed based on the TSH levels. It may take up to 8 weeks before the full effect of hormone therapy is seen. Levothyroxine has a peak of action of 1 to 3 weeks. The patient must regularly take replacement medication. Lifelong thyroid therapy is usually needed.

NURSING MANAGEMENT: HYPOTHYROIDISM

Assessment

Careful assessment may reveal early and subtle changes in a patient suspected of having hypothyroidism. Note any history of hyperthyroidism and treatment with antithyroid medications, RAI, or surgery. Ask the patient about using iodine-containing medications (Table 54.5). Note any changes in appetite, weight, activity level, speech, memory, and skin (e.g., increased dryness or thickening). Assess for cold intolerance, constipation, and signs of depression. Further assessment should focus on heart rate, tenderness over the thyroid gland, and edema in the extremities and face.

Clinical Problems

Clinical problems for the patient with hypothyroidism may include:

- Activity intolerance
- Constipation
- Nutritionally compromised

Additional information on clinical problems and interventions is presented in the eNursing Care Plan 54.2 for the patient with hypothyroidism (available on the website for this chapter).

Planning

The overall goals are that the patient with hypothyroidism will (1) have relief of symptoms, (2) maintain a euthyroid state, (3) maintain a positive self-image, and (4) adhere with lifelong thyroid therapy.

Implementation

Health Promotion

Routine screening of thyroid function is not recommended. High-risk persons should be screened for subclinical thyroid disease. Risk factors include being female, White ethnicity, advancing age or having type 1 diabetes, Down syndrome, family history of thyroid disease, goiter, previous hyperthyroidism, and external beam radiation in the head and neck area.[17]

Acute Care

Most people with hypothyroidism are treated on an outpatient basis. The person who develops myxedema coma needs acute nursing care, often in the ICU. They often need mechanical respiratory support and cardiac monitoring.

Give thyroid hormone therapy and all other medications IV because severe gastric hypomotility may prevent the absorption of oral agents. Monitor the core temperature for hypothermia that often occurs in myxedema and myxedema coma. Use gentle soap and moisturize often to prevent skin breakdown. Frequent position changes and a low-pressure mattress help maintain skin integrity.

Monitor the patient's progress by assessing vital signs, body weight, intake and output, and edema. Cardiac assessment is especially important because the cardiovascular response to hormone therapy determines the medication regimen. Note energy level and mental alertness. They should improve within 2 to 14 days and continue a steady progression to normal levels. Neurologic status and TSH levels are used to determine continuing treatment.

Ambulatory care. Provide patient teaching about medication management and complications (Table 54.14). At first the hypothyroid patient may have a hard time processing complex instruction. Give written instructions, repeat the information often, and assess the patient's comprehension level.

Stress the need for lifelong drug therapy and avoiding abruptly stopping drugs. Caution patients against doubling up on doses for any reason. Some patients notice weight loss and are tempted to increase dosing to achieve a desired weight. Teach the patient the expected and unexpected side effects, including the signs and symptoms of hypothyroidism and hyperthyroidism (Table 54.6). The manifestations of overdose are the same as hyperthyroidism. Tell the patient to contact the HCP at once

TABLE 54.14 PATIENT & CAREGIVER TEACHING

Hypothyroidism

Include the following instructions when teaching the patient and caregiver about management of hypothyroidism:

1. Discuss the importance of thyroid hormone therapy:
   - Need for lifelong therapy
   - Taking thyroid hormone in the morning before food
   - Need for regular follow-up care and monitoring of thyroid hormone levels
2. Caution the patient not to switch brands of the hormone since the bioavailability of thyroid hormones may differ.
3. Emphasize the need for a comfortable, warm environment because of cold intolerance.
4. Teach ways to prevent skin breakdown. Use soap sparingly, and apply lotion to skin.
5. Caution the patient, especially if an older adult, to avoid sedatives. If they must be used, suggest that the lowest dose be used. Caregiver should closely monitor mental status, level of consciousness, and respirations.
6. Discuss ways to minimize constipation, including:
   - Gradual increase in activity and exercise
   - Increased fiber in diet
   - Use of stool softeners
   - Regular bowel elimination time
   - Tell patient to avoid using enemas. They cause vagal stimulation, which can be hazardous if heart disease is present.

if symptoms, such as orthopnea, dyspnea, rapid pulse, palpitations, chest pain, nervousness, or insomnia, are present.

The patient with diabetes should check glucose levels at least daily because the return to the euthyroid state often increases insulin requirements. Thyroid drugs increase the effects of anticoagulants. Stress the need to remain under close medical observation until stable. Drug interactions are an important reason for patients to consult the HCP before switching brands of thyroid replacement medication. Switching brands may change bioavailability of the drug and physiologic response.

With treatment, striking transformations occur in both appearance and mental function. Most adults return to a normal state. Cardiovascular conditions may persist after correcting the hormone imbalance. Relapses occur if treatment is interrupted.

◆ Evaluation

The expected outcomes are that the patient with hypothyroidism will:

- Have relief from symptoms
- Maintain a euthyroid state with normal thyroid hormone and TSH levels
- Avoid complications of therapy
- Adhere to lifelong therapy

THYROID NODULES AND CANCER

A *thyroid nodule* (growth in the thyroid gland) may be benign or malignant (thyroid cancer). More than 95% of thyroid gland nodules are benign. The risk of developing a thyroid nodule increases with age. Benign nodules are usually not dangerous, but they can cause tracheal compression if they become too large. The risk of developing a thyroid nodule increases with age.

Thyroid cancer is the most common type of endocrine cancer. Around 62,450 new cases of thyroid cancer are diagnosed each year. The incidence of thyroid cancer has increased significantly in the past 25 years. It is the most rapidly increasing cancer in the United States. Thyroid cancer affects more women. The incidence is higher in Whites and Asian Americans.[18] Adults at risk include those who had head and neck radiation therapy during childhood, were exposed to radioactive fallout, or have a personal or family history of goiter.

Types of Thyroid Cancer

The 4 main types of thyroid cancer are papillary, follicular, medullary, and anaplastic. *Papillary* thyroid cancer is the most common type. It accounts for about 70% to 80% of thyroid cancers. Papillary cancer tends to grow slowly. It initially spreads to lymph nodes in the neck.

Follicular thyroid cancer makes up about 15% of thyroid cancers. It tends to occur in older patients. Follicular cancer first metastasizes into the cervical lymph nodes and then spreads to the neck, lungs, and bones.

Medullary thyroid cancer, accounts for only 10% of thyroid cancers. It is more likely to occur in families and be associated with other endocrine problems. It is diagnosed by genetic testing for a proto-oncogene called *RET*. Medullary thyroid cancer is a type of multiple endocrine neoplasia (MEN). It is often poorly differentiated and associated with early metastasis.

Anaplastic thyroid cancer occurs in less than 2% of patients with thyroid cancer. It is the most advanced and aggressive thyroid cancer. The patient is least likely to respond to treatment and has a poor prognosis.

Clinical Manifestations and Diagnostic Studies

The primary manifestation of thyroid cancer is a painless, palpable nodule or nodules in an enlarged thyroid gland. Most nodules are found during routine palpation of the neck. Firm, palpable, cervical masses suggest lymph node metastasis. Some patients may have trouble swallowing or breathing if tumor growth invades the trachea or esophagus. Hemoptysis and airway obstruction may occur if the trachea is involved. Patients generally are euthyroid.

Nodular enlargement of the thyroid gland or palpation of a mass requires further evaluation. Ultrasound is often the first test used. Follow-up testing may involve CT, MRI, and ultrasound-guided fine-needle aspiration (FNA). An FNA is done when a tissue sample for pathologic examination is needed. A thyroid scan may be done. The scan shows whether nodules on the thyroid are "hot" or "cold." "Hot" tumors take up RAI. They are almost always benign. If the nodule does not take up the RAI, it appears "cold." There is a higher risk for being cancer.

Increased serum calcitonin is associated with medullary thyroid cancer. In papillary and follicular cancers, thyroglobulin is high. In families with a history of medullary thyroid cancer, we encourage family members to have genetic testing and thyroid screening on a regular basis.

Interprofessional and Nursing Care

Surgical removal of the tumor is the main treatment for thyroid cancer. Procedures range from unilateral total lobectomy to near-total thyroidectomy with bilateral lobectomy. Lymph nodes in the neck may be removed to determine if the cancer has spread. Some patients may receive RAI after surgery to destroy any remaining cancer cells. RAI therapy improves survival rates in patients with papillary and follicular thyroid cancer. External beam radiation may be given as palliative treatment for patients with metastatic thyroid cancer.

Many thyroid cancers are TSH dependent. Thyroid hormone therapy in high doses is often prescribed to inhibit TSH secretion. Chemotherapy, including doxorubicin, may be used for advanced disease. Targeted therapies for metastatic cancer include Vandetanib (Caprelsa), lenvatinib (Lenvima), sorafenib tosylate (Nexavar), and cabozantinib (Cometriq). These drugs inhibit tyrosine kinases, enzymes that promote the growth of cancer cells. Nursing care for the patient with thyroid cancer is similar to that of a patient undergoing thyroidectomy. Because of the surgical site location and the risk for hypocalcemia, the patient needs frequent postoperative assessment. Assess the patient for airway obstruction, bleeding, and tetany since the parathyroid gland may have been disturbed or removed during surgery.

MULTIPLE ENDOCRINE NEOPLASIA

Multiple endocrine neoplasia (MEN) is an inherited condition characterized by hormone-secreting tumors.[19] It is caused by

the mutation of 1 of 2 genes, *MEN1* or *RET,* that normally control cell growth. Tumors may develop in childhood or later in life.

The 2 major types of MEN are type 1 and type 2. Both types are often inherited as autosomal dominant disorders. Persons with type 1 often have parathyroid gland hyperactivity (hyperparathyroidism). Other signs may include hyperactivity of the pituitary gland (prolactinoma) and pancreas (gastrinoma). In most cases, the tumors are initially benign. Some tumors later become malignant. Persons with type 2 neoplasia often have medullary thyroid carcinoma. They may develop pheochromocytoma (tumor of the adrenal glands).

Treatment includes conservative management (watchful waiting), drugs to block the effects of excess hormone, and surgical removal of the gland and/or tumor. Patients must have regular screening visits with the HCP so that new tumors may be detected early and existing tumors carefully monitored.

PARATHYROID GLAND PROBLEMS

HYPERPARATHYROIDISM

Etiology and Pathophysiology

Hyperparathyroidism is a condition involving an increased parathyroid hormone (PTH) secretion. PTH helps regulate serum calcium and phosphate levels by stimulating bone resorption of calcium, renal tubular reabsorption of calcium, and activation of vitamin D. Thus PTH oversecretion causes increased serum calcium levels.

Hyperparathyroidism is either primary, secondary, or tertiary. *Primary hyperparathyroidism* is due to an increased PTH secretion that leads to problems with calcium, phosphate, and bone metabolism.[20] It affects 25 of 100,000 persons per year. The peak incidence is in the 40s and 50s. It affects twice as many women as men. The most common cause is a benign tumor (adenoma) in the parathyroid gland. Patients who have had head and neck radiation have an increased risk for developing a parathyroid adenoma. Long-term lithium therapy is also associated with primary hyperparathyroidism.

Secondary hyperparathyroidism is a compensatory response to conditions that induce or cause hypocalcemia, the main stimulus of PTH secretion. These include vitamin D deficiencies, malabsorption, chronic kidney disease, and hyperphosphatemia.

Tertiary hyperparathyroidism occurs when there is hyperplasia of the parathyroid glands and a loss of negative feedback from circulating calcium levels. Thus there is autonomous PTH secretion even with normal calcium levels. This may happen in patients who have a kidney transplant after a long period of dialysis treatment for chronic kidney disease (see Chapter 51).

High PTH levels usually lead to hypercalcemia and hypophosphatemia. Multiple body systems are affected (Table 54.15). Decreased bone density can occur because of the effect of PTH on osteoclastic (bone resorption) and osteoblastic (bone formation) activity. The kidneys cannot reabsorb the excess calcium. This leads to high urinary calcium levels (hypercalciuria). This urinary calcium, along with a large amount of urinary phosphate, can lead to stone formation.

Clinical Manifestations and Complications

Manifestations range from an asymptomatic person (diagnosed through testing for unrelated problems) to a patient with overt symptoms. The manifestations are due to hypercalcemia (Table 54.15). Loss of appetite, constipation, fatigue, emotional disorders, shortened attention span, and muscle weakness, especially in the proximal muscles of the lower extremities, often occur. Complications include osteoporosis, renal failure, kidney stones, pancreatitis, cardiac changes, and long bone, rib, and vertebral fractures.

Diagnostic Studies

Patients with hyperparathyroidism have increased PTH levels. Serum calcium levels usually exceed 10 mg/dL (2.50 mmol/L). Because of its inverse relation with calcium, the serum phosphorus level is usually less than 3 mg/dL (0.1 mmol/L). Asymptomatic hypercalcemia is often found through a routine chemistry panel.

Other increased values include urine calcium, serum chloride, uric acid, creatinine, amylase (if pancreatitis is present), and alkaline phosphatase (in the presence of bone disease). Bone density measurements may be used to detect bone loss. Conversely, those with bone loss on a screening dual energy x-ray absorptiometry (DEXA) scan should be screened for hypercalcemia. MRI, CT, and/or ultrasound can detect an adenoma.

Interprofessional Care

The goal of treatment is to relieve symptoms and prevent complications caused by excess PTH. The choice of therapy depends on the urgency of the situation, degree of hypercalcemia, and underlying cause of the disorder.

Surgical Therapy

The most effective treatment of primary and secondary hyperparathyroidism is surgery. Surgery involves partial or complete removal of the parathyroid glands. The most common procedure involves endoscopy. It is done on an outpatient basis. Criteria for surgery include increased serum calcium levels (more than 1 mg/dL above the upper limit of normal), hypercalciuria (greater than 400 mg/day), markedly reduced bone mineral density, overt symptoms (e.g., neuromuscular effects, kidney stones), or age under 50 years. Parathyroidectomy leads to a rapid reduction of high calcium levels.

Patients who have multiple parathyroid glands removed may undergo autotransplantation of normal parathyroid tissue in the forearm or near the sternocleidomastoid muscle. This allows PTH secretion to continue with normal calcium levels. If autotransplantation is not possible or if it fails, the patient will need to take calcium supplements for life.

Nonsurgical Therapy

A conservative approach is often used in patients who are asymptomatic or have mild symptoms. Ongoing care includes regular measurement of serum PTH, calcium, phosphorus, alkaline phosphatase, creatinine and blood urea nitrogen (BUN) (to assess renal function), and urinary calcium excretion. Annual x-rays and DEXA scans assess for metabolic bone loss. Continued ambulation and avoiding immobility are important. Diet measures include high fluid and moderate calcium intake.

TABLE 54.15 Manifestations of Parathyroid Problems

Hyperfunction	Hypofunction
Cardiovascular System	
• ↑ BP	• ↓ BP
• Angina	• Edema
• Dysrhythmias	• Dysrhythmias
• Shortened ST segment	• Elongation of ST segment
• Shortened QT interval	• Prolonged QT interval
• ↑ Digitalis effect	• ↓ Cardiac output
Gastrointestinal System	
• Vague abdominal pain	• Abdominal cramps
• Anorexia	• Fecal incontinence (in older adult)
• Nausea and vomiting	• Malabsorption
• Constipation	
• Pancreatitis	
• Peptic ulcer disease	
• Cholelithiasis	
• Weight loss	
Laboratory Findings	
• ↑ Calcium	• ↓ Calcium
• ↓ Phosphorus	• ↑ Phosphorus
Musculoskeletal System	
• Weakness, fatigue	• Weakness, fatigue
• Skeletal pain	• Painful muscle cramps
• Backache	• Skeletal x-ray changes, osteosclerosis
• Pain on weight bearing	• Soft tissue calcification
• Osteoporosis	• Problems walking
• Pathologic fractures of long bones	
• Compression fractures of spine; kyphosis	
• ↓ Muscle tone, muscle atrophy	
Neurologic System	
• Lethargy, weakness, fatigue	• Weakness, fatigue
• Psychosis, depression	• Depression
• Depressed reflexes	• Hyperreflexia, muscle cramps
• Personality changes	• Personality changes
• Irritability	• Irritability
• Impaired memory	• Impaired memory
• Delirium, confusion, coma	• Disorientation, confusion (in older adult)
• Headache	• Headache, ↑ intracranial pressure
• Poor coordination	• Tetany, seizures
• Gait abnormalities	• Positive Chvostek and Trousseau signs
• Psychomotor retardation	• Tremor
• Paresthesias	• Paresthesias of lips, hands, feet
Renal/Urinary System	
• Hypercalciuria	• Urinary frequency
• Kidney stones	• Urinary incontinence
• Urinary tract infections	
• Polyuria	
Skin	
• Skin necrosis	• Dry, scaly skin
• Moist skin	• Hair loss on scalp and body
	• Brittle nails, transverse ridging
	• Lack of tooth enamel
Visual System	
• Impaired vision	• Eye changes, including lenticular opacities, cataracts, papilledema
• Corneal calcification	

Severe hypercalcemia is managed with IV sodium chloride and loop diuretics, such as furosemide, to increase urinary calcium excretion. Several drugs help to lower calcium levels, but they do not treat the underlying problem. Bisphosphonates (e.g., alendronate) inhibit osteoclastic bone resorption, normalizing serum calcium levels and improving bone mineral density. IV bisphosphonates (e.g., pamidronate) can quickly lower serum calcium in patients with dangerously high levels. Phosphates are given if the patient has normal renal function and low serum phosphate levels.

Calcimimetic agents (e.g., cinacalcet [Sensipar]) increase the sensitivity of calcium receptors on the parathyroid gland, resulting in decreased PTH secretion and calcium blood levels. They are useful in treating secondary hyperparathyroidism in those with chronic kidney disease on dialysis or in patients with parathyroid cancer.

❖ NURSING MANAGEMENT: HYPERPARATHYROIDISM

Nursing care for the patient after a parathyroidectomy is similar to that for a patient after thyroidectomy. The major complications are bleeding and fluid and electrolyte problems. *Tetany,* a condition of neuromuscular hyperexcitability from a sudden decrease in calcium levels, is another concern. It is usually apparent early in the postoperative period but may develop over several days. Mild tetany, characterized by unpleasant tingling of the hands and around the mouth, may be present but should decrease over time. If tetany becomes more severe (e.g., muscular spasms, laryngospasms), IV calcium may be given. IV calcium gluconate should be readily available for patients after parathyroidectomy in case acute tetany occurs.

Monitor intake and output to evaluate fluid status. Assess calcium, potassium, phosphate, and magnesium levels frequently. Monitor Chvostek and Trousseau signs (see Fig. 17.15). Encourage mobility to promote bone calcification.

If surgery is not done, treatment to relieve symptoms and prevent complications is started. Help the patient to adapt the meal plan to their lifestyle. A referral to a dietitian may be helpful. Because immobility can worsen bone loss, stress the importance of an exercise program. Encourage the patient to keep the regular follow-up appointments. Teach the patient the symptoms of hypocalcemia and hypercalcemia and to report them if they occur. Hypocalcemia and hypercalcemia are discussed in Chapter 17.

HYPOPARATHYROIDISM

Hypoparathyroidism is an uncommon condition associated with inadequate circulating PTH. It is characterized by hypocalcemia due to a lack of PTH to maintain serum calcium levels. PTH resistance at the cellular level may occur *(pseudohypoparathyroidism)*. This is caused by a genetic defect resulting in hypocalcemia despite normal or high PTH levels. It is often associated with hypothyroidism and hypogonadism.

The most common cause is iatrogenic. This may include accidental removal of the parathyroid glands or damage to the vascular supply of the glands during neck surgery (e.g., thyroidectomy). Idiopathic hypoparathyroidism resulting from the absence, fatty replacement, or atrophy of the glands is rare. It usually occurs early in life and may be associated with other endocrine disorders. Affected patients may have antiparathyroid antibodies. Severe hypomagnesemia (e.g., malnutrition, alcohol use, renal failure) can suppress PTH secretion. Other causes include tumors and heavy metal poisoning.

The features of acute hypoparathyroidism are due to hypocalcemia (Table 54.15). Sudden decreases in calcium levels cause tetany, characterized by tingling of the lips and stiffness in the extremities. Painful tonic spasms of smooth and skeletal muscles can cause dysphagia and laryngospasms, which compromise breathing. Lethargy, anxiety, and personality changes may occur. Abnormal laboratory findings include decreased serum calcium and PTH and increased phosphate levels.

Interprofessional and Nursing Care

Treatment goals are to treat acute complications, such as tetany, maintain normal serum calcium levels, and prevent long-term complications. Emergency treatment of tetany after surgery requires IV calcium administration.

Give IV calcium slowly. Use ECG monitoring when giving calcium, because high serum calcium levels can cause hypotension, serious dysrhythmias, or cardiac arrest. The patient who takes digoxin is especially vulnerable. Assess IV patency. Calcium chloride can cause venous irritation and inflammation. Extravasation may cause cellulitis, necrosis, and tissue sloughing.

Rebreathing may partially relieve the acute neuromuscular symptoms from hypocalcemia, including muscle cramps and mild tetany. Have the patient breathe in and out of a paper bag or breathing mask. This reduces CO_2 excretion from the lungs, increases carbonic acid levels in the blood, and lowers the pH. A lower pH (acidic environment) enhances calcium ionization. This causes more total body calcium to be available in the active form.

CHECK YOUR PRACTICE

You are caring for a 62-year-old patient admitted to your unit from the PACU. The patient had a total thyroidectomy for papillary thyroid cancer. As you are preparing to give oral pain medication, the patient says his mouth feels "numb" like it does after he goes to the dentist. The patient asks if this is normal.

- How do you respond?
- What complication do you suspect could be occurring?
- What assessments do you need to make?
- Describe the actions needed if this complication is occurring.

Teach the patient how to manage long-term drug and nutrition therapy. Most patients receive oral calcium supplements, magnesium supplements, and vitamin D. We usually do not recommend PTH replacement because of the expense and need for parenteral administration. Vitamin D (e.g., 1,25-dihydroxycholecalciferol, calcitriol) is used to enhance intestinal calcium absorption. It increases calcium levels rapidly and is quickly metabolized.

A high-calcium meal plan includes foods, such as dark green vegetables, soybeans, and tofu. Tell the patient to avoid foods containing oxalic acid (e.g., spinach, rhubarb) because they inhibit calcium absorption. Teach the patient about the need for follow-up care, including monitoring of calcium levels 3 or 4 times a year.

ADRENAL CORTEX PROBLEMS

Adrenal cortex steroid hormones have 3 main classifications: glucocorticoids, mineralocorticoids, and androgens. Glucocorticoids regulate metabolism, increase glucose levels, and are critical in the physiologic stress response. The primary glucocorticoid is cortisol. Mineralocorticoids regulate sodium and potassium balance. The primary mineralocorticoid is aldosterone. Androgens contribute to growth and development in both genders and to sexual development in men. The term *corticosteroid* refers to any of these 3 types of hormones made by the adrenal cortex.

CUSHING SYNDROME

Etiology and Pathophysiology

Cushing syndrome is a clinical condition that results from chronic exposure to excess corticosteroids, especially glucocorticoids.[21] Several conditions can cause Cushing syndrome. The most common is iatrogenic administration of exogenous corticosteroids (e.g., prednisone). About 85% of the cases of endogenous Cushing syndrome are due to an ACTH-secreting pituitary adenoma (Cushing disease). Less common causes include adrenal tumors and ectopic ACTH production by tumors (usually of the lung or pancreas) outside of the hypothalamic-pituitary-adrenal axis. Cushing disease and primary adrenal tumors are more common in women in the 20- to 40-year-old age-group. Ectopic ACTH production is more common in men (Box 54.1).

Clinical Manifestations

Manifestations occur in most body systems. They are related to excess corticosteroid levels (Table 54.16). Although signs of glucocorticoid excess usually predominate, symptoms of mineralocorticoid and androgen excess can occur.

Corticosteroid excess causes pronounced changes in physical appearance (Fig. 54.10). Weight gain is the most common. It results from the accumulation of adipose tissue in the trunk (centripetal obesity), face ("moon face"), and cervical areas ("buffalo hump") (Fig. 54.11). Hyperglycemia occurs because of glucose intolerance from cortisol-induced insulin resistance and increased gluconeogenesis by

TABLE 54.16 Manifestations of Adrenocortical Problems

System	Cushing Syndrome	Addison Disease
Glucocorticoids		
General appearance	Truncal obesity, thin extremities, rounding of face (moon face), fat deposits on back of neck and shoulders (buffalo hump) (Fig. 54.11)	Weight loss, emaciation
Cardiovascular	↑ BP, hypervolemia, edema of lower extremities	↓ BP, tendency to develop refractory shock, vasodilation
GI	↑ Secretion of pepsin and HCl acid, risk for peptic ulcer disease, anorexia	Anorexia, nausea and vomiting, cramping abdominal pain, diarrhea
Immune	Inhibition of immune response, suppression of allergic response	Tendency for coexisting autoimmune diseases
Metabolic	Hyperglycemia, negative nitrogen balance, dyslipidemia	↓ Sodium, insulin sensitivity, fever
Musculoskeletal	Muscle wasting in extremities, fatigue, osteoporosis, awkward gait, back pain, weakness, compression fractures	Fatigue
Psychologic	Euphoria, irritability, depression, insomnia, anxiety	Depression, exhaustion or irritability, confusion, delusions
Renal/urinary	Glycosuria, hypercalciuria, risk for kidney stones	
Skin	Thin, fragile skin, purplish red striae (Fig. 54.12). Petechial hemorrhages, bruises. Florid cheeks (plethora), acne, poor wound healing	Bronzed or smoky hyperpigmentation of face, neck, hands (especially creases) (Fig. 54.13), buccal membranes, nipples, genitalia, and scars (if pituitary function normal). Vitiligo, alopecia
Mineralocorticoids		
Cardiovascular	↑ BP, hypervolemia	Hypovolemia, tendency toward shock, decreased cardiac output
Fluid and electrolytes	Marked sodium and water retention, edema, marked ↓ potassium, alkalosis	Sodium loss, ↓ volume of extracellular fluid, ↑ potassium, salt craving
Androgens		
Musculoskeletal	Muscle wasting and weakness	↓ Muscle size and tone
Reproductive	*Women:* Menstrual irregularities and enlargement of clitoris *Men:* Gynecomastia and testicular atrophy	*Women:* ↓ Libido in women *Men:* No effect in men
Skin	Hirsutism, acne, hyperpigmentation	↓ Axillary and pubic hair (in women)

Fig. 54.10 Cushing syndrome. Facies include a rounded face ("moon face") with thin, reddened skin. Hirsutism may be present. (From Seidel HM, Ball JW, Dains JE, et al.: *Mosby's guide to physical examination,* ed 6, St Louis, 2006, Mosby.)

the liver. Muscle wasting causes weakness, especially in the extremities. A loss of bone matrix leads to osteoporosis and back pain. The loss of collagen makes the skin weaker, thinner, and more easily bruised. Purplish red striae (usually depressed below the skin surface) appear on the abdomen, breast, or buttocks (Fig. 54.12). Catabolic processes lead to a delay in wound healing.

Mineralocorticoid excess may cause hypokalemia from potassium excretion and hypertension from fluid retention. Adrenal androgen excess may cause severe acne, the development of male characteristics in women, and feminization in men. Menstrual problems and hirsutism in women and gynecomastia and impotence in men occur more often with adrenal cancer.

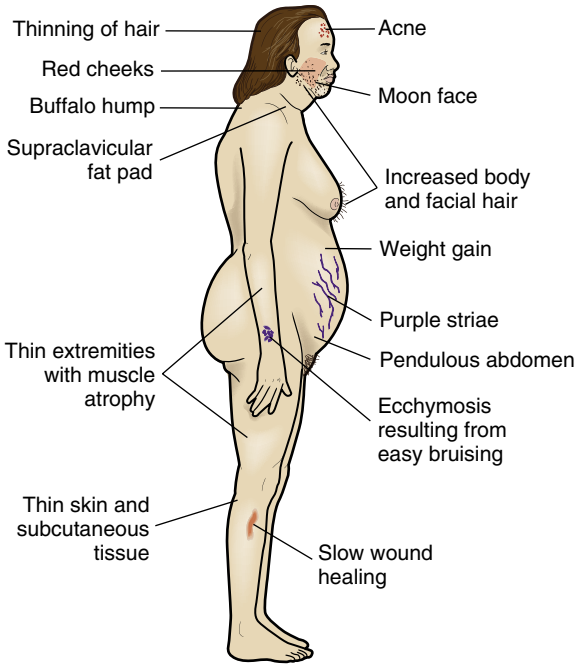

Fig. 54.11 Common characteristics of Cushing syndrome.

Fig. 54.12 Cushing syndrome. Truncal obesity; broad, purple striae; and easy bruising (left antecubital fossa). (From Chew SL, Leslie D: *Clinical endocrinology and diabetes: an illustrated colour text,* Edinburgh, 2006, Churchill Livingstone.)

Diagnostic Studies

Diagnosing Cushing syndrome begins with confirming increased plasma cortisol levels. We use 3 tests: (1) midnight or late-night salivary cortisol, (2) low-dose dexamethasone suppression test, and (3) 24-hour urine cortisol. Urine cortisol levels higher than 100 mcg/24 hr indicate Cushing syndrome. Urine levels of 17-ketosteroids may be high. A CT scan or MRI of the pituitary and adrenal glands can detect a tumor.

Plasma ACTH levels may be low, normal, or high, depending on the underlying cause. High or normal ACTH levels indicate Cushing disease. Low or undetectable levels indicate an adrenal or medication cause. Other findings that may be present but are not diagnostic of Cushing syndrome include leukocytosis, lymphopenia, eosinopenia, hyperglycemia, glycosuria, hypercalciuria, and osteoporosis. Hypokalemia and alkalosis occur with ectopic ACTH syndrome and adrenal cancer.

Interprofessional Care

The primary goal of treatment is to normalize hormone secretion. The treatment depends on the underlying cause (Table 54.17). If the cause is a pituitary adenoma, the standard treatment is surgical removal of the pituitary tumor using the transsphenoidal approach. Radiation therapy is an option for patients who are not surgical candidates.

An adrenalectomy is done if Cushing syndrome is caused by adrenal tumors or hyperplasia. Sometimes, bilateral adrenalectomy is needed. A laparoscopic approach is used unless adrenal cancer is suspected. Then an open surgical adrenalectomy is usually done.

Patients with ectopic ACTH-secreting tumors are best managed by removing the tumor (usually lung or pancreas). This is usually possible when the tumor is benign. If a cancerous tumor has already metastasized, surgical removal may not be possible or successful.

When the patient is a poor candidate for surgery or prior surgery has failed, we can try drug therapy. The goal of drug therapy is to suppress the synthesis and secretion of cortisol from the adrenal gland *(medical adrenalectomy)*. Drugs used include ketoconazole and mitotane. These are used cautiously because they are often toxic at the dosages needed to reduce cortisol secretion. Hydrocortisone or prednisone may be needed to avoid adrenal insufficiency. Mifepristone (Korlym) can help control hyperglycemia in patients with endogenous Cushing syndrome who have type 2 diabetes.

If Cushing syndrome developed because of prolonged use of corticosteroids (e.g., prednisone), we may try several options. We can gradually discontinue corticosteroid therapy, reduce the corticosteroid dose, or convert to alternate-day dosing. Gradual tapering of the corticosteroids is necessary to avoid potentially life-threatening adrenal insufficiency. In alternate-day dosing, twice the daily dosage of a shorter-acting corticosteroid is given every other morning to minimize hypothalamic-pituitary-adrenal suppression, growth suppression, and altered appearance. This plan is not an option if the corticosteroids are given as hormone therapy.

TABLE 54.17 Interprofessional Care

Cushing Syndrome

Diagnostic Assessment
- History and physical assessment
- Dexamethasone suppression test
- 24-Hr urine for free cortisol and 17-ketosteroids
- Plasma and salivary cortisol levels
- Plasma ACTH levels
- CBC with WBC differential
- Blood chemistries for sodium, potassium, glucose
- CT scan, MRI

Management

Pituitary Adenoma
- Transsphenoidal resection
- Radiation therapy

Adrenocortical Adenoma, Cancer, or Hyperplasia
- Adrenalectomy (open or laparoscopic)
- Drug therapy (e.g., ketoconazole, mitotane, mifepristone [Korlym])

Ectopic ACTH-Secreting Tumor
- Treatment of the tumor (surgical removal or radiation)

Exogenous Corticosteroid Therapy
- Discontinue or change the dose of exogenous corticosteroids

❖ NURSING MANAGEMENT: CUSHING SYNDROME

◆ Assessment

Subjective and objective data that should be obtained from a patient with Cushing syndrome are outlined in Table 54.18.

◆ Clinical Problems

Clinical problems for the patient with Cushing syndrome may include:
- Risk for infection
- Nutritionally compromised

TABLE 54.18 NURSING ASSESSMENT

Cushing Syndrome

Subjective Data

Important Health Information

Health history: Pituitary tumor (Cushing disease). Adrenal, pancreatic, or pulmonary cancer. GI bleeding, frequent infections

Medications: Corticosteroids

Functional Health Patterns

Health perception–health management: Malaise

Nutritional-metabolic: Weight gain, anorexia. Prolonged wound healing, easy bruising

Elimination: Polyuria

Activity-exercise: Weakness, fatigue

Sleep: Insomnia, poor sleep quality

Cognitive-perceptual: Headache. Back, joint, bone, and rib pain. Poor concentration and memory

Self-perception–self-concept: Negative feelings about changes in personal appearance

Sexuality-reproductive: Amenorrhea, impotence, ↓ libido

Coping–stress tolerance: Anxiety, mood changes, emotional lability, psychosis

Objective Data

Cardiovascular

↑ BP

General

Truncal obesity, supraclavicular fat pads, buffalo hump, moon face

Musculoskeletal

Muscle wasting, thin extremities, awkward gait

Reproductive

Gynecomastia, testicular atrophy (in men), enlarged clitoris (in women)

Skin

Hirsutism of body and face, thinning of head hair. Thin, friable skin. Acne, petechiae, purpura, hyperpigmentation. Purplish red striae on breasts, buttocks, and abdomen. Edema of lower extremities

Possible Diagnostic Findings

Hyperglycemia, ↓ potassium, dyslipidemia, polycythemia, lymphocytopenia, eosinopenia. ↑ Plasma cortisol, ↑ salivary cortisol. High, low, or normal ACTH levels. Abnormal dexamethasone suppression test. ↑ Urine free cortisol, 17-ketosteroids. Glycosuria, hypercalciuria. Osteoporosis on x-ray

- Disturbed body image
- Impaired tissue integrity

Additional information on clinical problems and interventions is presented in eNursing Care Plan 54.3 for the patient with Cushing syndrome (available on the website for this chapter).

Planning

The overall goals are that the patient with Cushing syndrome will (1) have relief of symptoms, (2) avoid serious complications, (3) maintain a positive self-image, and (4) actively take part in the therapeutic plan.

Implementation

Health Promotion

Health promotion focuses on identifying patients at risk for Cushing syndrome. Patients receiving long-term, exogenous corticosteroids are at risk. Teaching related to using medications and monitoring side effects is an important preventive measure.

Acute Care

The patient with Cushing syndrome is seriously ill. Because the therapy has many side effects, assessment focuses on signs and symptoms of hormone and drug toxicity and complicating conditions (e.g., CVD, diabetes, infection). Monitor vital signs, daily weight, and glucose. Assess for infection. Because signs and symptoms of inflammation (e.g., fever, redness) may be minimal or absent, assess for pain, loss of function, and purulent drainage. Monitor for signs and symptoms of thromboembolic events, such as pulmonary emboli (e.g., sudden chest pain, dyspnea, tachypnea).

Another important focus of care is emotional support. Changes in appearance, such as truncal obesity, multiple bruises, hirsutism in women, and gynecomastia in men, can be distressing. The patient may feel unattractive, repulsive, or unwanted. You can help by being sensitive to the patient's feelings and offering respect and unconditional acceptance (Box 54.2). Reassure the patient that the physical changes and much of the emotional lability will resolve when hormone levels return to normal.

If treatment involves surgical removal of a pituitary adenoma, an adrenal tumor, or 1 or both adrenal glands, nursing care will include preoperative and postoperative care.

Preoperative care. Before surgery, the patient should be in optimal physical condition. Hypertension and hyperglycemia must be under control. Hypokalemia must be corrected with diet and potassium supplements. A high-protein diet helps correct protein depletion. Preoperative teaching depends on the type of surgery planned (hypophysectomy or adrenalectomy). Include information about the expected care after surgery.

Postoperative care. Surgery on the adrenal glands poses great risks. Because the adrenal glands are vascular, there is an increased risk for bleeding. After both laparoscopic and open adrenalectomy, the patient may have a nasogastric tube, a urinary catheter, IV therapy, and central venous pressure monitoring. Initiate VTE prophylaxis.

Manipulating glandular tissue during surgery may release large amounts of hormones into the circulation. This can produce marked fluctuations in the metabolic processes affected by these hormones. After surgery, BP, fluid balance, and electrolyte levels may be unstable due to these hormone fluctuations.

High doses of corticosteroids (e.g., hydrocortisone) are given IV during surgery and for several days afterward to ensure adequate responses to the stress of the procedure. If large amounts of endogenous hormone were released into the systemic circulation during surgery, the patient is likely to have hypertension, increasing the risk for bleeding. High corticosteroid levels cause problems with glycemic control, increase risk for infection, and delay wound healing.

The critical period for circulatory instability is 24 to 48 hours after surgery. During this time, you must be alert for signs of

BOX 54.2 EVIDENCE-BASED PRACTICE

Health-Related Quality of Life in Patients With Cushing Syndrome

You are working in the endocrinology clinic when B.F., a 47-year-old patient, checks in for an appointment. B.F. was diagnosed with Cushing syndrome after long-term use of glucocorticoid inhalers for treatment of asthma but is now in biochemical remission. His wife is with him today. When B.F. is having blood drawn for laboratory testing, his wife tells you he seems depressed and rarely sleeps through the night. She adds, "He battled so hard to get that disease in remission…did everything he was supposed to do…but he doesn't seem to enjoy life now."

Making Clinical Decisions

Synthesis of Best Available Evidence

Long-term exposure to excessive cortisol affects a patient's health. This can affect health-related quality of life. While cortisol secretion can normalize (biochemical remission), clinical features of Cushing syndrome may be slower to resolve (e.g., obesity, muscle weakness, skin changes). Research suggests patients may have difficulty achieving recovery of all social, professional, and personal aspects of daily functioning.

Sleep problems have been found through self-report of patients in remission of Cushing syndrome. Impaired sleep can affect quality of life, including psychologic aspects of well-being. Research suggests physical activity may affect sleep quality.

Clinician Expertise

When B.F. returns to the examination room after laboratory testing, you take his vital signs and begin usual intake questions. You also ask, "How have you been sleeping? Do you have enough energy for regular activity?" The patient looks at his wife but initially says nothing. You continue, "We know from research that people like you, who are in biochemical remission from Cushing syndrome, may have poor sleep quality and may even become depressed during their clinical recovery. Physical activity can not only improve sleep but can help with some of the other symptoms that may be bothering you."

Patient Preferences and Values

B.F. responds, "Some days I don't really feel like doing much, but I know I need to get active again to try to lose weight. Are there any limits to what I can do?" You encourage B.F. responding, "Let's talk about the things you like to do that will help you become more active again."

Implications for Nursing Practice

1. What aspects of health-related quality of life may be affected by Cushing syndrome?
2. How can we best address these issues with our patients?

Reference for Evidence

Moyers SA, Tiemensma J: The association between physical activity, sleep, and quality of life in in patients in bio-chemical remission from Cushing's syndrome, *Qual Life Res* 29:2089, 2020.

corticosteroid imbalance. Report any rapid or significant changes in BP, respirations, or heart rate. Monitor intake and output carefully and assess for imbalances. Give IV corticosteroids as ordered. The dosage is adjusted depending on the patient's manifestations and fluid and electrolyte balance. Oral doses are given as tolerated. After IV corticosteroids are withdrawn, keep the IV line open for quick administration of corticosteroids or vasopressors. Obtain morning urine samples at the same time each morning for cortisol measurement to evaluate the surgery's effectiveness.

If corticosteroid dosage is tapered too quickly after surgery, acute adrenal insufficiency may develop. Vomiting, weakness, dehydration, and hypotension are signs of hypocortisolism. The patient may have painful joints, itching, or peeling skin and severe emotional problems. Report these signs and symptoms so that drug doses can be adjusted as needed.

The patient is usually kept on bed rest until the BP stabilizes. Be alert for subtle signs of infection because the usual inflammatory responses are suppressed. To prevent infection, provide meticulous care when changing the dressing and during any other procedures that involve access to body cavities, circulation, or areas under the skin.

◆ Ambulatory Care

Discharge teaching is based on the patient's lack of endogenous corticosteroids and resulting inability to react physiologically to stressors. Consider a home health nurse referral, especially for older adults, because of the need for ongoing evaluation and teaching. Teach the patient to always wear a Medic Alert bracelet and carry medical identification and instructions in a wallet or purse. Teach the patient to avoid exposure to extreme temperatures, infections, and emotional situations. Stress may cause acute adrenal insufficiency because the remaining adrenal tissue cannot meet an increased hormone demand. Many patients need lifetime replacement therapy. They should be prepared for it to take several months to adjust the hormone dose satisfactorily. Teach patients to adjust their corticosteroid replacement therapy by their stress levels. Consult with the patient's HCP to determine the parameters for dosage changes if this plan is feasible. If the patient cannot adjust their own medication or if weakness, fainting, fever, or nausea and vomiting occur, the patient should contact the HCP for a possible adjustment in corticosteroid dosage.

◆ Evaluation

The expected outcomes are that the patient with Cushing syndrome will:

- Have no signs or symptoms of infection
- Maintain weight appropriate for height
- State acceptance of appearance and treatment plan
- Show healing of skin and maintaining intact skin

ADRENOCORTICAL INSUFFICIENCY

Etiology and Pathophysiology

Adrenocortical insufficiency (hypofunction of the adrenal cortex) may be from a primary cause (**Addison disease**) or a secondary cause (lack of pituitary ACTH secretion). In Addison disease, all 3 classes of adrenal corticosteroids (glucocorticoids, mineralocorticoids, and androgens) are reduced. In secondary adrenocortical insufficiency, corticosteroids and androgens are deficient but mineralocorticoids rarely are. ACTH deficiency may be caused by pituitary disease or suppression of the hypothalamic-pituitary axis because of the use of exogenous corticosteroids.

Up to 80% of Addison disease cases in the United States are caused by an autoimmune response.[22] Autoimmune adrenalitis causes the adrenal cortex to be destroyed by antibodies. This

Fig. 54.13 Hyperpigmentation typically seen in Addison disease. (From Chew SL, Leslie D: *Clinical endocrinology and diabetes: an illustrated colour text,* Edinburgh, 2006, Churchill Livingstone.)

results in loss of glucocorticoid, mineralocorticoid, and adrenal androgen hormones. Addison disease can be present along with other endocrine problems. This is known as *autoimmune polyglandular syndrome*. It is most common in white females. Those with autoimmune adrenalitis often have other autoimmune disorders, such as type 1 diabetes, autoimmune thyroid disease, pernicious anemia, and celiac disease.

Although tuberculosis causes Addison disease worldwide, it is now an uncommon cause in the United States. Other causes include amyloidosis, fungal infections (e.g., histoplasmosis), acquired immunodeficiency syndrome (AIDS), and metastatic cancer. Iatrogenic Addison disease may be due to adrenal hemorrhage, often related to anticoagulant therapy, chemotherapy, or bilateral adrenalectomy. Adrenal insufficiency most often occurs in adults younger than 60 years of age. It affects both genders equally.

Clinical Manifestations

Because manifestations do not tend to become evident until 90% of the adrenal cortex is destroyed, the disease is often advanced before it is diagnosed. The manifestations have a slow onset and include anorexia, nausea, progressive weakness, fatigue, and weight loss. Increased ACTH causes the striking bronze-colored skin hyperpigmentation. It is seen mainly in sun-exposed areas of the body, at pressure points, over joints, and in the creases, especially palmar creases (Fig. 54.13). Skin changes are likely due to increased secretion of β-lipotropin (which contains melanocyte-stimulating hormone [MSH]). MSH is increased because of decreased negative feedback and subsequent low corticosteroid levels. Other manifestations include abdominal pain, diarrhea, headache, orthostatic hypotension, salt craving, and joint pain. Irritability and depression may occur in primary adrenal hypofunction.

Patients with secondary adrenocortical hypofunction may have many signs and symptoms similar to those of patients with Addison disease. However, they usually do not have hyperpigmented skin because ACTH levels are low.

Complications

Patients with adrenocortical insufficiency are at risk for acute adrenal insufficiency *(addisonian crisis)*.[23] It is a life-threatening emergency caused by insufficient adrenocortical hormones or a sudden sharp decrease in these hormones. Triggers of addisonian crisis is include (1) stress (e.g., infection, surgery), (2) sudden withdrawal of corticosteroid hormone therapy, (3) adrenal surgery, or (4) sudden pituitary gland destruction.

During acute adrenal insufficiency, the patient has severe manifestations of glucocorticoid and mineralocorticoid deficiencies. These include hypotension, tachycardia, dehydration, hyponatremia, hyperkalemia, hypoglycemia, fever, weakness, and confusion. Hypotension may lead to shock. Circulatory collapse from adrenal insufficiency is often unresponsive to the usual treatment (vasopressors and fluid replacement). GI manifestations include severe vomiting, diarrhea, and pain in the abdomen. Pain may occur in the lower back and legs.

Diagnostic Studies

The ACTH stimulation test is a common test to diagnose adrenal insufficiency. Baseline cortisol and ACTH levels are measured, and the patient is given an IV injection of synthetic ACTH (cosyntropin). Cortisol and ACTH levels are rechecked after 30 and 60 minutes. The normal response is a rise in blood cortisol levels. People with Addison disease have little or no increase in cortisol levels. Those with primary adrenal insufficiency have a high ACTH level.

When the response to the ACTH test is abnormal, a corticotropin-releasing hormone (CRH) stimulation test may be done. The patient is given an IV injection of synthetic CRH, and blood is taken after 30 and 60 minutes. Those with Addison disease have high ACTH levels but no cortisol. People with secondary adrenal insufficiency from pituitary or hypothalamus problems do not make ACTH or have a delayed response.

Other abnormal laboratory findings may include hyperkalemia, hypochloremia, hyponatremia, hypoglycemia, anemia, and increased BUN levels. An ECG may show low voltage and peaked T waves caused by hyperkalemia. CT scans and MRI can identify other causes, including tumors, fungal infections, tuberculosis, or adrenal calcification.

Interprofessional and Nursing Care

Treatment focuses on managing the underlying cause when possible. The mainstay is often lifelong hormone therapy with glucocorticoids and mineralocorticoids (Table 54.19). Overall, patients who take their medications consistently can expect a normal life expectancy. Hydrocortisone, the most common form of hormone therapy, has both glucocorticoid and mineralocorticoid properties. Mineralocorticoids are replaced with fludrocortisone. Women need androgen replacement with dehydroepiandrosterone (DHEA) as their only source of androgen production is the adrenal glands. Increased salt is added to the diet.

As a nurse, you have a key role in the long-term management of Addison disease. The serious nature of the disease and the need for lifelong hormone therapy necessitate a comprehensive teaching plan. Table 54.20 outlines the major areas to include in a teaching plan.

Glucocorticoids are usually given in divided doses, two-thirds in the morning and one-third in the afternoon. Mineralocorticoids are given once daily, preferably in the morning. This schedule reflects normal circadian rhythm in

TABLE 54.19 Interprofessional Care

Addison Disease

Diagnostic Assessment

- History and physical assessment
- ACTH stimulation test
- Serum cortisol and ACTH
- Urine cortisol and aldosterone
- CRH suppression test
- Serum electrolytes
- CT scan, MRI

Management

- Daily glucocorticoid (e.g., prednisone, hydrocortisone) replacement (two-thirds on awakening in morning, one-third in late afternoon)
- Daily mineralocorticoid (fludrocortisone) in morning
- ↑ Salt in the diet
- Androgen replacement with dehydroepiandrosterone (DHEA) for women
- Salt additives for excess heat or humidity
- ↑ Doses of glucocorticoid for stress situations (e.g., surgery, hospitalization)

TABLE 54.20 PATIENT & CAREGIVER TEACHING

Addison Disease

Include the following information in the teaching plan for the patient with Addison disease and the caregiver:

1. Names, dosages, and actions of drugs
2. Symptoms of overdosage and underdosage
3. Conditions requiring increased dosage (e.g., trauma, infection, surgery, emotional crisis)
4. Action to take related to changes in medication
   - Increased dose of corticosteroid
   - Self-administration of large dose of corticosteroid IM
   - Consult with HCP
5. Preventing infection and need for prompt and vigorous treatment of existing infections
6. Need for lifelong replacement therapy
7. Need for lifelong medical supervision
8. Need to carry medical identification
9. Fall prevention
10. Adverse effects of corticosteroid therapy and prevention techniques
11. Special instruction for patients with diabetes and management of glucose when taking corticosteroids

endogenous hormone secretion and decreases the side effects of corticosteroid therapy. Teach patients using mineralocorticoid therapy how to take their BP, increase salt intake, and report any significant changes to the HCP.

The patient with Addison disease needs an increased dosage of corticosteroids in stressful situations to prevent addisonian crisis. Examples of situations requiring corticosteroid adjustment are fever, influenza, tooth extraction, and rigorous physical activity, such as playing sports on a hot day or distance running. Provide written and verbal instructions on when to change the dose. Review stress management techniques. If vomiting or diarrhea occurs, as may happen with gastroenteritis, the patient should notify the HCP at once. They may need electrolyte replacement and IV cortisol administration.

Teach patients the signs and symptoms of corticosteroid deficiency and excess (Cushing syndrome) and to report these signs to the HCP so that the drug dose can be adjusted. The patient should wear an identification bracelet (Medic Alert) and carry a wallet card saying they have Addison disease so that appropriate therapy can be started in an emergency. The patient should carry an emergency kit with 100 mg of IM hydrocortisone and syringes. Teach the patient and caregiver how to give an IM injection.

When the patient with Addison disease is hospitalized, nursing care focuses on monitoring the patient while correcting fluid and electrolyte balance. Assess vital signs and neurologic status. Monitor for signs of fluid volume deficit and electrolyte imbalance. Obtain a daily weight, and keep an accurate intake and output record. Take a medication history to see if there are drugs that can interact with corticosteroids. These drugs include oral hypoglycemics, cardiac glycosides, oral contraceptives, anticoagulants, and NSAIDs.

Note changes in BP, weight gain, weakness, and other manifestations of Cushing syndrome. Guard the patient against exposure to infection and help with daily hygiene. Protect the patient from noise, light, and environmental temperature extremes. The patient cannot cope with these stresses because of the inability to make corticosteroids.

Addisonian crisis is a life-threatening emergency requiring aggressive management. Treatment is directed toward shock management and high-dose hydrocortisone replacement. Large volumes of IV fluid are given to reverse hypotension and electrolyte imbalances until BP returns to normal.

CORTICOSTEROID THERAPY

Corticosteroids are effective in treating many problems (Table 54.21). However, long-term corticosteroid therapy at therapeutic doses often leads to serious complications and side effects (Table 54.22). For this reason, corticosteroid therapy is not recommended for minor chronic conditions. Therapy should be reserved for problems that have a risk for death, permanent loss of function, or for which short-term therapy is likely to produce remission or recovery. We must weigh the potential benefits of treatment against the risks.

CHECK YOUR PRACTICE

You are working in the outpatient clinic. Your 30-year-old female patient has Cushing syndrome from high doses of prednisone use for autoimmune hepatitis. At her office visit today, she tells you, "I haven't been taking my prednisone because I'm gaining weight and I'm not happy with the way I look."

- How would you respond to her?

A beneficial effect of corticosteroids in one situation may be a harmful one in another. For example, decreasing inflammation in arthritis is an important therapeutic effect, but increasing the risk for infection is a harmful effect. Suppressing inflammation and the immune response may help save lives in persons with

TABLE 54.21 Drug Therapy

Diseases/Disorders Treated With Corticosteroids

Hormone Therapy
- Adrenal insufficiency
- Congenital adrenal hyperplasia

Therapeutic Effect

Allergic Reactions
- Anaphylaxis
- Bee stings
- Contact dermatitis
- Drug reactions
- Serum sickness
- Urticaria

Connective Tissue Problems
- Mixed connective tissue disorders
- Polymyositis
- Polyarteritis nodosa
- Rheumatoid arthritis
- Systemic lupus erythematosus

Endocrine Problems
- Hypercalcemia
- Hashimoto thyroiditis
- Thyrotoxicosis

GI Problems
- Inflammatory bowel disease
- Celiac disease

Liver Problems
- Alcoholic hepatitis
- Autoimmune hepatitis

Neurologic Problems
- Cerebral edema and increased intracranial pressure
- Head trauma

Pulmonary Diseases
- Aspiration pneumonia
- Asthma
- Chronic obstructive pulmonary disease

Other Problems
- Skin diseases
- Cancer, leukemia, lymphoma
- Immunosuppression
- Inflammation
- Nephrotic syndrome

DRUG ALERT

Corticosteroids
- Teach the patient not to abruptly stop these drugs.
- Monitor the patient for signs of infection.
- Have patients with diabetes closely monitor glucose.

TABLE 54.22 Drug Therapy

Effects and Side Effects of Corticosteroids
- Delayed wound healing with ↑ risk for wound dehiscence
- Fat from extremities redistributed to trunk and face
- Glucose intolerance
- Hypertension with ↑ risk for heart failure
- Hypocalcemia related to anti–vitamin D effect
- Hypokalemia
- ↑ Risk for infection
- Infection develops more rapidly and spreads more widely
- Mood and behavior changes
- Pathologic fractures, especially compression fractures of the vertebrae (osteoporosis)
- Peptic ulcer disease
- Pituitary ACTH synthesis suppressed
- Skeletal muscle atrophy and weakness
- Suppressed inflammatory response

anaphylaxis and in those receiving an organ transplant, but it can activate latent tuberculosis and increase the risk for infection and cancer. The vasopressive effect of corticosteroids is critical in allowing a person to function in stressful situations but can cause hypertension when used for drug therapy.

Detailed teaching is needed to ensure patient adherence. Corticosteroids given as nonreplacement therapy are taken once daily or once every other day. They should be taken early in the morning with food to decrease GI irritation. Because exogenous corticosteroid use may suppress endogenous ACTH and cortisol (suppression is time and dose dependent), emphasize the danger of abruptly stopping corticosteroid therapy to patients and caregivers. Corticosteroids taken for longer than 1 week will suppress adrenal production, and oral corticosteroids must be tapered. Ensure that higher doses of corticosteroids are prescribed in situations of physical or emotional stress.

Corticosteroid-induced osteoporosis is an important concern for patients who receive corticosteroid treatment for long periods (longer than 3 months).[24] Therapies to reduce bone resorption include increased calcium intake, vitamin D supplements, bisphosphonates (e.g., alendronate), and a low-impact exercise program. Measures to minimize the side effects and complications of corticosteroid therapy are outlined in Table 54.23.

HYPERALDOSTERONISM

Hyperaldosteronism (Conn syndrome) is characterized by excess aldosterone secretion. The main effects of aldosterone are (1) sodium retention and (2) potassium and hydrogen ion excretion. Thus the hallmark of this disease is hypertension with hypokalemic alkalosis. *Primary hyperaldosteronism* (PA) is most often caused by a small solitary adrenocortical adenoma. Sometimes, multiple lesions are involved and are associated with bilateral adrenal hyperplasia.

PA affects women more than men and usually occurs between 30 and 50 years of age. A genetic link has been found in some patients. PA causes up to 2% of all cases of hypertension. *Secondary hyperaldosteronism* occurs in response to a nonadrenal cause of increased aldosterone levels, such as renal artery stenosis, renin-secreting tumors, and chronic kidney disease.

Increased aldosterone levels cause sodium retention and potassium excretion. Sodium retention leads to hypernatremia, hypertension, and headache. Edema does not usually occur because the rate of sodium excretion increases, preventing more severe sodium retention. Potassium wasting leads to hypokalemia, which causes generalized muscle weakness, fatigue, dysrhythmias, glucose intolerance, and metabolic alkalosis that may lead to tetany.

Hyperaldosteronism should be suspected in hypertensive patients with hypokalemia who are not being treated with diuretics. PA causes increased sodium and aldosterone levels, decreased potassium levels, and decreased renin activity. A CT scan or MRI can detect an adenoma. If a tumor is not found, plasma 18-hydroxycorticosterone is measured after overnight bed rest. A level greater than 50 ng/dL indicates an adenoma.

Interprofessional and Nursing Care

The preferred treatment for PA is surgical removal of the adenoma (adrenalectomy).[25] A laparoscopic approach is most often used. Before surgery, patients should receive potassium-sparing diuretics (e.g., spironolactone) and antihypertensive agents to

TABLE 54.23 PATIENT & CAREGIVER TEACHING

Corticosteroid Therapy

Include the following instructions when teaching the patient and caregiver to manage corticosteroid therapy:

1. Follow a diet high in protein, calcium (at least 1500 mg/day), and potassium and low in fat and concentrated simple carbohydrates, such as sugar, syrups, and candy.
2. Ensure adequate rest and sleep, such as daily naps and avoiding caffeine late in the day.
3. Take part in an exercise program to help maintain bone integrity.
4. Recognize edema and ways to restrict sodium intake to <2000 mg/day if edema occurs.
5. Monitor glucose levels and recognize symptoms of hyperglycemia (e.g., polydipsia, polyuria, blurred vision). Report hyperglycemic symptoms or capillary glucose levels >120 mg/dL (10 mmol/L).
6. Notify HCP if heartburn after meals or epigastric pain that is not relieved by antacids occurs.
7. See an eye specialist yearly to assess for cataracts.
8. Use safety measures, such as getting up slowly from bed or a chair and good lighting, to avoid accidental injury.
9. Maintain appropriate hygiene practices.
10. Avoid contact with persons with colds or other contagious illnesses to prevent infection.
11. Inform all HCPs about long-term corticosteroid use.
12. Recognize need for higher doses of corticosteroids in times of physical and emotional stress.
13. Never abruptly stop the corticosteroids because this could lead to addisonian crisis and death.

normalize potassium levels and BP. Spironolactone and eplerenone block the binding of aldosterone to the mineralocorticoid receptor in the terminal distal tubules and collecting ducts of the kidney, thus increasing sodium and water excretion and potassium retention. Oral potassium supplements and sodium restrictions may be needed. However, potassium supplementation and a potassium-sparing diuretic should not be started simultaneously because of the risk for hyperkalemia.

Patients with bilateral adrenal hyperplasia are treated with a potassium-sparing diuretic. Calcium channel blockers may be used to control BP. Dexamethasone may be used to decrease adrenal hyperplasia.

Nursing care includes careful assessment of fluid and electrolyte balance (especially potassium) and cardiovascular status. Monitor BP frequently before and after surgery because unilateral adrenalectomy is successful in controlling hypertension in only 80% of patients with an adenoma. Teach patients receiving spironolactone about the possible side effects of gynecomastia, impotence, and menstrual disorders, as well as the signs and symptoms of hypokalemia and hyperkalemia. Review how to monitor their BP and the need for frequent monitoring. Stress the need for continued health care.

ADRENAL MEDULLA PROBLEMS

PHEOCHROMOCYTOMA

Pheochromocytoma is a rare condition caused by a tumor in the adrenal medulla. It affects the chromaffin cells, resulting in excess production of catecholamines (epinephrine, norepinephrine). The most dangerous immediate effect is severe hypertension. If left untreated, it may lead to encephalopathy, diabetes, cardiomyopathy, multiple organ failure, and death. It most often occurs in young to middle-aged adults. Pheochromocytoma may be inherited in persons with MEN.

The most striking findings are severe, episodic hypertension accompanied by severe, pounding headache; tachycardia with palpitations; profuse sweating; and unexplained abdominal or chest pain. Attacks can be induced by direct trauma, mechanical pressure to the tumor, stress (e.g., surgery, exercise, defecation, sexual intercourse, alcohol use, smoking), or many drugs, including antihypertensives, opioids, radiologic contrast media, and tricyclic antidepressants. Attacks can last from a few minutes to several hours.

The simplest and most reliable diagnostic test is measurement of urinary fractionated metanephrines (catecholamine metabolites) and fractionated catecholamines and creatinine, usually done as a 24-hour urine collection. [26] Values are increased in at least 95% of persons with pheochromocytoma. Serum catecholamines may be increased during an "attack." CT scans and MRI can detect tumors. Do not palpate the abdomen of a patient with suspected pheochromocytoma. It may cause the sudden release of catecholamines and severe hypertension.

Interprofessional and Nursing Care

The main treatment is surgical removal of the tumor. Treatment with α- and β-adrenergic receptor blockers is needed before surgery to control BP and prevent an intraoperative hypertensive crisis. Therapy begins with an α-adrenergic receptor blocker (e.g., doxazosin, prazosin, phenoxybenzamine) 10 to 14 days before surgery to reduce BP. After adequate α-adrenergic blockade, β-adrenergic receptor blockers (e.g., propranolol) are used to decrease tachycardia and dysrhythmias. If β-blockers are started too early, unopposed α-adrenergic stimulation can cause a hypertensive crisis. Therapy can cause orthostatic hypotension. Teach the patient to change positions slowly.

Surgery is usually done using a laparoscopic approach. Removing the adrenal tumor often cures the hypertension, but it does persist in about 10% to 30% of patients. If surgery is not an option, metyrosine (Demser) can decrease catecholamine production by the tumor.

Case finding is an important nursing role. The diagnosis of pheochromocytoma is often missed. Any patient with hypertension and symptoms of sympathoadrenal stimulation should be referred to an HCP. Assess for the classic triad of symptoms of pheochromocytoma: severe pounding headache, tachycardia, and profuse sweating. Monitor the BP often if the patient is having an "attack."

Make the patient as comfortable as possible. Monitor glucose levels to assess for diabetes. Patients need rest, proper nutrition, and emotional support during this period. Surgical care is similar to that for any patient undergoing adrenalectomy. Note that BP fluctuations from catecholamine excesses tend to be severe and must be carefully monitored. Emphasize the importance of follow-up and routine BP monitoring because hypertension may persist even when the tumor is removed.

Case Study

Graves Disease

(© Hemera Technologies/AbleStock.com/Thinkstock.)

Patient Profile

R.D., a 52-year-old woman, was admitted to the hospital with a high fever. No infection is found. Based upon her history, assessment, and laboratory findings, the HCP diagnosed R.D. with Graves disease.

Subjective Data

- Reports recent job loss because she is no longer able to tolerate work-related stress
- Symptoms include fatigue, unintentional weight loss, insomnia, palpitations, vision problems, sweating, heat intolerance

Objective Data

Physical Assessment

- Fever of 104°F (40°C)
- BP of 150/80 mm Hg, pulse of 132 beats/min, and respiratory rate of 26 breaths/min
- Hot, moist skin
- Fine tremors of the hands
- 4+ deep tendon reflexes and muscle strength of 1 to 2 out of 5
- Swelling to the anterior neck
- Excessive tearing of the eyes

Interprofessional Care

- Subtotal thyroidectomy planned for 2 months later
- Started on methimazole (Tapazole) and propranolol (Inderal LA)

Discussion Questions

1. ***Recognize***: Explain the cause of R.D.'s symptoms.
2. ***Analyze***: What diagnostic studies were probably ordered? What would the results have been to establish the diagnosis of Graves disease?
3. ***Analyze***: Why was surgery delayed?
4. ***Prioritize:*** What is the interprofessional team's top priority at this time for R.D.?
5. ***Prioritize:*** Based on the assessment data presented, what are the priority clinical problems?
6. ***Plan:*** What are her teaching needs at this time?
7. ***Act:*** What teaching will you provide after surgery so that R.D. can successfully self-manage her care?
8. ***Evaluate:*** What is the expected outcome of drug therapy?
9. ***Safety:*** Why is R.D. counseled to give up her long-standing cigarette smoking habit?

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Which interventions would the nurse include in the care for a patient who underwent transsphenoidal excision of the pituitary gland? (*select all that apply*)
   - **a.** Frequent monitoring of serum and urine osmolarity
   - **b.** Assessment of visual acuity and extraocular movement
   - **c.** Keeping the patient in a recumbent position at all times
   - **d.** Teaching the patient about the need for lifelong hormone therapy
   - **e.** Instructing the patient to blow their nose frequently to relieve cerebral pressure
2. A patient with lung cancer develops SIADH. Which are anticipated findings?
   - **a.** Hypernatremia and hyperkalemia
   - **b.** Thirst, muscle cramping, and headache
   - **c.** High urine output, weight gain, and vomiting
   - **d.** Weight gain and decreased glomerular filtration rate
3. The nurse reviews the laboratory results of a patient with primary hypothyroidism. The nurse would expect to find
   - **a.** a low TSH.
   - **b.** an elevated TSH.
   - **c.** an elevated free T_4.
   - **d.** decreased low-density lipoproteins (LDLs).
4. After thyroid surgery, the nurse suspects damage of the parathyroid glands when the patient develops
   - **a.** hyperthermia and severe tachycardia.
   - **b.** hypercalcemia and shortness of breath.
   - **c.** laryngospasms and tingling in the hands and feet
   - **d.** hypophosphatemia, hypertension, vomiting, and chest pain.
5. The nurse teaching the patient with Addison disease determines additional teaching is needed when the patient states
   - **a.** "I should take my prednisone twice a day."
   - **b.** "I should call my HCP if I develop vomiting or diarrhea."
   - **c.** "If I get influenza, I should decrease my prednisone dose."
   - **d.** "I will pick up my emergency hydrocortisone from the pharmacy."
6. A nursing priority for a patient who underwent removal of a pheochromocytoma includes
   - **a.** assessing for weight gain.
   - **b.** administering IV calcium.
   - **c.** close monitoring of blood pressure.
   - **d.** restricting fluid and sodium intake.
7. To control the side effects of corticosteroid therapy, the nurse teaches the patient who is taking corticosteroids to
   - **a.** limit calcium intake.
   - **b.** perform glucose monitoring for hyperglycemia.
   - **c.** avoid immunizations due to high risk for infections.
   - **d.** stop steroids immediately if the patient gains weight.

1. a, b, d; 2. b; 3. b; 4. c; 5. c; 6. c; 7. b.

Assessment: Reproductive System

Ashton T. Strachan

http://evolve.elsevier.com/Lewis/medsurg/

CONCEPTUAL FOCUS

Hormonal Regulation
Reproduction
Sexuality

LEARNING OUTCOMES

1. Describe the structures and functions of the male and female reproductive systems.
2. Outline the functions of the major hormones essential for the functioning of the male and female reproductive systems.
3. Explain the physiologic changes during the stages of a sexual response.
4. Link the age-related changes of the reproductive system to the differences in assessment findings.
5. Obtain significant subjective and objective data related to the reproductive system and information about sexual function.
6. Perform a physical assessment of the reproductive system using the appropriate techniques.
7. Distinguish normal from common abnormal findings of a physical assessment of the reproductive system.
8. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the reproductive system.

KEY TERMS

amenorrhea
epididymis
estrogen
gonads
menarche
menopause
menstrual cycle
progesterone
spermatogenesis
testosterone
uterus
vulva

STRUCTURES AND FUNCTIONS OF MALE AND FEMALE REPRODUCTIVE SYSTEMS

The male and female reproductive systems consist of primary (essential) organs and secondary (accessory) organs. The primary reproductive organs are the **gonads.** The female gonads are the ovaries. The male gonads are the testes. The main purpose of the gonads is secretion of hormones and production of gametes (ova and sperm, sex cells that unite during fertilization to form a new cell called a *zygote*). Secondary organs begin their maturity at puberty under the influence of sex hormones. They are responsible for (1) transporting and nourishing the ova (eggs) and sperm, and (2) preserving and protecting the fertilized ova.

Male Reproductive System

The 3 main roles of the male reproductive system are (1) sperm production and transportation, (2) deposition of sperm in the female reproductive tract, and (3) hormone secretion. The primary male organs are the testes. Secondary organs include ducts (epididymis, ductus deferens, ejaculatory duct, urethra), sex glands (prostate gland, Cowper glands, seminal vesicles), and the external genitalia (scrotum, penis) (Fig. 55.1).

Testes

The paired testes are ovoid, smooth, firm organs. They measure 1.4 to 2.2 in (3.5 to 5.6 cm) long and 0.8 to 1.2 in (2 to 3 cm) wide. They lie within the scrotum. It is a loose protective sac composed of a thin outer layer of skin over a tough connective tissue layer. Within the testes, coiled structures, called the seminiferous tubules, form *spermatozoa* (immature sperm). The process of sperm production is called **spermatogenesis.** Males make sperm throughout their reproductive life cycle. Interstitial cells lie between the seminiferous tubules. These cells make the male sex hormone, testosterone.

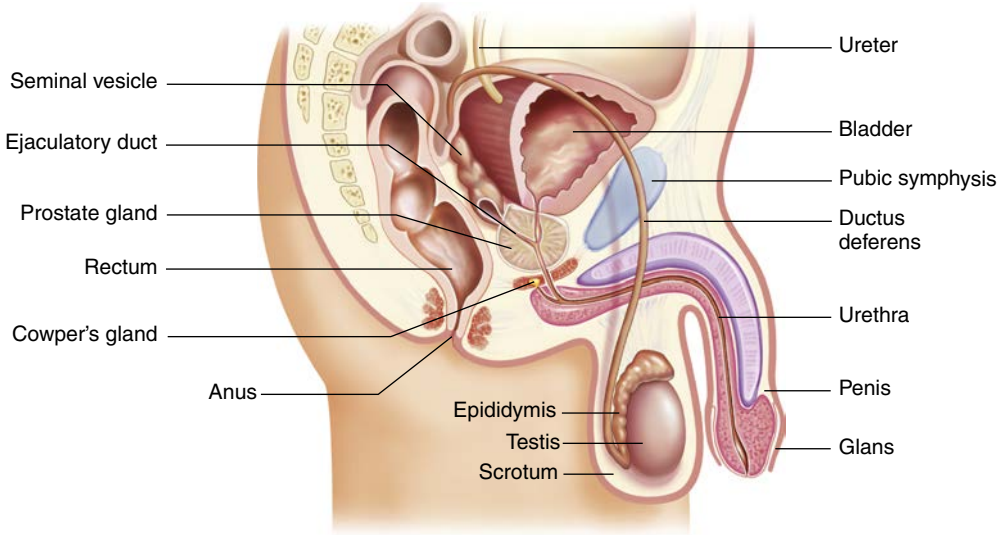

Fig. 55.1 Male reproductive tract. (Modified from Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.)

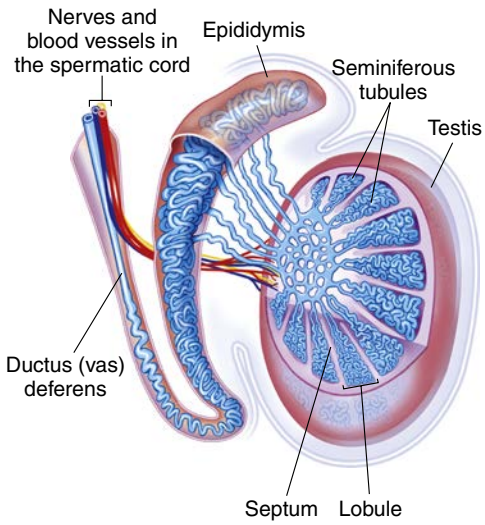

Fig. 55.2 Seminiferous tubules, testis, epididymis, and ductus (vas) deferens in the male. (Modified from Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.)

Ducts

Sperm formed in the seminiferous tubules move through a series of ducts. These ducts transport sperm from the testes to the outside of the body. As sperm exit the testes, they enter and pass through the epididymis, ductus deferens, ejaculatory duct, and urethra.

The **epididymis** is a comma-shaped structure found behind and on top of each testis within the scrotum (Figs. 55.1 and 55.2). It is a long, tightly coiled structure that, uncoiled, measures about 20 ft in length.[1] The epididymis transports sperm as they mature. Sperm exit the epididymis through a long, thick tube called the *ductus deferens*.

The ductus deferens (also called the *vas deferens*) is continuous with the epididymis within the scrotal sac. It travels upward through the scrotum and continues through the inguinal ring into the abdominal cavity. The spermatic cord is composed of a connective tissue sheath that encloses the ductus deferens, arteries, veins, nerves, and lymph vessels as it ascends through the inguinal canal (Fig. 55.2). In the abdominal cavity, the ductus deferens travels up, over, and behind the bladder. Behind the bladder, the ductus deferens joins the seminal vesicle to form the ejaculatory duct (Fig. 55.1).

The ejaculatory duct passes downward through the prostate gland, connecting with the urethra. The urethra extends from the bladder, through the prostate, and ends in a slit-like opening (the meatus) on the ventral side of the *glans,* the tip of the penis. During ejaculation, sperm travel through the urethra and out of the penis.

Glands

The seminal vesicles, prostate gland, and Cowper (bulbourethral) glands are the accessory glands. These glands make and secrete seminal fluid *(semen),* which surrounds the sperm and forms the *ejaculate.* The ejaculate fluid serves as a medium for the transport of sperm. It creates an alkaline, nutritious environment that promotes sperm motility and survival.

The seminal vesicles lie behind the bladder, between the bladder and rectum. The ducts of the seminal vesicles fuse with the ductus deferens to form the ejaculatory ducts. They enter the prostate gland, which lies beneath the bladder. Its posterior surface is in contact with the rectal wall. The prostate normally measures 0.8 in (2 cm) wide and 1.2 in (3 cm) long. It is divided into right and left lateral lobes and an anteroposterior median lobe. Cowper glands lie on each side of the urethra and slightly behind it, just below the prostate. The ducts of these glands enter directly into the urethra.

External Genitalia

The external male genitalia consist of the penis and scrotum. The penis consists of a shaft and tip, called the *glans.* The glans is covered by a fold of skin, the prepuce (or foreskin), that forms at the junction of the glans and shaft of the penis. In circumcised males, the prepuce has been removed. The shaft consists

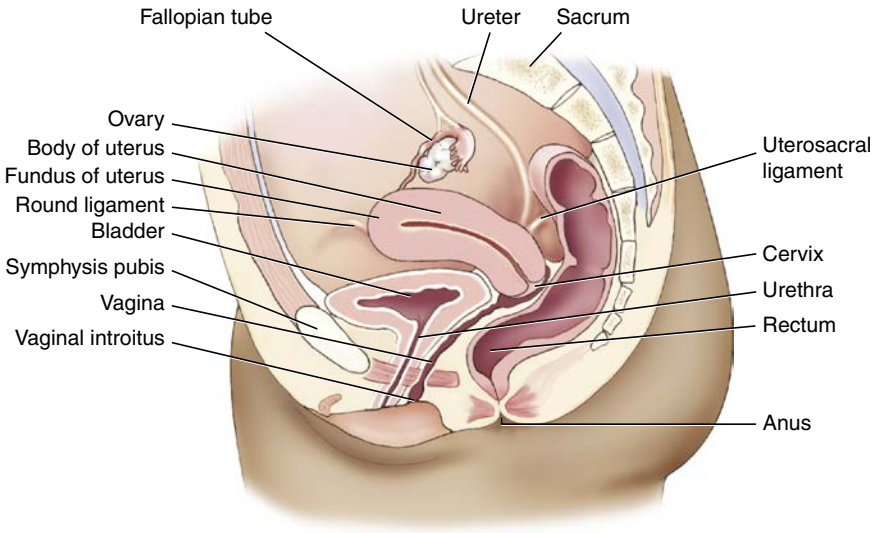

Fig. 55.3 Female reproductive tract. (Modified from McKenry L, Tessier E, Hogan M: *Mosby's pharmacology in nursing,* St Louis, 2006, Mosby.)

of erectile tissue composed of the corpus cavernosum, corpus spongiosum (fibrous sheath that encases the erectile tissue), and urethra. The skin covering the penis is thin, loose, and hairless.

Female Reproductive System

The 3 main roles of the female reproductive system are (1) ova production, (2) hormone secretion, and (3) protect and facilitate the development of the fetus in a pregnant female. The primary female organs are the paired ovaries. Secondary organs include the ducts (fallopian tubes), uterus, vagina, sex glands (Bartholin glands, breasts), and external genitalia (vulva).

Pelvic Organs

Ovaries. The ovaries are found on either side of the uterus, just behind and below the fallopian tubes (Fig. 55.3). The almond-shaped ovaries are firm and solid. They are around 0.6 in (1.5 cm) wide and 1.2 in (3 cm) long. Their functions include ovulation and secretion of the 2 major reproductive hormones: estrogen and progesterone.

The outer zone of the ovary has follicles with germ cells, or *oocytes.* Each follicle contains a primordial (immature) oocyte surrounded by granulosa and theca cells. These 2 layers protect and nourish the oocyte until the follicle reaches maturity and ovulation occurs. However, not all follicles reach maturity. In a process termed *atresia,* most of the immature follicles become smaller and are reabsorbed by the body. Thus, the number of follicles declines from 700,000 at birth to around 300,000 at *menarche* (first menstruation).[2] This is the female's lifetime supply of sex cells. As a woman ages, the number and quality of oocytes decline. A normal healthy woman releases around 300 to 500 oocytes by ovulation during the reproductive years.[3]

Fallopian tubes. The fallopian tubes transport the ovum toward the uterus, facilitating fertilization or implantation. The tubes are uterine appendages that end by curling around the ovary. The distal ends of the fallopian tubes consist of fingerlike projections called *fimbriae.* They sweep the ovum from the ruptured ovarian follicle (ovulation) into the fallopian tube. The tubes, which average 4.8 in (12 cm) in length, extend from the fimbriae to the superior lateral borders of the uterus.

Normally, each month during a woman's reproductive years, 1 ovarian follicle reaches maturity. That ovum is ovulated, or expelled, from the ovary through the stimulus of the gonadotropic hormones: follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The ovum then travels through a fallopian tube, where fertilization by sperm may occur (if sperm are present). Fertilization usually takes place within the outer one third of the fallopian tubes. An ovum can be fertilized up to 72 hours after its release.

Uterus. The **uterus** is a pear-shaped, hollow, muscular organ found between the bladder and rectum (Fig. 55.3). In the mature *nulliparous* (never pregnant) woman, the uterus is about 2.4 to 3.2 in (6 to 8 cm) long and 1.6 in (4 cm) wide. The uterine walls consist of an outer serosal layer, the *perimetrium;* a middle muscular layer, the *myometrium;* and an inner mucosal layer, the *endometrium.*

The uterus consists of the fundus, body (or corpus), and cervix (Fig. 55.3). The body makes up about 80% of the uterus. It connects with the cervix at the isthmus, or neck. The cervix is the lower part of the uterus. It projects into the anterior wall of the vaginal canal. It makes up about 15% to 20% of the uterus in the nulliparous female. The cervix consists of the *ectocervix,* the outer part that protrudes into the vagina, and the *endocervix,* the canal in the opening of the cervix. The cervical canal is 0.8 to 1.6 in (2 to 4 cm) long. The opening of the cervix is the *cervical os* (Fig. 55.4).

The ectocervix is covered with squamous epithelial cells. This gives it a smooth, pinkish appearance. The endocervix is lined with columnar epithelial cells, which give it a rough, reddened appearance. The junction at which the 2 types of epithelial cells (squamous and columnar) meet is the *squamocolumnar junction* (Fig. 55.4). Cells sampled from the squamocolumnar junction are examined as part of a Papanicolaou (Pap) test, which is part of cervical cancer screening.

The cervical os is relatively tightly closed. It does allow for menses to be expelled and sperm to enter the uterus. Mucus made by the cervix (under the influence of estrogen) facilitates the entrance of sperm into the uterus. Under normal conditions, the cervical mucus becomes watery, stretchy, and more abundant at ovulation. The postovulatory cervical mucus, under the influence of progesterone, is thick and inhibits sperm passage. The cervix can stretch to allow passage of a fetus during the birth process. The columnar epithelium, under hormonal influence, provides elasticity during labor.

Vagina. The vagina is a tubular structure 3 to 4 in (7.6 to 10 cm) long. The anterior vaginal wall lies along the urethra and bladder. The posterior vaginal wall is next to the rectum. It is lined with squamous epithelium. In reproductive-age women, the vagina has multiple transverse folds called *rugae.* Vaginal secretions consist of cervical mucus, desquamated epithelium, and, during sexual stimulation, a watery secretion. These fluids help protect against vaginal infection. The muscular and erectile tissue of the vaginal walls allows enough dilation and contraction to accommodate the passage of the fetus during labor and penetration of the penis during intercourse.

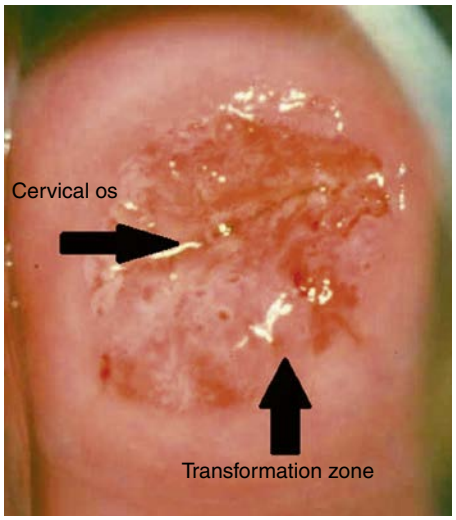

Fig. 55.4 Cervical os and squamocolumnar junction (transformation zone). (Courtesy Candy Tedschi, NP, Great Neck, NY.)

External Genitalia

The external part of the female reproductive system (Fig. 55.5) is often called the **vulva.** It consists of the mons pubis, labia majora, labia minora, vestibule, clitoris, urethral meatus, Skene glands, vaginal introitus (opening), and Bartholin glands.

The *mons pubis* is a fatty layer lying over the pubic bone. It is covered with coarse hair that lies in a triangular pattern. The labia majora are folds of adipose tissue that form the outer borders of the vulva. The hairless labia minora form the borders of the vaginal orifice and extend anteriorly to enclose the clitoris.

The *vestibule* is the space between the labia minora that is seen when they are held apart. It extends from the clitoris to the *posterior fourchette* (a mucous membrane band that forms the posterior ends of the labia minora). The perineum is the area between the vagina and anus. The vaginal introitus (vaginal opening) is surrounded by thin membranous tissue called the *hymen.* It is usually perforated and has many variations in shape. In the adult woman, the hymen usually appears as folds or hymenal tags *(carunculae myrtiformes).* It separates the external genitalia from the vagina.

The *clitoris* is erectile tissue that becomes engorged during sexual excitation. It lies anterior to the urethral meatus and the vaginal orifice. It is usually covered by the prepuce. Clitoral stimulation is an important part of sexual activity for many women.

Ducts of the Skene glands lie alongside the urinary meatus and correspond to the prostate gland in males. We think they help lubricate the urinary meatus. Bartholin glands are found at the posterior and lateral aspects of the vaginal orifice. They secrete a thin, mucoid material we think contributes slightly to lubrication during sexual intercourse. These glands are not usually palpable unless sebaceous-like cysts form or they are swollen from an infection, such as a sexually transmitted infection (STI). Bartholin glands correspond to Cowper glands in males.

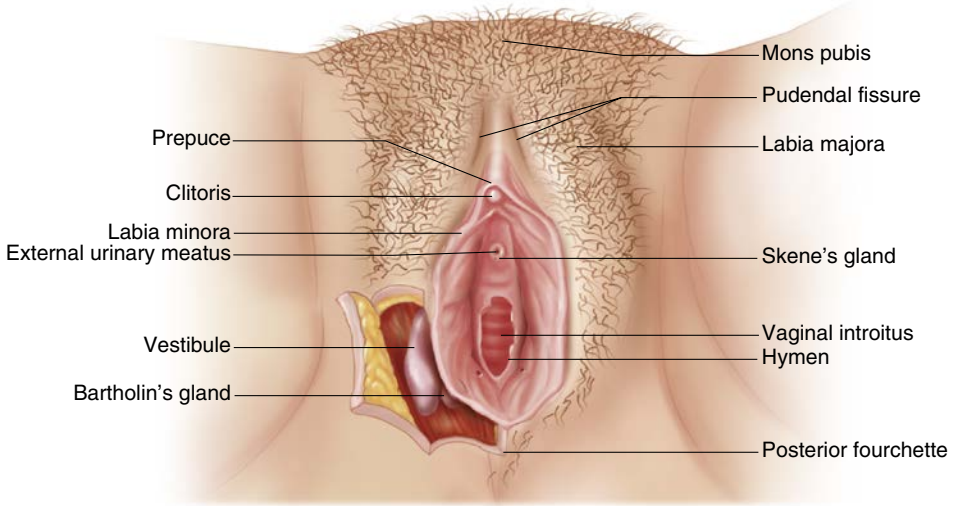

Fig. 55.5 External female genitalia. (Modified from Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.)

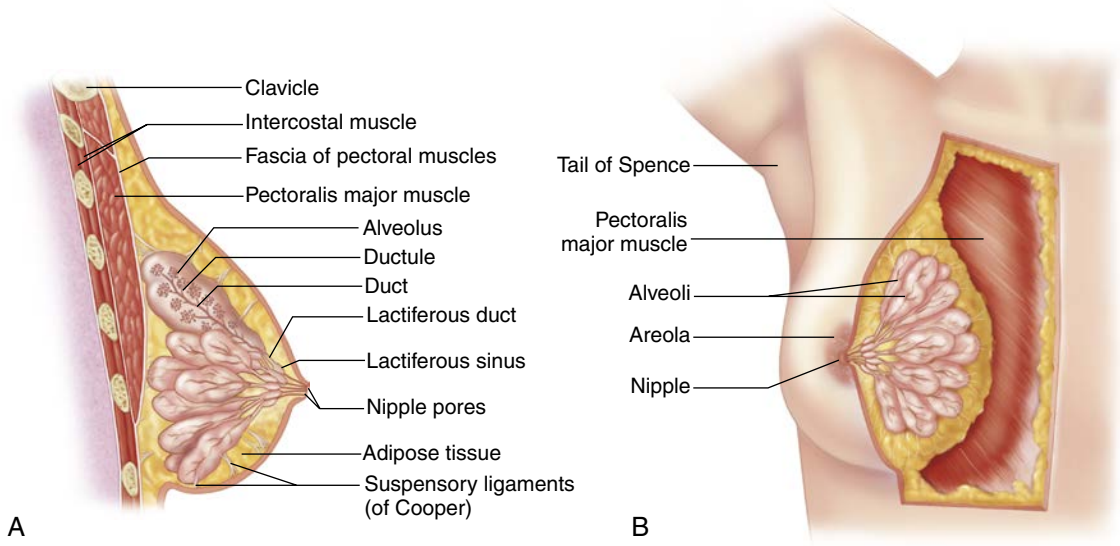

Fig. 55.6 The lactating female breast. (A) Glandular structures are anchored to the overlying skin and the pectoralis muscle by suspensory ligaments of Cooper. Each lobule of glandular tissue is drained by a lactiferous duct that eventually opens through the nipple. (B) Anterior view of a lactating breast. In nonlactating breasts, glandular tissue is less evident, with adipose tissue making up most of the breast. (Modified from Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.)

Breasts

The breasts are a secondary sex characteristic that develops during puberty in response to estrogen and progesterone. Cyclic hormonal changes lead to regular changes in breast tissue to prepare it for lactation when fertilization and pregnancy occur.

The breasts extend from the 2nd to the 6th ribs. The extension of breast tissue into the upper-outer quadrant into the axilla is an area referred to as the *tail of Spence* (Fig. 55.6). The fully mature breast is dome shaped and has a pigmented center called the *areola.* The areolar region contains Montgomery tubercles, which are similar to sebaceous glands. They help lubricate the nipple. During lactation, the alveoli secrete milk. The milk then flows into a ductal system and is transported to the lactiferous sinuses. The nipple has 15 to 20 tiny openings through which the milk flows during breastfeeding. The fibrous and fatty tissue that supports and separates the channels of the mammary duct system is responsible for the varying sizes and shapes of the breasts.

Neuroendocrine Regulation of Reproductive System

The hypothalamus, pituitary gland, and gonads secrete several hormones (Fig. 55.7). (Endocrine hormones are discussed in Chapter 52.) These hormones regulate the processes of ovulation, sperm formation, and fertilization, and the formation and function of the secondary sex characteristics. The hypothalamus secretes gonadotropin-releasing hormone (GnRH). GnRH stimulates the anterior pituitary gland to secrete its hormones, including FSH and LH. LH in males is sometimes called *interstitial cell–stimulating hormone (ICSH).* The gonadal hormones are estrogen, progesterone, and testosterone.

In women, FSH production stimulates the growth and maturity of the ovarian follicles necessary for ovulation. The mature follicle makes estrogen, which suppresses the release of FSH. Inhibin is another hormone secreted by the ovarian follicle. It

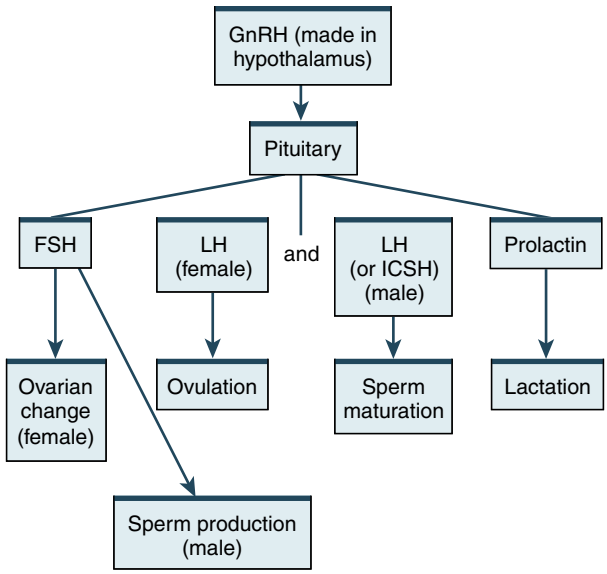

Fig. 55.7 Hypothalamic-pituitary-gonadal axis. Only the major pituitary hormone actions are depicted. *FSH,* Follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *ICSH,* interstitial cell–stimulating hormone; *LH,* luteinizing hormone.

inhibits GnRH and FSH secretion. In men, FSH stimulates the seminiferous tubules to make sperm.

LH contributes to the ovulatory process. It causes follicles to complete maturation and undergo ovulation. LH affects the development of a ruptured follicle (area where ovum exited during ovulation), which turns into a corpus luteum, which secretes progesterone. **Progesterone** plays a major role in the menstrual cycle, specifically in the secretory phase. It maintains the rich vascular state of the uterus in preparation for fertilization and implantation. Adequate progesterone is needed to maintain an implanted ovum. Like estrogen, progesterone

TABLE 55.1 Gonadal Feedback Mechanisms

Negative Feedback

Female

↓Estrogen → ↑GnRH (hypothalamus) → ↑ FSH (pituitary) → ↑ Estrogen (ovaries)

Male

↓Testosterone → ↑GnRH (hypothalamus) → ↑ FSH and LH (or ICSH) (pituitary) → ↑ Testosterone (testes)

Positive Feedback

↑Estrogen → ↑ GnRH (hypothalamus) → ↑ LH (pituitary)

FSH, Follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *ICSH,* interstitial cell–stimulating hormone; *LH,* luteinizing hormone.

is involved in the body changes associated with pregnancy. In men, LH triggers testosterone production by the interstitial cells of the testes and is essential for the full maturation of sperm.

In women, prolactin stimulates the development and growth of the mammary glands. During lactation, it initiates and maintains milk production. In men, prolactin has no known function.

In women the ovaries make the gonadal hormones, estrogen and progesterone. Small amounts of an estrogen precursor are also made in the adrenal cortices. **Estrogen** is essential to the development and maintenance of the secondary sex characteristics, proliferative phase of the menstrual cycle immediately after menstruation, and uterine changes essential to pregnancy. In men, most estrogen is made in the adrenal cortices. We do not understand the role of estrogen in men.

In men, the major gonadal hormone is testosterone, which is made by the testes. **Testosterone** is responsible for the development and maintenance of secondary sex characteristics and adequate spermatogenesis. In women, the adrenal glands and ovaries make small amounts of androgens.

The circulating levels of gonadal hormones are controlled mainly by a *negative feedback process*. Receptors within the hypothalamus and pituitary are sensitive to the circulating blood levels of the hormones (Table 55.1). Increased hormone levels stimulate a hypothalamic response to decrease the high circulating levels. Likewise, low circulating levels provoke a hypothalamic response that increases the low circulating levels. For example, low circulating testosterone levels stimulate the hypothalamus to secrete GnRH. This triggers the anterior pituitary to secrete greater amounts of FSH and LH, which in turn cause an increase in the testosterone production. The high level of testosterone signals a decrease in GnRH production, and thus FSH and LH.

In women, however, there is a slight variation in the control of gonadal hormones. The circulating levels are controlled through a combination of both a negative and positive feedback system. A *negative feedback control* mechanism exists similar to that described for men. Low circulating estrogen levels stimulate the hypothalamus to increase its production of GnRH. GnRH stimulates the pituitary to secrete greater amounts of

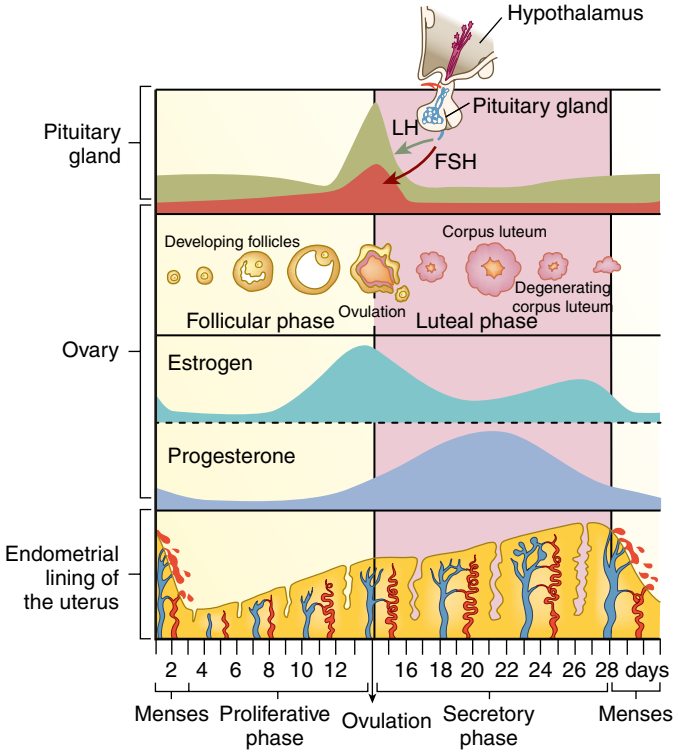

Fig. 55.8 Events of the menstrual cycle. The *lines* depict the changes in blood hormone levels, the development of the follicles, and the changes in the endometrium during the cycle. (Modified from Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.)

FSH and LH, resulting in increased estrogen production by the ovaries. Higher levels of circulating estrogen result in a decreasing secretion of GnRH and thus a decrease in the secretion of FSH by the pituitary.

Women also have a *positive feedback control* mechanism. Here, with increased levels of circulating estrogen, more GnRH is made, resulting in an increased level of LH from the pituitary. Likewise, low estrogen levels result in a lower level of LH.

Menarche

Menarche is the first episode of menstrual bleeding, indicating that a girl has reached puberty. Menarche usually occurs at around 12 to 13 years of age but can occur as early as 10 years of age in some girls. Menstrual cycles are often irregular for the first 1 to 2 years after menarche because of *anovulatory cycles* (cycles without ovulation).

Menstrual Cycle

The major functions of the ovaries are ovulation and the secretion of hormones. These functions are accomplished during the normal **menstrual cycle**, a monthly process mediated by the hormonal activity of the hypothalamus, pituitary gland, and ovaries. Menstruation occurs during each month in which an ovum is not fertilized (Fig. 55.8). The length of the menstrual cycle ranges from 21 to 35 days, with an average of 28 days. Most women have regular cycles. Irregular cycles may occur and can be due to a variety of factors, such as hormonal fluctuations, medications, or conditions, such as uterine fibroids. Table 55.2 describes characteristics of the menstrual cycle.

TABLE 55.2 Menstruation

Characteristic	Implications
Menarche	
• Occurs between ages 10 and 16 years • Average age at onset is 12–13 years	• Possible endocrine or developmental problem when delayed.
Interval	
• Usually is 21–35 days • Regular cycles as short as 17 days or as long as 45 days are considered normal if pattern is consistent for the person	• Keep track of periods via an app or calendar to identify menstrual cycle pattern • Expect some irregularity in perimenopausal period • Drugs (e.g., opioids, contraceptives) and stressful life events can result in missed periods
Duration	
• Menstrual flow generally lasts 2–8 days	• Pattern is fairly constant, but variations do exist
Amount	
• Menstrual flow varies from 20–80 mL per menses. Average is 30 mL • Amount varies among women and in same woman at different times • It is usually heaviest first 2 days	• Count pads or tampons used per day • Average tampon or pad (when completely saturated) absorbs 20–30 mL • Very heavy flow is indicated by complete soaking of 2 pads in 1–2 hr • Flow increases and then gradually decreases in perimenopausal period • IUD or drugs, such as anticoagulants and thiazides, can cause heavy menses • Women with uterine fibroids may have increased or heavy menses
Composition	
• Menstrual discharge is mixture of endometrium, blood, mucus, and vaginal cells • Dark red, less viscous than blood, and usually does not clot	• Clots indicate heavy flow or vaginal pooling

We divide the menstrual cycle into 3 phases. They are labeled in relation to uterine and ovarian changes: (1) the *proliferative*, or *follicular, phase*; (2) the *secretory*, or *luteal, phase*; and (3) the *menstrual*, or *ischemic, phase*. The menstrual cycle begins on the 1st day of menstruation. It usually lasts 4 to 6 days. The 1st day of the menstrual cycle is known as the last menstrual period (LMP). During menstruation, estrogen and progesterone levels are low, but FSH levels begin to increase. During the follicular phase, a single follicle matures fully under FSH stimulation. The mechanism that ensures that usually only 1 follicle reaches maturity is not known. The mature follicle stimulates estrogen production, causing a negative feedback with resulting decreased FSH secretion.

Although FSH stimulates the 1st stage of follicular maturation, complete maturation and ovulation occur only in the presence of LH. When estrogen levels peak on about the 12th day of the cycle, there is a surge of LH. This triggers ovulation 1 or 2 days later. After ovulation, LH promotes the development of the corpus luteum, a temporary functional cyst that forms with the ruptured follicle.

The fully developed corpus luteum continues to secrete estrogen and initiates progesterone secretion. If fertilization occurs, estrogen and progesterone continue to be secreted because of the continued activity of the corpus luteum from stimulation by human chorionic gonadotropin (hCG). If fertilization does not take place, menstruation occurs because of a decrease in estrogen production and progesterone withdrawal.

During the *follicular phase*, the endometrial lining of the uterus undergoes change. As more estrogen is made, the endometrial lining goes through proliferative changes, including an increase in the length of blood vessels and glandular tissue.

With ovulation and the resulting increased levels of progesterone, the *luteal* (or *secretory*) *phase* begins. If the corpus luteum regresses (when fertilization does not occur) and estrogen and progesterone levels fall, the endometrial lining can no longer be supported. As a result, the blood vessels contract, and tissue begins to slough (fall away). This sloughing results in menses and the start of the menstrual phase.

Menopause

Menopause is the physiologic cessation of menses from declining ovarian function. It is considered complete after 1 year of **amenorrhea** (absence of menstruation). Menopause is discussed in Chapter 58.

Phases of Sexual Response

The sexual response is a complex interplay of psychologic and physiologic phenomena. It is influenced by several variables (e.g., stress, illness). The changes that occur during sexual excitement are similar for men and women. Masters and Johnson described the sexual response in terms of the excitement, plateau, orgasmic, and resolution phases.[4]

Male Sexual Response

The penis and urethra are essential to the transport of sperm during intercourse. This transport is facilitated by penile erection in response to sexual stimulation during the *excitement phase*. Erection results from the filling of the large venous sinuses within the erectile tissue of the penis. In the flaccid state the sinuses hold only a small amount of blood. During an erection, they are congested with blood. Because the penis is richly endowed with sympathetic, parasympathetic, and pudendal nerve endings, it is readily stimulated to erection. The loose skin of the penis becomes taut from venous congestion. This tautness allows for easy insertion during penetrative sex.

As the man reaches the *plateau phase*, the erection is maintained. The penis increases in diameter from a slight increase in vasocongestion. Testicle size also increases. Sometimes the glans penis becomes reddish purple.

The contractions of the penile and urethral musculature during the *orgasmic phase* propel the sperm outward through the meatus. In this process, termed *ejaculation,* sperm are released into the ductus deferens. Sperm advance through the urethra, where fluids from the prostate and seminal vesicles are added to the ejaculate. The sperm continue their path through the urethra, receiving a small amount of fluid from the Cowper glands. They are finally ejaculated through the urinary meatus. *Orgasm* is characterized by the rapid release of vasocongestion and muscular tension through rhythmic contractions. This occurs primarily in the penis, prostate gland, and seminal vesicles. After ejaculation, a man enters the *resolution phase*. The penis undergoes involution, gradually returning to its unstimulated, flaccid state.

Female Sexual Response

The changes that occur in a woman during sexual excitation are similar to those in a man. In response to stimulation, the clitoris becomes congested and vaginal lubrication increases from secretions from the cervix, Bartholin glands, and vaginal walls. This initial response is the excitation phase.

As excitation is maintained in the plateau phase, the vagina expands, and the uterus is elevated. In the orgasmic phase, contractions occur in the uterus from the fundus to the lower uterine segment. There is a slight relaxation of the cervical os, which helps the entrance of the sperm, and rhythmic contractions of the vagina. Muscular tension is rapidly released through rhythmic contractions in the clitoris, vagina, and uterus. A resolution phase follows, in which these organs return to their preexcitation state. However, women do not have to go through the resolution (refractory) recovery state before they can be orgasmic again. They can be multiorgasmic without resolution between orgasms.

Gerontologic Considerations: Effects of Aging on Reproductive Systems

With advancing age, changes occur in the reproductive systems (Table 55.3). In women, many of these changes are related to decreased estrogen production due to menopause.[5] Decreased estrogen and other sex steroids in postmenopausal women causes breast and genital atrophy, reduced bone mass, and increased rate of atherosclerosis. Vaginal dryness may occur, which can lead to urogenital atrophy and changes in the composition of the vaginal *microbiome* (the aggregate of microorganisms and their genetic material).[6]

Testosterone levels decline in men as they age. Manifestations of this decline are more gradual in men. They can be physical, psychologic, or sexual. Changes include an increase in prostate size and a decrease in testosterone level, sperm production, muscle tone of the scrotum, and size and firmness of the testicles. Erectile dysfunction (ED) and sexual problems occur in some men because of these changes (Box 55.1).

Many factors affect sexuality in later life. Gradual changes occur in the sexual response. The cumulative effects of these changes, as well as the negative social attitude toward sexuality in older adults, can affect the sexual practices of older adults.

TABLE 55.3 GERONTOLOGIC ASSESSMENT DIFFERENCES

Reproductive Systems

Structure	Changes	Assessment Findings Abnormalities
Male		
Breasts	Enlargement	Gynecomastia (abnormal enlargement)
Penis	↓ Subcutaneous fat	Easily retractable foreskin (if uncircumcised) ↓ Size Fewer sustained erections
Prostate	Benign hyperplasia	Enlargement, urinary obstruction, incontinence
Testes	↓ Testosterone production	↓ Size, firmness
Female		
Breasts	↓ Subcutaneous fat, increased fibrous tissue, ↓ skin turgor	Less resilient, looser, more pendulous tissue ↓ Size Duct around nipple may feel like stringy strand
Ovaries	↓ Ovarian function	Nonpalpable ovaries are normal postmenopause
Urethra	↓ Muscle tone, mucosal thinning	Possible UTIs, painful urination (dysuria), urgency, frequency, incontinence
Uterus	↓ Thickness of myometrium	Uterine prolapse
Vagina	Tissue atrophy, ↓ muscle tone, alkaline pH	Mucosa becomes pale, dry, smooth and thins Vagina narrows and shortens
Vulva	↓ Skin turgor	Atrophy ↓ Amount of pubic hair ↓ Size of clitoris and labia

BOX 55.1 BIOLOGIC SEX CONSIDERATIONS

Effects of Aging on Sexual Function

Men	Women
• ↑ Stimulation necessary for erection	• ↓ Vaginal lubrication
• ↓ Force of ejaculation	• ↓ Sensitivity with labia shrinking and more clitoris exposed
• ↓ Ability to attain or sustain erection	• Difficulty maintaining arousal
• ↓ Size and rigidity of the penis at full erection	• Difficulty achieving orgasm
• ↓ Libido and interest in sex	• ↓ Libido and interest in sex

Illness, disability, medicines, and surgeries can affect a person's ability to take part in sexual activities.

Nurses play a vital role in providing accurate and unbiased information about sexuality and age. Emphasize the normalcy of sexual activity in older adults and refer them to resources that address such issues.

Case Study

Patient Introduction

(© Benjamin A. Peterson/Mother Image/mother image/Fuse/Thinkstock.)

C.W. is a 23-year-old woman who is being seen for pelvic pain and irregular menstrual bleeding for the past several months. She takes oral contraceptive pills (OCPs) but occasionally forgets to take them. C.W. takes naproxen as needed for pain.

Discussion Questions

1. What are the possible causes for C.W.'s irregular menstrual bleeding?
2. What assessment questions would you ask C.W.?
3. How would you individualize the assessment based on her age, ethnic/cultural background, and condition?

You will learn more about C.W. and her condition as you read through this assessment chapter.

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

ASSESSMENT OF MALE AND FEMALE REPRODUCTIVE SYSTEMS

Subjective Data

Important Health Information

In addition to general health information, obtain information specifically related to the reproductive system. Many people consider reproduction and sexual issues personal and private. The extent and depth of the interview about a patient's sexuality and reproductive health depend on your expertise and the patient's needs and willingness to discuss the topic. Assess your comfort with your own sexuality because any discomfort in questioning becomes obvious to the patient.

A professional demeanor is important when taking a reproductive or sexual history. Develop trust with the patient. Conduct interviews in an environment that provides reassurance, confidentiality, and a nonjudgmental attitude. Be sensitive, use gender-neutral terms when asking about partners, and maintain an awareness of a patient's culture and beliefs. Begin with the least sensitive information (e.g., menstrual history) before asking questions about more sensitive issues, such as sexual practices or STIs.

Health history. The health history should include information about major illnesses, hospitalizations, immunizations, and surgeries. Ask about any infections involving the reproductive system, including STIs. Take a complete obstetric and gynecologic history from patients assigned female at birth.

Mumps and rubella affect reproductive function. Mumps in young men increases the risk for sterility. Bilateral testicular atrophy may occur from mumps-related orchitis. Ask male patients if they have had mumps, were immunized with the mumps vaccine, or have any signs of sterility.

Rubella is a concern to women of childbearing age. Having rubella during the first 3 months of pregnancy increases the risk for congenital anomalies. So, encourage rubella immunization for all women of childbearing age who are not immunized or have not had the disease. Antibody titers can determine rubella immunity. Do not immunize a woman if they are already pregnant.[7] Advise patients to avoid becoming pregnant for 1 month after vaccination, or ideally, after immunity has been confirmed by antibody titers.

Ask the patient about current health status and any acute or chronic health problems. Chronic illnesses, such as cardiovascular disease, respiratory problems, anemia, cancer, and kidney and urinary tract problems, may affect the reproductive system and sexual functioning.

Ask questions relating to possible endocrine problems, including diabetes, hypothyroidism, and hyperthyroidism. These disorders directly interfere with women's menstrual cycles and sexual performance. Men with diabetes may have ED and retrograde ejaculation. In women with uncontrolled diabetes, pregnancy may pose significant health risks to both the woman and fetus.

Determine if the patient had a stroke. In men, strokes may cause physiologic or psychologic ED. Men who had a myocardial infarction (MI) may have ED because of fear that sexual activity could precipitate another MI. Post-MI medication, such as β-blockers, may affect a man's ability to achieve an erection.[8] Although most patients have concerns about sexual activity after an MI, many are not comfortable expressing these fears to the nurse. Be sensitive to this concern.

Note any allergies. Is the patient allergic to latex or drugs, including sulfonamides, macrolides, cephalosporins, tetracyclines, or penicillin? These drugs are often used to treat reproductive and genitourinary (GU) problems, such as STIs and urinary tract infections (UTIs). Silicone and latex are often used in diaphragms and condoms. An allergy to these substances precludes their use as contraception.

Medications. Obtain a complete medication history. Include the reason for use, dosage, and length of time that the drug has been taken. Ask about the use of herbal products and diet and nutrition supplements. Psychotropic agents may interfere with sexual performance. Antihypertensives, such as amlodipine (Norvasc), lisinopril, propranolol (Inderal), and clonidine, may cause ED. Drugs such as alcohol, marijuana, barbiturates, amphetamines, or cocaine can affect the reproductive system.

In women, note the use of hormonal contraceptives and hormone therapy (HT). The long-term use of combined HT (specifically a combination of oral conjugated equine estrogen and a progestin, *medroxyprogesterone acetate*) increases the risk for stroke, breast cancer, deep vein thrombosis, and gallbladder disease.[9] These risks are higher in women who also use tobacco products. Women may seek treatment based on the degree of symptoms and associated morbidities to help balance their quality of life with menopausal symptoms.[10]

A history of cholecystitis and hepatitis is important because these conditions may be contraindications for the use of OCPs. OCPs often aggravate cholecystitis. Chronic liver inflammation generally precludes the use of estrogen products because they are metabolized by the liver. Chronic obstructive pulmonary disease may be a contraindication to OCP use because progesterone thickens respiratory secretions.

Surgery or other treatments. Note any surgical procedures. Common surgeries involving the female reproductive system are listed in Table 58.7. Record any therapeutic or spontaneous abortions and type of intervention (medical versus surgical abortion).

TABLE 55.4 HEALTH HISTORY

Reproductive System

Health Perception–Health Management

- How would you describe your overall health?
- Describe the health of your family members. Any history of breast, uterine, ovarian, or prostate cancer?[a]

Women

- Do you perform breast self-examination? Any concerns?
- When was your last Pap test and the results?[a]
- Any prior abnormalities with your Pap tests?
- When was your last mammogram and the results?[a]
- Any prior abnormalities with your mammograms?

Men

- Do you perform testicular self-examination? Any concerns?

Nutritional-Metabolic

- Describe what you usually eat and drink.
- Have you had any changes in weight?[a]
- How do you feel about your current weight?
- Do you take any nutrition supplements, such as calcium or vitamins?[a]
- Do you have any diet restrictions?[a]

Elimination

- Do you have problems with urination (e.g., pain, burning, dribbling, incontinence, frequency)?[a]
- Have you had bladder infections? If so, when? How often?
- Do you have problems with bowel movements?[a]
- Do you have any constipation, loose stools, or blood with stools?[a]
- Do you use laxatives?[a]

Activity-Exercise

- What activities do you typically do each day?
- Do you have enough energy for your desired activities?

Sleep-Rest

- How many hours do you typically sleep each night?
- Do you feel rested after sleep?
- Do you have any problems sleeping?[a]

Cognitive-Perceptual

- Do you have pain? If yes, where?
- Do you have pain during sexual activity?[a]

Self-Perception–Self-Concept

- How would you describe yourself?
- Have there been any recent changes that have made you feel differently about yourself?[a]
- Are you having any problems that are affecting your sexuality? [a]

Role-Relationship

- Describe your living arrangements. With whom do you live?
- Do you have a significant other? If yes, is this relationship satisfying?
- Are you having any role-related problems in your family?[a] At work?[a]
- What are the relationships among your family members?

Sexuality-Reproductive

- Are you sexually active? If so, how many partners do you have?
- What kind of sex do you engage in (oral, vaginal, anal)?
- How do you protect yourself against sexually transmitted infections and unwanted pregnancy?
- Are you satisfied with your present means of sexual expression? If not, explain.
- Have you had any recent changes in your sexual practices?[a]

Women

- How old were you when you had your first menstrual period? (Menarche)
- What was the first day of your last menstrual period?
- Describe your period. How many days does it last? How often does it come (e.g., every 28 days)?
- Do you have pain with your period? Do you pass clots?
- Do you feel your flow is heavy or excessive?
- How old were you when you went through menopause?
- Have you had any postmenopausal bleeding or spotting?[a]
- Pregnancy history: How many times have you been pregnant? How many living children do you have? Have you ever had any miscarriages or abortions? Did they need medical intervention?

Men

- Do you have any problem obtaining or sustaining an erection?
- Do you have any problems with ejaculation?

Coping–Stress Tolerance

- Have there been any major changes in your life within the past couple of years?[a]
- What is stressful in your life right now?
- How do you handle health problems when they occur?
- Do you feel safe in your home? Work? Has anyone ever tried to hurt or harm you?

Value-Belief

- What beliefs do you have about your health and illnesses?
- Do you use home remedies?[a]
- Is religion an important part of your life?[a]
- Do you think that any of your personal beliefs or values may be compromised because of your treatment?[a]

[a] If yes, describe.

Functional Health Patterns

The key questions to ask a patient with a reproductive problem are outlined in Table 55.4.

Health perception–health management pattern. Discuss the patient's perception of their own health and measures that they take to maintain health. Ask about self-examination practices and screenings. Mammography and periodic cervical Pap tests are key to a woman's health. Men are at risk for testicular and prostate cancer. However, controversy exists about the benefits of routine screening for these cancers.[11] All patients should discuss the benefits and risks of screening with their HCP.

BOX 55.2 GENETIC RISK ALERT

- Breast, ovarian, uterine, and prostate cancer have known genetic risk factors.
- Having a 1st-degree relative with any of these cancers significantly increases the risk for cancer for the patient.
- The risk increases if several family members have had these cancers over succeeding generations.
- Persons with a known hereditary predisposition to breast or ovarian cancer can use this information to make informed decisions about how to minimize their risks.

An accurate family history is vital. Ask about a history of cancer, especially cancer of the reproductive organs (Box 55.2). Note a family history of diabetes, hypothyroidism, hyperthyroidism, hypertension, stroke, angina, MI, endocrine problems, or anemia.

Assess the patient's lifestyle choices. Determine whether a patient has smoked or currently smokes, the amount (if any) of alcohol use, or if they use illicit drugs. Risks associated with smoking include ectopic pregnancy, miscarriage, an increased risk for perinatal mortality and morbidity, placental abnormalities, preterm delivery, and congenital facial defects of the fetus.[12] Smoking increases the risk for mortality in women who use OCPs. Smoking in women is also related to early menopause. Decreased sperm counts and ED are seen in male smokers. Smoking is a known cofactor for persistence of *human papillomavirus* (HPV) infection for oral and anogenital cancers among men and women.[13]

Nutritional-metabolic pattern. Anemia is a common problem in women in their reproductive years, especially during pregnancy and the postpartum period. Evaluate the adequacy of the diet with this in mind. Iron deficiency anemia is the most common cause of anemia in menstruating females.

Take a thorough nutrition and psychologic history to assess for the presence of an eating disorder. Anorexia nervosa can cause amenorrhea and other problems, such as osteoporosis. Obesity can be related to polycystic ovarian syndrome and may be a precursor to type 2 diabetes.

From early adolescence, teach women about adequate calcium and vitamin D intake to prevent osteoporosis. Estimate the patient's daily calcium intake to determine whether supplementation is needed. Evaluate folic acid intake for women in their reproductive years because a deficiency can result in spina bifida and other fetal neural tube defects.[14]

Elimination pattern. Many gynecologic problems can result in GU problems. Urinary incontinence is common in older women. Factors associated with incontinence include relaxation of the pelvic musculature caused by multiple births, advancing age, fibroid tumors, diabetes, obesity, and weight gain. Condom, diaphragm, and spermicide use increases the risk for UTIs. Men may have urethritis, an inflammation of the urethra, which may be caused by an STI. Urethritis can cause painful urination. Benign prostatic hyperplasia (BPH) is common in older men. It can cause urinary retention or difficulty in starting the urinary stream.

Activity-exercise pattern. Record the amount, type, and intensity of activity and exercise. Lack of weight-bearing exercise is an important factor in the development of osteoporosis, especially in postmenopausal women. Anemia can result in fatigue and activity intolerance and interfere with performing activities of daily living. Adolescent females who engage in excessive leanness sports may have *female athlete triad.* It is characterized by secondary amenorrhea, low energy availability, and osteoporosis.[15]

Sleep-rest pattern. Sleep patterns may be affected during the postpartum period and while raising young children. Hot flashes and sweating during perimenopause can cause serious sleep interruption when the woman awakens in a drenching sweat. The need to change her clothing and bedding further disrupts sleep. Insomnia is common among perimenopausal women. Daytime fatigue can result from sleep problems. In men, frequent urination at night related to prostate enlargement or HT for prostate cancer can disturb sleep.

Cognitive-perceptual pattern. Pelvic pain can occur with various gynecologic disorders, such as pelvic inflammatory disease, ovarian cysts, and endometriosis. *Dyspareunia* (painful intercourse) can be problematic for women in the postmenopausal period. The pain with intercourse can create a reluctance to take part in sexual activity and strain relationships with sexual partners. Refer women with dyspareunia to their HCP.

Self-perception–self-concept pattern. Changes that occur with aging, such as pendulous breasts and vaginal dryness in women and decreased penis size in men, may lead to distress. The subtle changes associated with sexuality and advancing age may affect self-concept.

Role-relationship pattern. Obtain information about the family structure and occupation. Ask about recent changes in work-related relationships or family conflict. Assess the patient's role in the family as a starting point to determine family dynamics. Changes within the family, such as marriage, divorce, or birth of a child, affect roles and relationships.

Sexuality-reproductive pattern. For women, obtain a menstrual and a chronologic obstetric history. The menstrual history includes the first day of the LMP, description of menstrual flow, age of menarche, and, if applicable, age at menopause. Menstrual history data are used in the detection of pregnancy, infertility, and many gynecologic problems. Have the patient describe any changes in her usual menstrual pattern to determine whether the change is transient and unimportant or connected with a more serious problem. Terminology that describes abnormal uterine bleeding patterns is discussed in Chapter 58.

Identify changes in menstrual patterns from the use of OCPs, intrauterine devices (IUDs), birth control patches, vaginal rings, progestin-only implants, or medroxyprogesterone injections. OCPs usually decrease the amount and duration of flow. Some IUDs are used for both contraception and as a nonsurgical treatment for heavy menstrual bleeding. However, some IUDs increase menstrual flow.

The obstetric history includes the number of pregnancies, full-term births, preterm births, stillbirths, living children, and abortions (including spontaneous [miscarriage], ectopic, induced). Document the course of each pregnancy. Include the duration of each pregnancy, date of delivery, problems that occurred, and any medical or surgical treatment that was needed.

Table 55.5 outlines *The 5 Ps of Sexual Health* approach for taking a sexual history. Never assume a patient's sexual orientation. Ask patients about their general satisfaction with their sexuality. Ask them about sexual beliefs and practices and whether they achieve orgasm. Explore any unexplained change in sexual practices or performance. Reproductive problems can cause physiologic or psychologic problems that can lead to painful intercourse, ED, sexual problems, or infertility.

Coping–stress tolerance pattern. The stress related to situations such as pregnancy or menopause increases dependence on support systems. Determine whom the support people are in the patient's life. The diagnosis of an STI can cause stress for the patient and partner. Explore ways to manage this stress with patients by encouraging them to share their concerns.

Value-belief pattern. Sexual and reproductive functioning is closely related to cultural, religious, moral, and ethical values. Be aware of your own beliefs in these areas. Recognize and

TABLE 55.5 Sexual History Format

The Five Ps of Taking a Sexual History[a]

The 5 *Ps*	Questions
1. **Partners**	• Are you currently sexually active? (yes or no) • Do you have sex with men, women, or both? • In the past 2 months, with how many partners have you had sex? • In the past 12 months, with how many partners have you had sex?
2. **Practices**	• To understand your risk for STIs, I need to understand the kind of sex you have had recently. • Genital (penis in the vagina) • Anal (penis in the anus) • Oral (mouth on penis, vagina, or anus)
3. **Protection from STIs**	• Do you and your partner(s) use any protection against STIs? • What kind? • How often?
4. **Past history of STIs**	• Have you ever had an STI? • What type? • When? • How were you treated?
5. **Pregnancy prevention**	• Are you or your partner trying to get pregnant? • If not, what are you doing to prevent pregnancy?

[a]Modify this guide as needed to be culturally appropriate, based on culture or gender dynamics.

Case Study

Subjective Data

(© Benjamin A. Peterson/Mother Image/mother image/Fuse/Thinkstock.)

A focused assessment of C.W. revealed the following information:

Health Perception–Health Management: In good health. Pap smear 2 years ago was normal. Has not had any surgeries

Nutritional-Metabolic: 5 ft 2 in, 130 lb (BMI 23.7 kg/m^2)

Elimination: Denies any changes with urination or bowel movements

Activity-Exercise: Exercises at gym 2 times a week

Cognitive-Perceptual: Denies dyspareunia

Self-Perception–Self Concept: In graduate school and hopes to graduate next year.

Role-Relationship: Single, lives with 2 other young women in off-campus housing

Sexuality-Reproductive: Menarche at age 12. Last menstrual period 2 weeks ago. Menses is usually every 28 days, lasting 2 days, but has noted irregular bleeding with increased pelvic pain over past few months. Sexually active with men and women, with 6 lifetime partners. In a mutually monogamous relationship of 2 years duration with a male partner. Practices vaginal and oral sex.

Coping–Stress Tolerance: Denies stressors

Value-Belief: Raised Catholic, but does not attend mass

Discussion Questions

1. Which subjective assessment findings concern you most?
2. What should be included in the physical assessment?

You will learn more about physical assessment of the reproductive system in the next section.

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

sensitively react to the patient's personal beliefs associated with reproductive and sexuality issues.

Objective Data

Physical Assessment: Male

The assessment of the external male genitalia includes inspection and palpation of the pubis, penis, and scrotum. The patient may be lying or standing. The standing position is preferred. Sit in front of the standing patient. Use gloves when assessing the male genitalia.

If breast cancer is suspected or there is a strong family history of breast cancer in a male patient, a clinical breast examination is conducted in the same pattern for a male patient as a female breast examination (see Fig. 56.1).

Pubis. Assess for hair distribution and presence of body lice. Normally, the hair is in a diamond-shaped pattern and coarser than scalp hair. The absence of hair is not normal unless the man is shaving or waxing the pubic hair. Carefully assess the skin for irritation and inflammation.

Penis and scrotum. Inspect the penis for any lesions, bleeding, or swelling. Note the location of the urethral meatus and the presence of a foreskin. If present, retract the foreskin and note any redness, discharge, irritation, lesions, or swelling from the meatus. Replace the foreskin over the glans after observation. Inspect the scrotum by lifting each testis to inspect all sides of the scrotal sac. Palpate the testes for tenderness or masses. The left testis usually hangs lower than the right. An undescended testis *(cryptorchidism)* is a major risk factor for testicular cancer and a potential cause of male infertility.

Anus. Note if the buttocks have any lesions, swelling, or inflammation. Spread the buttocks apart with both hands to expose the anus. Inspect the anal sphincter and perineal regions for fissures, lesions, masses, and hemorrhoids. The anus should be free from inflammation or skin changes.

Physical Assessment: Female

Physical assessment often begins with inspection and palpation of the breasts and axillae, then proceeds to the abdomen and genitalia. Examining the abdomen provides an opportunity to detect pain or any masses that may involve the GU system. Abdominal assessment is discussed in Chapter 43.

Breasts. To perform a breast examination, first examine the breasts by visual inspection. With the patient seated, inspect the breasts for symmetry, size, shape, skin color, vascular patterns, dimpling, and unusual lesions. Ask the patient to put the arms at the sides, arms overhead, lean forward, and press hands on hips. Observe for any abnormalities during these maneuvers. Palpate the axillae and clavicular areas for enlarged lymph nodes.

After the patient assumes the supine position, place a pillow under the back on the side to be examined. Ask the patient to put the arm above and behind the head. This flattens breast tissue and make palpation easier. Then palpate the breast in a systematic fashion, preferably using a vertical line (see Fig. 56.1). Use the distal finger pads of the index, middle, and ring fingers for palpation. Include the axillary tail of Spence. This area of the breast lies adjacent to the upper outer quadrant. It is where

most breast cancer develops. Palpate the areolae for masses. Document the color, consistency, and odor of any discharge. For patients at average risk who have no breast symptoms, the benefit of routine clinical breast examinations to detect early breast cancer is unclear. Teach patients to be familiar with how their breasts feel and report any changes or concerns to the HCP.[16]

External genitalia. The assessment of the external female genitalia includes inspection and palpation of the mons pubis, vulva, and anus. Use gloves for the assessment. Assess for hair distribution, presence of body lice, lesions, redness, edema, or discharge. Many women remove hair from the genital region via shaving, waxing, or laser hair removal. They may develop folliculitis (infection of the hair follicle). Separate the labia to fully inspect the clitoris, urethral meatus, and vaginal orifice. Spread the buttocks apart to inspect the anus for fissures, lesions, and hemorrhoids.

Internal pelvic examination. HCPs with advanced or specialized training usually do this part of the examination. During the speculum examination, the HCP inspects the walls of the vagina and cervix for inflammation, discharge, polyps, and suspicious growths. A Pap test and specimens for nucleic acid amplification tests (NAATs) for STI sampling and microscopic examination may be obtained. After the speculum examination, a bimanual examination may be done to assess the size, shape, and consistency of the uterus and ovaries. The ovaries and tubes are not normally palpable.

Table 55.6 gives an example of a recording format for the physical assessment findings. Tables 55.7 through 55.9 summarize assessment abnormalities of the breasts, female reproductive system, and male reproductive system, respectively.

A *focused assessment* is used to evaluate the status of previously identified reproductive problems and to monitor for signs of new problems. A focused assessment of the reproductive system is presented in Box 55.3.

Case Study

Objective Data: Physical Assessment

(© Benjamin A. Peterson/Mother Image/mother image/Fuse/Thinkstock.)

Focused assessment of C.W. reveals the following:

BP is 108/72 mm Hg; her pulse is 78 beats/min and regular. Temp 97.8°F. Skin warm and dry without lesions. No cyanosis of lips, mucous membranes, or nail beds. Thyroid is slightly enlarged. Abdomen soft and nontender. External genitalia examination is normal. Bimanual examination by the HCP is negative for cervical motion tenderness, uterine anomalies. She has pain on left side with palpation of a soft mass consistent with an ovarian cyst.

Discussion Questions

1. Based on the subjective and objective assessment findings, what diagnostic tests would you anticipate being ordered for C.W.?

You will learn more about diagnostic studies related to the reproductive system in the next section.

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

TABLE 55.6 Normal Physical Assessment of the Reproductive System

Male	Female
Breasts	
Nipples soft. No lumps, nodules, swelling, or enlarged tissue noted.	Symmetric without dimpling. Nipples soft. No drainage, retraction, or lesions noted. No masses or tenderness. No lymphadenopathy.
External Genitalia	
Diamond-shaped hair distribution. No penile lesions or discharge noted. Scrotum symmetric, no masses, descended testes. No inguinal hernia.	Triangular hair distribution. Genitalia dark pink, no lesions, redness, swelling, or inflammation in perineal region. No vaginal discharge noted. No tenderness with palpation of Skene ducts and Bartholin glands.
Anus	
No hemorrhoids, fissures, or lesions noted.	No hemorrhoids, fissures, or lesions noted.

DIAGNOSTIC STUDIES OF REPRODUCTIVE SYSTEMS

The most common diagnostic studies used to assess the reproductive systems are described in Tables 55.10 through 55.14. Diagnostic studies of the endocrine system may also be done in a person with a reproductive system problem (see Tables 52.6 and 52.7).

Case Study

Objective Data: Diagnostic Studies

(© Benjamin A. Peterson/Mother Image/mother image/Fuse/Thinkstock.)

The following laboratory and diagnostic tests are ordered for C.W.:

C.W. has a urine pregnancy test, urinalysis, pelvic and transvaginal ultrasound, complete blood count (CBC), thyroid stimulating hormone (TSH), and testing for STIs (HIV, syphilis, gonorrhea, chlamydia). Her results are:

Urine pregnancy test: Negative
Urinalysis: Normal
CBC: hemoglobin, 14.1 g/dL, hematocrit, 36.5%, WBC 11.5
TSH: 0.3 IU/L
HIV Antigen/Antibody: Nonreactive (Negative)
Syphilis: Nonreactive (Negative)
Gonorrhea and chlamydia tests: Negative

The pelvic and transvaginal ultrasound revealed a normal uterus and ovaries with good blood flow and a 4-cm ovarian cyst.

Discussion Questions

1. Which diagnostic and laboratory test results are of concern to you?
2. What patient teaching can you provide C.W. based on her diagnostic test results?

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

TABLE 55.7 ASSESSMENT ABNORMALITIES

Breast

Finding	Description	Possible Cause and Significance
Dimpling	Unilateral, recent onset, no pain	Cancer
Nipple inversion or retraction	Recent onset, redness, pain, unilateral	Abscess, inflammation, cancer
	Recent onset (usually within past year), unilateral, nontender	Cancer
Nipple scaling or irritation	Unilateral or bilateral, crusting, possible ulceration	Paget disease, eczema, infection
Nipple secretions		
• Galactorrhea (female)	Milky, no relationship to lactation, unilateral or bilateral, intermittent or consistent	Drug therapy, especially phenothiazines, tricyclic antidepressants, methyldopa. Hypofunction or hyperfunction of thyroid or adrenal glands. Hypothalamus or pituitary tumor. Excess estrogen. Prolonged suckling or breast foreplay
• Galactorrhea (male)	Milky, bilateral	Chorioepithelioma of testes, pituitary tumor
• Multicolored or dark green discharge	Thick, sticky, often bilateral	Ductal ectasia
• Purulent	Gray-green or yellow color. Often unilateral. May have pain, redness, induration, nipple inversion	Puerperal (after birth) mastitis or abscess
	Same as above but usually without nipple inversion	Infected sebaceous cyst
• Serosanguineous or bloody drainage	Unilateral	Papillomatosis (widespread development of nipple-like growths), intraductal papilloma, cancer (male and female)
• Serous discharge	Clear appearance, unilateral or bilateral, intermittent or consistent	Intraductal papilloma
Nodules, lumps, or masses	Multiple, bilateral, well-delineated, soft or firm, mobile cysts. Pain. Premenstrual occurrence	Fibrocystic changes
	Rubbery consistency, fluid-filled interior, pain	Ductal ectasia
	Soft, mobile, well-delineated cyst, painless	Lipoma, fibroadenoma
	Redness, tenderness, induration	Infected sebaceous cysts, abscesses
	Usually singular, hard, irregularly shaped, poorly delineated, nonmobile	Cancer

TABLE 55.8 ASSESSMENT ABNORMALITIES

Female Reproductive System

Finding and Description	Possible Cause and Significance
Vulvar Discharge	
Thin gray or white, copious flow, malodorous or fishy, vulvar irritation	Bacterial vaginosis infection
White, thick, curdy, itching, redness, no odor or yeast-like smell	Candidiasis (*Candida* or yeast infection), vaginitis
Mucopurulent discharge; bloody discharge	*Chlamydia trachomatis* or *Neisseria gonorrhoeae* infection, menstruation, trauma, cancer
Frothy green or yellow color; malodorous	*Trichomonas vaginalis*
Vulvar Growths	
Soft, fleshy growth, nontender	Condyloma acuminatum (genital warts)
Flat and warty appearance, nontender	Condyloma latum
Same as either of above, possible pain	Cancer
Reddened base, vesicles, and small erosions; pain	Lymphogranuloma venereum, genital herpes, chancroid
Indurated, firm ulcers, no pain	Chancre (syphilis), granuloma inguinale
Vulvar Redness	
Bright or beefy red color, itching	*Candida albicans*, allergy, chemical vaginitis
Reddened base, painful vesicles or ulcerations	Genital herpes
Macules or papules, itching	Chancroid, contact dermatitis, scabies, pediculosis
Abdominal Pain, Tenderness, or Pelvic Masses	
Intermittent or consistent tenderness in right or left lower quadrant	Salpingitis, ectopic pregnancy, ruptured ovarian cyst, pelvic inflammatory disease, tubal or ovarian abscess
Periumbilical location, consistent occurrence	Cystitis, endometritis, ectopic pregnancy
Abdominal or pelvic pain, especially with menses, radiates to back, rectum or vagina.	Endometriosis
Pelvic masses	Fibroids, ovarian cysts, cancer

TABLE 55.9 ASSESSMENT ABNORMALITIES

Male Reproductive System

Finding and Description	Possible Cause and Significance
Inguinal Masses	
Bulging unilateral mass during straining	Inguinal hernia
1– 3 cm nodules	Lymphadenopathy
Penile Discharge	
Clear to purulent color, minimal to copious flow	Urethritis or gonorrhea, *Chlamydia trachomatis* infection, trauma
Penile Growths or Masses	
Indurated, smooth, disk-like appearance. Painless, single lesion	Chancre (syphilis)
Papular to irregularly shaped ulceration with pus, no induration	Chancroid
Ulceration with induration and nodularity	Cancer
Flat, wartlike nodule	Condyloma latum
Raised, fleshy, moist, elongated projections with single or multiple projections	Condyloma acuminatum (genital warts)
Localized swelling with retracted, tight foreskin	Paraphimosis (inability to replace foreskin to its normal position after retraction), trauma
Scrotal Masses	
Localized swelling with tenderness, unilateral or bilateral	Epididymitis, testicular torsion, orchitis (mumps)
Swelling, tenderness	Incarcerated hernia
Swelling without pain. Unilateral or bilateral. Translucent, cordlike, or wormlike appearance	Hydrocele, spermatocele, varicocele, hematocele
Firm, nodular testes or epididymis. Often unilateral	Tuberculosis, cancer
Scrotal or Penile Redness	
Macules and papules	Scabies, pediculosis
Vesicles, Erosions, or Ulcers	
Painful, reddened base. Vesicular or small erosions	Genital herpes, balanitis, chancroid
Painless, singular, small erosion with eventual lymphadenopathy	Lymphogranuloma venereum, cancer

BOX 55.3 FOCUSED ASSESSMENT

Reproductive System

Use this checklist to ensure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Vaginal or vulvar: discharge, lesions, itching, unusual bleeding, odor	Y	N
Penile pain, lesions, discharge	Y	N
Drugs: OCPs, antihypertensives, psychotropics, hormones	Y	N
Clinical assessment of reproductive systems (breast, pelvis, testicular, prostate) and results	Y	N
Pain: abdomen, pelvis, or genitalia	Y	N

Objective: Diagnostic

Check the following for results and critical values.

Serum/urine hCG	✓
Serum PSA	✓
CBC	✓
Hormone studies (testosterone, progesterone, estrogen, FSH, LH, TSH)	✓
NAAT STI results (e.g., *Chlamydia*, gonorrhea, *Trichomonas*)	✓
Testing for other STIs (HIV, syphilis)	
In office testing (e.g., wet mounts, pH assessment)	✓
Mammography and/or breast ultrasound	✓
Ultrasound: abdominal, pelvic, transvaginal, prostate	✓

Objective: Physical Assessment

Inspect

External genitalia for redness, swelling, discharge, lesions	✓
Breasts for swelling, dimpling, retraction, drainage, redness, skin changes, masses	✓

Palpate

Breast tissue for masses or tenderness	✓
External genitalia: tenderness, pain	✓

CBC, Complete blood count; *FSH,* follicle-stimulating hormone; *hCG,* human chorionic gonadotropin; *LH,* luteinizing hormone; *NAAT,* Nucleic acid amplification test; *PSA,* Prostate-specific antigen; *STI,* sexually transmitted infection; *TSH,* thyroid stimulating hormone.

TABLE 55.10 Serology Studies

Male and Female Reproductive Systems

Study	Reference Interval	Description and Purpose
Anti-müllerian hormone (AMH)	*Female:* 13–45 years: 0.9–9.5 ng/mL >45 years: <1.0 ng/mL	Measures ovarian function. Level reflects size of the remaining egg supply ("ovarian reserve"). May be done when a woman has manifestations of polycystic ovarian syndrome (PCOS). Used to monitor AMH-producing ovarian tumor. Females with ↑ AMH levels have a better response to ovarian stimulation during fertility treatments.

TABLE 55.10 Serology Studies—cont'd

Male and Female Reproductive Systems

Study	Reference Interval	Description and Purpose
Estradiol	*Female:* Follicular phase: 20–350 pg/mL (73–1285 pmol/L) Luteal phase: 30–450 pg/mL (110–1652 pmol/L) Postmenopause: ≤20 pg/mL (≤73 pmol/L) *Male:* 10–50 pg/mL (37–184 pmol/L)	Measures ovarian function. Useful in assessing estrogen-secreting tumors and precocious female puberty. Can confirm perimenopausal status. ↑ Levels in men may indicate testicular tumor.
Follicle-stimulating hormone (FSH)	In 24-hr urine samples: *Female:* Follicular phase: 2–15 U/24 hr Midcycle: 8–60 U/24 hr Luteal phase: 2–10 U/24 hr Postmenopause: 35–100 U/24 hr *Male:* 3–11 U/24 hr In blood: *Female:* Follicular phase: 1.37–9.9 mU/mL Ovulatory phase: 6.17–17.2 mU/mL Luteal phase: 1.09–9.2 mU/mL Postmenopause: 19.3–100.6 mU/mL *Male:* 1.42–15.4 mU/mL	Assesses gonadal function. Abnormal levels may indicate pituitary problem. ↑ in menopause. Can confirm menopausal status.
Human chorionic gonadotropin (hCG)	Qualitative: Negative Quantitative: <5 mIU/mL (<5 IU/L) (males and nonpregnant females)	Detects pregnancy. Detects hydatidiform mole and chorioepithelioma (in men and women). Done with urine or blood.
Luteinizing hormone (LH)	*Female:* Premenopause: 5–25 IU/L, with higher peaks at ovulation Postmenopause: 14–52.3 IU/L *Male:* 1.8–8.6 IU/L	Associated with ovulation in women and testosterone production in men. Used in women in the workup of infertility and menstrual irregularities.
Progesterone	*Female:* Follicular phase: 15–70 ng/dL (0.5–2.2 nmol/L) Luteal phase: 200–2500 ng/dL (6.4–79.5 nmol/L) Postmenopause: <40 ng/dL (1.28 nmol/L) *Male:* 13–97 ng/dL (0.4–3.1 nmol/L)	Assesses infertility, monitors success of drugs for infertility or the effect of progesterone treatment. Determines whether ovulation is occurring. Diagnoses problems with adrenal glands and some cancers.
Prolactin	*Female:* 3.8–23.2 ng/mL (3.8–23.2 mg/L) *Male:* 3.0–14.7 ng/mL (3.0–14.7 mg/L)	Detects pituitary problems that can cause amenorrhea, decreased libido, and impotence.
Prostate-specific antigen (PSA)	*Male:* <2.5 ng/mL (<2.5 mcg/L)	Detects prostate problems.
Testosterone	In 24-hr urine samples: *Female:* 2–12 mcg/24 hr (6.9–41.6 nmol/24 hr) *Male:* 40–135 mcg/24 hr (139–469 nmol/24 hr) In blood: *Female:*15–70 ng/dL (0.52–2.43 nmol/L) *Male:* 280–1100 ng/dL (10.4–38.17 nmol/L)	Detects tumors and developmental anomalies of the testicles. Used to assess male infertility.

TABLE 55.11 Radiologic Studies

Male and Female Reproductive Systems

Study	Description and Purpose
CT scan of pelvis	Detects tumors in the pelvis.
Mammography	X-ray image used to assess breast tissue. Detects benign and malignant masses. See Chapter 56 for mammography screening guidelines.
MRI	Radio waves and magnetic field used to assess soft tissue. Useful after an abnormal mammogram or in women with dense breast tissue. Breast MRI may be with mammography to detect breast cancer in women at high risk for breast cancer. Used to diagnose abnormalities in female and male reproductive systems.
Ultrasound (US) (breast, pelvic, testicular, transvaginal [TV], rectal [TRUS])	Measures and records high-frequency sound waves as they pass through tissues of variable density. Breast US: Used to detect fluid-filled masses and for follow-up screening after mammography in women with dense breast tissue. Pelvic and TV US: In women, used to detect pelvic masses, such as ectopic pregnancy, ovarian cysts, fibroids, and cancer. Testicular US: Detects testicular masses and testicular torsion. TRUS: Used to diagnose prostate tumors.

TABLE 55.12 Interventional Studies

Study	Description and Purpose	Nursing Responsibility
Colposcopy	Direct visualization of cervix with binocular microscope. Allows magnification of cervix and study of cellular abnormalities. Used as follow-up for abnormal Pap test. Cervical biopsy(ies) may be taken. Assesses for vaginal or vulvar dysplasia.	*Before:* Teach patient about the procedure. Tell patient this test is similar to a speculum examination. *After*: If a biopsy was done, tell patient there may be some vaginal bleeding and to avoid sexual intercourse until healed.
Conization	Cone-shaped sample of squamocolumnar tissue of cervix removed for direct study.	*Before:* Teach patient about the procedure. Requires anesthesia. *After:* Tell patient to avoid sexual intercourse and tampons for 3–4 weeks. May have some discharge or spotting for 1 week. 3 weeks follow-up necessary.
Dilation and curettage (D&C)	Surgery procedure that dilates cervix and allows curetting of endometrial lining. Used in assessment of abnormal bleeding and cytologic evaluation of lining.	*Before:* Teach patient about procedure and sedation. *After:* Assess degree of bleeding with frequent pad check during first 24 hr.
Hysterosalpingogram (HSG)	Involves instillation of contrast media through cervix into uterine cavity and through fallopian tubes. X-ray images taken to detect abnormalities of uterus and its adnexa (ovaries and tubes) as contrast progresses through them. Often part of infertility assessment (e.g., to detect adhesions, abnormal uterine shape, blockage of tubal pathways).	*Before:* Teach patient about procedure and that it may be uncomfortable. Contrast medium given. *After:* Tell patient she may have slight vaginal bleeding and cramping. Monitor for foul-smelling vaginal discharge, severe pain, fever, or chills.
Hysteroscopy	Allows visualization of uterine lining through insertion of scope through cervix. Used to diagnose and treat abnormal bleeding, such as polyps and fibroids. Biopsy may be done during procedure. May be part of infertility assessment.	*Before:* Should be NPO for at least 6 hr prior. May be done in the HCP's office or an outpatient setting. *After:* Tell patient that mild cramping and slight bloody discharge is normal.
Laparoscopy	Allows visualization of pelvic structures via fiberoptic scopes inserted through small abdominal incisions. Instillation of CO_2 into the abdominal cavity improves visualization. Used in diagnostic assessment of uterus, tubes, and ovaries (Fig. 55.9). Often used for tubal sterilization or part of infertility assessment.	*Before:* Prepare patient for surgery with preoperative teaching and sedation. *After:* Tell patient referred shoulder pain is likely from residual gas in the abdomen. A heating pad may help. A slight discharge or spotting for 2–5 days is normal.
Loop electrosurgical excision procedure (LEEP)	Excision of cervical tissue via an electrosurgical instrument. Diagnoses and treats cervical dysplasia. Minimal amount of tissue removed and preserves childbearing ability.	*Before:* Teach about procedure. May be done in the HCP's office. Patient may feel slight tingling or abdominal cramping during procedure. *After:* Tell patient that discharge, bleeding, and cramping may occur for 1–3 days.
Ultrasound-guided biopsy	Use of ultrasound guidance while performing a biopsy. Ultrasound used to direct the biopsy needle into the region of interest and obtain a sample of tissue. Can diagnose infection, inflammation, or mass.	*Before:* Teach about procedure. Usually done as an outpatient. *After:* Tell patient to monitor for signs and symptoms of infection at biopsy site.

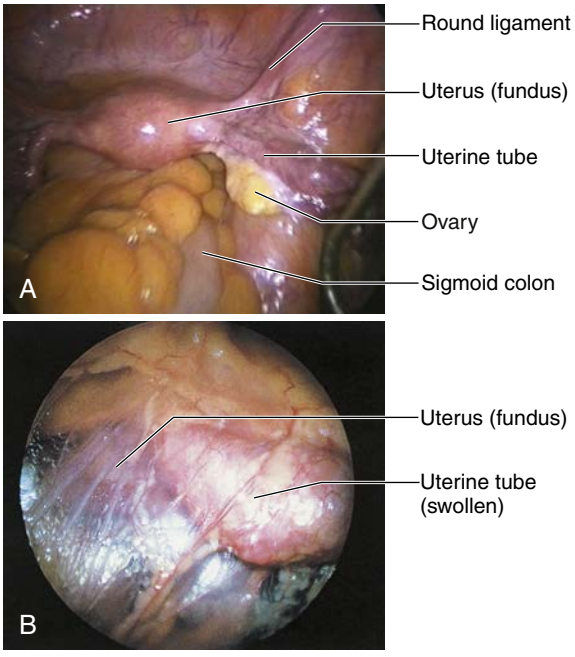

Fig. 55.9 Laparoscopic views of the female pelvis. (A) Normal image. (B) Pelvic inflammatory disease. Note reddish inflammatory membrane covering and fixing the ovary and uterus to the surrounding structures. (A, From Abrahams P, Marks S, Hutching R: *McMinn's color atlas of human anatomy,* ed 5, Philadelphia, 2003, Saunders. B, From Symonds EM, MacPherson MB: *Color atlas of obstetrics and gynecology,* London, 1994, Mosby Wolfe.)

TABLE 55.13 Cytology and Microbiologic Studies

Study	Description and Purpose
Cultures	Specimens from urine to assess for gonorrhea, chlamydia, or UTIs. Rectal and throat cultures may be taken depending on data from sexual history.
Gram stain	Used for rapid detection of gonorrhea. Presence of gram-negative intracellular diplococci generally needs treatment. Not highly accurate for women. Alternative chlamydia test.
Nucleic acid amplification test (NAAT)	Nonculture test used to identify small amounts of DNA or RNA in test samples. Sensitivity similar to culture tests. Uses ligase or polymerase chain reaction that amplifies the signal of the nucleic acids in the test sample so that they are easier to identify. Preferred method to test for gonorrhea, chlamydia, and trichomoniasis. Can be done on a wide variety of samples, including vaginal, endocervical, urethral, urine, rectal, and pharyngeal.
Papanicolaou (Pap) test	Microscopic study of exfoliated cervical cells to detect abnormal cells. *Conventional cytology* entails fixing cells directly to a slide at the time of collection and sending the slide to the laboratory for interpretation. In *liquid-based cytology* the specimen is sent to the laboratory in a liquid solution that preserves it and is processed for microscopic evaluation at the laboratory. Testing for HPV may be done on specimen obtained for liquid-based Pap test.
Wet mounts	Direct microscopic examination of vaginal discharge specimen is done immediately after collection. Determines presence or absence and number of *Trichomonas* organisms, bacteria, white and red blood cells, and candidal buds or hyphae.

TABLE 55.14 Fertility Studies

Study	Description and Purpose
Basal body temperature assessment	Indirectly indicates whether ovulation has occurred. Temperature rises at ovulation and stays high during secretory phase of normal menstrual cycle.
Semen analysis	Assesses semen for volume (2–5 mL), viscosity, sperm count (>20 million/mL), sperm motility (60% motile), and percent of abnormal sperm (60% with normal structure).
Serum anti-müllerian hormone, estradiol, FSH, progesterone	Same as serology studies. See Table 55.10.
Urinary LH	Over-the-counter "ovulation predictor kits." Identifies midcycle LH surge that precedes ovulation by 1–2 days.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A normal male reproductive function that may be altered in a patient who had an orchiectomy (removal of testes) is the production of
   - **a.** PSA.
   - **b.** GnRH.
   - **c.** testosterone.
   - **d.** seminal fluid.
2. Follicle stimulating hormone (FSH) *(select all that apply)*
   - **a.** results in ovulation.
   - **b.** initiates lactation in women.
   - **c.** affects development of ruptured follicles in women.
   - **d.** stimulates seminiferous tubules to make sperm in men.
   - **e.** stimulates growth and maturity of ovarian follicles in women.
3. Male orgasm is characterized by
   - **a.** engorgement of testicles.
   - **b.** resolution and involution of the penis.
   - **c.** filling of the venous sinuses within erectile tissue of the penis.
   - **d.** rapid release of vasocongestion and muscular tension through rhythmic contractions.
4. An age-related finding when assessing an older man's reproductive system is
   - **a.** increased libido.
   - **b.** increased skin turgor.
   - **c.** increase in prostate size.
   - **d.** increase in muscle tone.
5. The 5Ps of sexual history taking includes asking questions about *(select all that apply)*
   - **a.** sexual practices.
   - **b.** gender of partners.
   - **c.** erectile dysfunction.
   - **d.** use of alcohol or drugs while having sex.
   - **e.** past treatment of sexually transmitted infections
6. When performing a breast exam on a patient, which positions are recommended? *(select all that apply)*
   - **a.** Sitting, leaning forward
   - **b.** While sitting and arms raised
   - **c.** Sitting with hands placed on hips
   - **d.** Laying supine with hands by their side
   - **e.** On their side, with one hand on the hip
7. Which condition would the nurse suspect in a patient with a red, tender vulvar lesion?
   - **a.** Genital herpes
   - **b.** Endometriosis
   - **c.** *Neisseria gonorrhoeae*
   - **d.** Condyloma acuminatum
8. The nurse is caring for a patient scheduled for a transvaginal ultrasound. The nurse explains to the woman that
   - **a.** the procedure treats cervical dysplasia.
   - **b.** bleeding and discharge are common after the procedure.
   - **c.** the procedure involves curettage of the endometrial lining.
   - **d.** the uterus, ovaries, and potential abnormal findings can be visualized.

1. c; 2. d, e; 3. d; 4. c; 5. a, b, e; 6. a, b, c; 7. a; 8. d.

Breast Problems

Deena D. Dell

http://evolve.elsevier.com/Lewis/medsurg/

CONCEPTUAL FOCUS

Coping
Cellular Regulation
Infection
Pain
Sexuality

LEARNING OUTCOMES

1. State screening guidelines for the early detection of breast cancer.
2. Explain the types, causes, clinical manifestations, and interprofessional and nursing management of common benign breast problems.
3. State the risk factors for breast cancer.
4. Describe the pathophysiology and clinical manifestations of breast cancer.
5. Describe the interprofessional and nursing management of breast cancer.
6. Specify the physical and psychologic aspects of nursing management for the patient undergoing breast cancer surgery.
7. Explain the indications for, types and complications of, and nursing management after reconstructive breast surgery.

KEY TERMS

ductal ectasia
fibroadenoma
fibrocystic changes
galactorrhea
gynecomastia
intraductal papilloma
lumpectomy
lymphedema
mammoplasty
mastalgia
mastitis
Paget disease

Breast problems are a significant health concern for women. Whether the actual diagnosis is a benign condition or cancer, the initial discovery of a lump or change in the breast often triggers intense feelings of anxiety and fear. The potential loss of a breast, or part of a breast, may be devastating for many women because of the significant psychologic, social, sexual, and body image implications associated with it.

The most common breast problems are fibrocystic changes, fibroadenoma, intraductal papilloma, ductal ectasia, and breast cancer. In a woman's lifetime, there is a 1 in 8 (12%) chance that she will be diagnosed with breast cancer.[1] Although rare, breast cancer does occur in men. Being aware of personal risk, including genetic factors, and taking part in recommended screening are important health promotion activities.

ASSESSMENT OF BREAST PROBLEMS

Breast Cancer Screening Guidelines

Screening guidelines for the early detection of breast cancer vary depending on a woman's age and risk (Table 56.1).[2] Average risk women include those with no personal history of breast cancer, a strong family of breast cancer, a genetic mutation known to increase breast cancer, and has not had chest radiation therapy before the age of 30.

Women at increased risk for breast cancer (family history, genetic link, prior breast cancer, history of thoracic radiation therapy, or certain atypical findings on a prior breast biopsy) should talk with their HCP about the benefits and limitations of starting screening earlier with 3D mammography and breast magnetic resonance imaging (MRI) and having more frequent

clinical breast encounters. A clinical encounter includes an assessment of risk factors, instruction in ways to reduce the risk factors, and a clinical breast examination (CBE).[3]

Consistent breast self-examination (BSE) may be a useful way to increase self-awareness of how one's breasts normally look and feel. However, research has shown that BSE has no effect on reducing deaths from breast cancer. However, you still need to teach women the importance of knowing how their breasts look and feel and to report breast changes (e.g., nipple discharge, a lump) to their HCP.[3]

If a woman wants to learn about BSE, include information about the potential benefits and limitations. Allow time for questions and a return demonstration. For women who choose to perform BSE, teach the method described at www.breastcancer.org/symptoms/testing/types/self_exam/.

TABLE 56.1 Breast Cancer Screening Guidelines

The American Cancer Society (ACS) recommends the following guidelines for screening women at average risk for breast cancer:

- Women should undergo regular screening mammography starting at age 45 years
- Women should be offered the chance to begin annual screening between the ages of 40 and 44
- Women aged 45–54 years should be screened annually
- Women 55 years and older can switch to every other year screening or can continue screening annually
- Women should continue screening if their overall health is good, and they have a life expectancy of 10 years or longer
- The ACS does not recommend CBE as screening for breast cancer

Diagnostic Studies

Radiologic Studies

We use several techniques to screen for breast problems or help diagnose a suspicious physical finding. *Mammography* is used to view the breast's internal structure using x-rays (Fig. 56.1). It can detect suspicious lumps that cannot be felt. Mammography has significantly improved the early and accurate detection of breast cancer. Improved imaging technology has reduced the radiation dose from mammography.

A comparison of current and prior mammograms may show early tissue changes. Because some tumors metastasize late, early detection by mammography allows for earlier treatment and the prevention of metastasis. In younger women, mammography is less sensitive because of the greater density of breast tissue, resulting in more false-negative results. Having dense breasts makes mammographic detection of cancer more difficult.

With *digital mammography* x-ray images are digitally coded and stored in a computer (Fig. 56.1). It is more accurate than traditional film mammography in younger women with dense breasts. The availability and associated costs of digital mammography are issues with this technology.

3D mammography, or tomosynthesis mammography, produces a 3D image of the breast. It gives a clearer view of overlapping breast tissue structures. It can increase the number of cancers detected and decrease the number of false-positive results (a result stating a cancer is present when it is not).

Calcifications are the most easily recognized mammogram abnormality (Fig. 56.1). They are deposits of calcium crystals that form in the breast. Causes include inflammation, trauma, and aging. Although most calcifications are benign, they may occur with breast cancer.

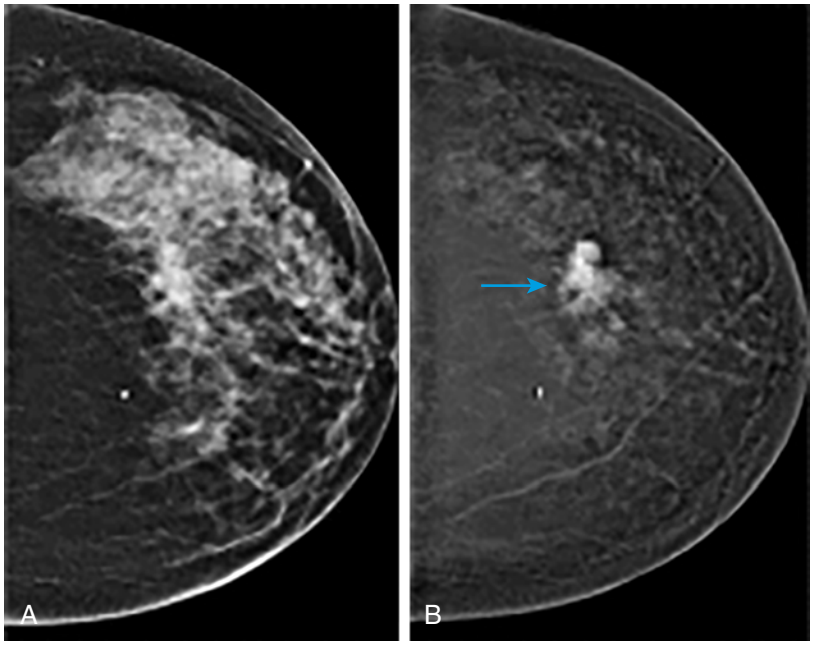

Fig. 56.1 Screening mammogram showing dense breast tissue and benign, scattered microcalcifications. (A) Using conventional x-rays. (B) Using digital x-rays. (From Patel B, Lobbes M, Lewin J: Contrast enhanced spectral mammography: a review, *Semin Ultrasound CT MR* 39:70, 2018e.)

About 10% to 15% of all breast cancers cannot be seen on mammography. They may be detected by palpation or other breast imaging studies, such as ultrasound and MRI. If the clinical findings are suspicious and the mammogram is normal, an ultrasound or MRI may be done. Based on these findings, a biopsy may be done.

Ultrasound is used in conjunction with mammography to discern a solid mass from a cystic mass, to evaluate a mass in a pregnant or lactating woman, and to locate and biopsy a suspicious lesion. MRI is recommended as a screening tool in addition to mammography for women who are at high risk for breast cancer (e.g., first-degree relative with a *BRCA* mutation).

Biopsies

A definitive diagnosis of a suspicious area is made by analyzing biopsied tissue. Biopsy techniques include *fine-needle aspiration* (FNA), core (core needle), vacuum-assisted, and excisional biopsies.

FNA biopsy is done by inserting a needle into a lesion to sample fluid from a breast cyst, remove cells from intercellular spaces, or sample cells from a solid mass. Before the procedure, the breast area is first locally anesthetized. Then, the needle is placed into the breast, and fluid and cells are aspirated into a syringe. Usually, 3 or 4 passes are made. If the results are negative with a suspicious lesion, another biopsy may be necessary.

A *core (core needle) biopsy* involves removing small samples of breast tissue using a hollow "core" needle. For palpable lesions, this is done by fixing the lesion with one hand and performing a needle biopsy with the other. In the case of nonpalpable lesions, *stereotactic mammography,* ultrasound, or MRI image guidance is used. Stereotactic mammography uses computers to pinpoint the exact location of a breast mass based on mammograms. With ultrasound, the HCP watches the needle on the ultrasound monitor to help guide it to the area of concern. A core biopsy is more accurate because it removes more tissue than an FNA.

Vacuum-assisted biopsy is a version of core biopsy that uses a vacuum technique to help collect the tissue sample. In core biopsy, several separate needle insertions are used to obtain multiple samples. During vacuum-assisted biopsy, the needle is inserted only once into the breast, and the needle can be rotated, allowing for multiple samples through a single needle insertion.

Minimally invasive breast biopsies have become the standard of care for diagnosing abnormalities found either on imaging studies or through CBE. However, in some cases, an *excisional biopsy* is recommended. An excisional biopsy is done in an operating room.

BENIGN BREAST PROBLEMS

MASTALGIA

Mastalgia, or breast pain, is the most common breast-related symptom reported in women. The most common form is *cyclic mastalgia,* which coincides with the menstrual cycle.[4] Women describe it as diffuse bilateral breast tenderness or heaviness. Breast pain may last 2 or 3 days or most of the month. It is related to hormonal sensitivity. Symptoms often decrease with menopause.

Noncyclic mastalgia has no relationship to the menstrual cycle. It can continue into menopause. Pain may be constant or intermittent throughout the month and last for several years. Symptoms include a burning, aching, or soreness in the breast. It usually affects only 1 breast. The pain may be from trauma, fat necrosis, ductal ectasia, costochondritis, or arthritic pain in the chest or neck radiating to the breast.

For patients with breast pain, mammography and targeted ultrasound are often done to exclude cancer and provide information on the cause of the pain. Reassure women that mastalgia is not a usual sign of breast cancer.[4]

There is no specific treatment for breast pain. Some relief for cyclic pain may occur by reducing intake of caffeine and fat; taking vitamin E or gamma-linolenic acid (evening primrose oil); and continually wearing a supportive bra. Compresses, ice, analgesics, and antiinflammatory drugs may help. Tamoxifen may provide relief in up to 70% of women with few side effects. Bromocriptine, a prolactin inhibitor, may provide some with relief. It causes GI upset and lightheadedness. Danazol is an FDA-approved treatment. The androgenic side effects (acne, edema, hirsutism) make this therapy unacceptable for many women.

BREAST INFECTIONS

Mastitis

Mastitis is an inflammatory breast condition. It occurs most often in lactating women (Table 56.2). *Lactational mastitis* presents as a localized area that is red, painful, and tender to palpation. Fever is often present. The infection develops when pathogens (usually staphylococci) gain access to the breast through a cracked nipple. In its early stages, mastitis can be cured with antibiotics. Breastfeeding should continue unless an abscess is forming, or there is purulent drainage. The mother may wish to use a nipple shield or to hand-express milk from the involved breast until the pain subsides. The woman should see her HCP promptly to begin antibiotic therapy. Any breast that stays red, tender, and not responsive to antibiotics requires follow-up care and evaluation for inflammatory breast cancer.[4,5]

Mastitis sometimes develops in women who are not lactating. This is called *periductal mastitis.* It occurs most often in regular smokers aged late 20s to early 30s. Treatment is the same as for lactating mastitis.

Lactational Breast Abscess

If lactational mastitis persists after several days of antibiotic therapy, a lactational breast abscess may be present. In this condition, the skin may become red and edematous over the involved breast, often with a corresponding palpable mass. The patient may have a fever. Antibiotics alone are insufficient treatment for a breast abscess. Ultrasound-guided drainage of the abscess or surgical incision and drainage are done. The drainage is cultured, and sensitivities are obtained. Antibiotic therapy is started. Breastfeeding can continue in most cases with ongoing treatment.

TABLE 56.2 Common Benign Breast Problems

Disorder	Risk Factors	Clinical Manifestations
Lactational mastitis	Occurs in up to 33% of postpartum lactating mothers (both primipara and multipara). Usually within first 3 months after birth	• Warm to touch, indurated, painful, often unilateral • Most often caused by *Staphylococcus aureus*
Fibrocystic changes	Most common between ages 30 and 50	• Not usually discrete masses—nodularity instead • Usually accompanied by cyclic pain and tenderness • Mass(es) often cyclic in occurrence (movable, soft)
Cysts	Most common over age 35. Incidence decreases after menopause. Develop in over half of women in North America	• Palpable fluid-filled mass (movable, soft, tender) • Multiple cysts can occur and recur • Rarely associated with breast cancer
Fibroadenoma	Often occurs in teens and those in their 20s	• Palpable mass (firm, movable), usually 1–3 cm in size • Rarely associated with breast cancer
Fat necrosis	Many women report a history of trauma to breast	• Usually a hard, tender, mobile, indurated mass with irregular borders
Ductal ectasia	Most common in women over 60 years old. Considered a normal part of aging. May be due to duct obstruction or mastitis	• Nipple fixation, usually accompanied by nipple discharge of thick gray material • Breast pain often present

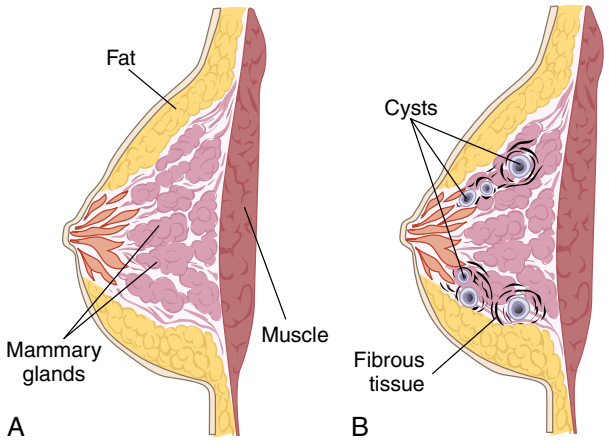

Fig. 56.2 (A) Normal breast tissue. (B) Fibrocystic breast tissue.

FIBROCYSTIC CHANGES

Fibrocystic changes are benign conditions characterized by changes in breast tissue (Fig. 56.2).[6,7] Fibrocystic changes are the most common breast disorder. They occur in more than 30% to 60% of women of reproductive age. Fibrocystic changes occur most often between ages 30 and 50 but may begin under 21 years of age in as many as 10% of women. Many women report premenstrual abnormalities, early menarche or late menopause, or a history of spontaneous abortion. Others at risk include nulliparous women and nonusers of oral contraceptives.

Fibrocystic changes include excess fibrous tissue, hyperplasia of the epithelial lining of the mammary ducts, proliferation of mammary ducts, and cysts. We think these changes are due to a heightened responsiveness of breast tissue to circulating estrogen and progesterone. They may cause pain from chronic inflammation, edema, nerve irritation, and fibrosis. Pain and nodularity often increase over time. They tend to subside after menopause unless the woman is taking high doses of estrogen replacement. Symptoms often worsen in the premenstrual phase and subside after menstruation.

Manifestations of fibrocystic breast changes include 1 or more palpable lumps that are often round, well delineated, and freely movable within the breast (Table 56.2). Discomfort ranging from tenderness to pain may occur. The lump usually increases in size and sometimes tenderness before menstruation. Cysts may enlarge or shrink rapidly. Nipple discharge from fibrocystic breasts is often green or dark brown, not bloody.

Alone, fibrocystic changes do not increase breast cancer risk. Masses or nodules can appear in both breasts. They often occur in the upper, outer quadrants and usually bilaterally.

Mammography may be helpful in distinguishing fibrocystic changes from breast cancer. In some women, the breast tissue is so dense that it is hard to obtain a mammogram. In these situations, ultrasound can better distinguish a fluid-filled cyst from a solid mass.

Interprofessional and Nursing Care

With the discovery of a discrete mass in the breast by a woman or the HCP, aspiration or biopsy may be done. If the nodularity is recurrent, we may wait 7 to 10 days to see if any changes are related to the menstrual cycle. With large or frequent cysts, an excisional biopsy may be preferred over repeated aspiration. An excisional biopsy may be done if (1) no fluid is found on aspiration, (2) the fluid is hemorrhagic, or (3) a residual mass remains after fluid aspiration.

Severe fibrocystic changes may make palpating the breast more difficult. Teach the woman with cystic changes to maintain regular follow-up care with the HCP. Encourage breast self-awareness and to report any changes found so they can be evaluated.

Treatment for a fibrocystic condition is similar to that described earlier for mastalgia. Teach the woman with fibrocystic breasts that she may expect cysts to reoccur in 1 or both breasts until menopause and that the cysts may enlarge or become painful just before menstruation. Reassure her that the cysts do not "turn into" cancer. Tell her that the HCP should examine any new lump that does not respond in a cyclic manner over 1 to 2 weeks.

FIBROADENOMA

Fibroadenoma is the most common cause of discrete benign breast lumps in young women. It generally occurs in women in their teens and 20s. They occur more often in Black than White women.

The possible cause may be increased estrogen sensitivity in a localized area of the breast. Fibroadenomas are usually small (but can be large [2 to 3 cm]), painless, round, well delineated, and very mobile. They are usually solid, firm, and rubbery in consistency. There is no accompanying retraction or nipple discharge. The fibroadenoma may appear as a single unilateral mass, although multiple bilateral fibroadenomas may occur. Growth is slow and often ceases when the size reaches 2 to 3 cm. Menstruation does not affect size. However, pregnancy can stimulate dramatic growth.

Fibroadenomas are easily detected by physical assessment. They may be visible on mammography and ultrasound. However, definitive diagnosis requires FNA, core, or excisional biopsy and tissue examination to exclude a cancer. Treatment can include observation with regular monitoring if cancer is not present, there are no symptoms, and the mass stays less than 3 cm. A fibroadenoma that increases in size and/or is symptomatic should be removed by surgical resection or, in some cases, cryotherapy. All new lesions should be evaluated by breast ultrasound and possible biopsy.

NIPPLE DISCHARGE

Nipple discharge may occur spontaneously or because of nipple manipulation. Secretions can be clear, serous, bloody, or brown to green. A milky secretion is due to inappropriate lactation, or **galactorrhea**.

Disorders associated with nipple discharge include benign breast conditions, such as fibrocystic changes, intraductal papilloma, or ductal ectasia. It may be a result of certain medicines or endocrine or neurologic problems. Sometimes there is no known cause. In most cases, nipple discharge is not caused by cancer. However, spontaneous, unilateral discharge that can be reproduced on exam warrants further evaluation. A cytology slide of the secretion can help determine the specific cause and recommended treatment.

ATYPICAL HYPERPLASIA

Atypical hyperplasia is usually found after a biopsy is done to evaluate a suspicious area found on a mammogram or during a CBE. It can be in either the ducts (atypical ductal hyperplasia) or in the lobules (atypical lobular hyperplasia). Both increase the risk for breast cancer. To follow up on a diagnosis of atypical hyperplasia, an excisional biopsy or lumpectomy may be done to remove all the affected tissue.[6]

INTRADUCTAL PAPILLOMA

An **intraductal papilloma** is a benign, soft or hard, wart-like growth found in the mammary ducts. It is usually unilateral. Typically, the nipple has a bloody discharge that can be intermittent or spontaneous. Most intraductal papillomas are beneath the areola. They may be hard to palpate. They usually occur in women 35 to 55 years of age. A single duct or several ducts may be involved. Papillomas have a slightly increased risk for developing breast cancer, so a core biopsy is recommended. If there are any abnormal cells, surgical excision of the papilloma and the involved duct or duct system is done.[8]

DUCTAL ECTASIA

Ductal ectasia (duct dilation) is a benign breast disease of perimenopausal and postmenopausal women involving the ducts in the subareolar area. It usually involves several bilateral ducts. Nipple discharge is the main symptom. Ductal ectasia is initially painless but may progress to burning, itching, pain around the nipple, and swelling in the areolar area. Inflammatory signs are often present. The nipple may retract. The discharge may become bloody in more advanced disease. It is not associated with cancer. If an abscess develops, warm compresses and antibiotics are usually effective treatments. Therapy consists of close follow-up examinations or surgical excision of the involved ducts.

MALE GYNECOMASTIA

Gynecomastia is a transient, noninflammatory enlargement of 1 or both breasts. It is the most common breast problem in men. The condition is usually temporary and benign. Gynecomastia itself is not a risk factor for breast cancer. The most common cause is a change in the normal ratio of active androgen to estrogen in plasma or within the breast itself.[9]

Gynecomastia can occur in puberty. During puberty, there is often a transient relative imbalance between estrogen and testosterone, leading to gynecomastia. It usually resolves by age 20 years when the person reaches adult androgen-to-estrogen ratios. Reassure the parent and teenager about the benign nature of the condition.

Gynecomastia can also be a sign of other problems. It may occur with testicular tumors, adrenal cancer, pituitary adenomas, hyperthyroidism, and liver disease. It can be a side effect of drug therapy, particularly with estrogen and androgen, digitalis, isoniazid, ranitidine, and spironolactone. Marijuana use can also cause gynecomastia.

Senescent Gynecomastia

Senescent gynecomastia occurs in many older men. The likely cause is high plasma estrogen levels with the increased conversion of androgens to estrogens in peripheral circulation. Although initially unilateral, the tender, firm, centrally located enlargement may become bilateral. A discrete, circumscribed mass with gynecomastia must be biopsied to determine if it is the rare breast cancer in males. Senescent hyperplasia needs no treatment. It usually regresses within 6 to 12 months.

Gerontologic Considerations: Age-Related Breast Changes

The loss of subcutaneous fat and structural support and the atrophy of mammary glands often result in pendulous breasts in

the postmenopausal woman. Encourage older women to wear a well-fitting bra. Adequate support can improve physical appearance and reduce pain in the back, shoulders, and neck. It can also prevent *intertrigo,* dermatitis caused by friction between opposing surfaces of skin.

The decrease in glandular tissue makes a breast mass easier to palpate. This decreased density likely results from age-related decreases in estrogen. Rib margins may be palpable in a thin woman and can be confused with a mass. That is why it is so important that women become familiar with their own breasts and what is normal for them. Because the incidence of breast cancer increases with age, encourage breast awareness in older women. Encourage them to have an annual mammogram and CBE and have any breast-related concern evaluated by their HCP.

BREAST CANCER

Breast cancer is the most common cancer in American women except for skin cancer. It is second only to lung cancer as the leading cause of death from cancer in women. In the United States, more than 276,480 new cases of invasive breast cancer and more than 48,530 cases of in situ breast cancer are diagnosed each year. Another 2620 cases of breast cancer happen in men. About 42,690 deaths occur each year from breast cancer.[10]

The incidence of breast cancer is slowly decreasing, with a slight drop in the number of deaths from breast cancer. This decline may be due to the decreased use of hormone therapy after menopause as well as earlier detection and treatment advances. Breast cancer survivors are the largest group of any cancer survivors.

Etiology and Risk Factors

We do not completely understand the cause of breast cancer. We know there are several risk factors (Table 56.3). Risk factors appear to be cumulative and interacting. So, the presence of multiple risk factors may greatly increase the overall risk, especially for women with a positive family history.

Risk Factors for Women

The strongest risk factors include female gender and advancing age.[10] Women are at far greater risk than men. 99% of breast cancers occur in women. Increasing age increases the risk for developing breast cancer. The incidence of breast cancer in women under 25 years of age is very low. Risk increases gradually until age 55. After age 55, the incidence increases dramatically.

Hormonal regulation of the breast is related to cancer development, but we do not understand exactly how. The hormones estrogen and progesterone may act as tumor promoters to stimulate breast cancer growth if cancer changes in the cells have already occurred. The Women's Health Initiative study showed that combined hormone therapy (estrogen plus progesterone) (1) increases the risk for breast cancer after as little as 2 years use and (2) increased the risk for having a larger, more advanced breast cancer at diagnosis. However, this risk decreases within 5 years of stopping hormone therapy. Some studies show that using estrogen therapy alone for longer than 15 years (for women with a prior hysterectomy) increases long-term risk. A link also exists between oral contraceptive use and increased risk for breast cancer. This risk decreases when use stops and is gone after 10 years.

Modifiable risk factors include excess weight gain during adulthood, sedentary lifestyle, smoking, fat intake, obesity, nightshift work, and alcohol use. Environmental factors, such as radiation exposure and using hair dyes and straighteners, may play a role.

Genetic Link

Family history of breast cancer is an important risk factor, especially if the family member also had ovarian cancer, was

TABLE 56.3 Risk Factors for Breast Cancer

Risk Factor	Comments
Age ≥55 years	Majority found in postmenopausal women After age 60, ↑ in incidence
Alcohol use	Drinking ≥1 alcoholic beverage per day may have an ↑ risk
Benign breast disease with atypical epithelial hyperplasia, lobular carcinoma in situ	Atypical changes in breast biopsy ↑ risk
Chemicals in environment, cosmetics (parabens, phthalates), food	Emerging risk: may be hormone disruptors
Early menarche (before age 12), late menopause (after age 55)	A long menstrual history ↑ risk
Exposure to ionizing radiation	Radiation damages DNA (e.g., prior treatment for Hodgkin lymphoma)
Family history	Breast cancer, ovarian, pancreatic and high-grade prostate cancer in a first-degree relative, particularly when premenopausal or bilateral
Female	Women account for 99% of breast cancer cases
First full-term pregnancy after age 30, nulliparity, no breastfeeding	Prolonged exposure to unopposed estrogen ↑ risk
Genetic factors *(BRCA1, BRCA2, P53, PTEN, PALB2, ATM, CHEK2, NBM)*	Gene mutations play a role in up to 10% of breast cancer cases
Hair chemicals in permanent dyes and hair straightening products	Emerging risk: especially in Black women
Height, being taller	May be due to factors related to early growth
Hormone use	Use of estrogen and/or progesterone as hormone therapy, especially in postmenopausal women
Light exposure at night	Emerging risk: seen in night shift workers
Long-term heavy smoking	May ↑ risk, especially in women who begin smoking before first pregnancy
Obesity, weight gain after menopause	Fat cells store estrogen, which ↑ the risk for developing breast cancer
Personal history of breast, colon, endometrial, or ovarian cancer	Personal history significantly ↑ risk for breast cancer, risk for cancer in other breast, and recurrence
Physical inactivity	Risk ↑s most after menopause
Race and ethnicity	See Box 56.2

premenopausal, or had bilateral breast cancer. Having any first-degree relative (mother, father, sister, brother, daughter) with breast cancer doubles a woman's risk for breast cancer, especially if the relative was diagnosed at a young age.[11] A breast cancer risk assessment tool for HCPs is available (www.cancer.gov/bcrisktool). Genetic counseling must be considered for a person at high risk for breast cancer.

Up to 10% of all breast cancers are hereditary. This means that the person inherited specific genetic abnormalities that contribute to breast cancer development (Box 56.1). Most inherited cases of breast cancer are related to mutations in 2 genes: *BRCA1* and *BRCA2. BRCA* stands for *BR*east *CA*ncer. Everyone has *BRCA* genes. The *BRCA1* gene, found on chromosome 17, is a tumor suppressor gene that inhibits tumor development when functioning normally. The *BRCA2* gene, found on chromosome 11, is another tumor suppressor gene. Women with a mutation of this gene have a similar risk for breast cancer.[11]

BOX 56.1 GENETICS IN CLINICAL PRACTICE

Breast Cancer

Genetic Basis

- Mutations occur in *BRCA1* and/or *BRCA2* genes.
- Normally, these genes are tumor suppressor genes involved in DNA repair.
- Transmission is autosomal dominant.
- Other genes (e.g., *ATM, CHEK2, TP53, PTEN, PALB2, NBM, NF1, STK11, CHD1, READ 56C, BRIP1, BARD1, STK11, MSI, NTRK*) may increase the risk for breast cancer.

Incidence

- Up to 10% of breast cancers are related to *BRCA1* and *BRCA2* gene mutations.
- As many as 1 in 300–800 women in the United States have *BRCA1* and *BRCA2* gene mutations.[12]
- Women with *BRCA1* and *BRCA2* gene mutations have a 41%–90% lifetime risk for developing breast cancer along with an increased risk for developing cancer in the other breast.
- Mutations in *BRCA* genes may cause as many as 90% of all inherited breast cancers.
- *BRCA1* and *BRCA2* gene mutations are associated with early-onset breast cancer that is more likely to involve both breasts.
- Men with mutations in *BRCA1* and *BRCA2* have an increased risk for breast cancer and prostate cancer.
- Family history of both breast and ovarian cancer increases the risk for having a *BRCA* mutation.

Genetic Testing

- DNA testing is available for *BRCA1* and *BRCA2* gene mutations.
- Genetic tests can analyze an entire panel of genes.

Clinical Implications

- Bilateral oophorectomy and/or bilateral mastectomy reduces the risk for breast cancer and ovarian cancer in women with *BRCA1* and *BRCA2* mutations.
- Women with *BRCA* mutations have a higher risk for developing ovarian, colon, pancreatic, and uterine cancers.[12]
- Genetic counseling and testing for *BRCA* mutations should be offered to patients whose personal or family history puts them at high risk for a genetic predisposition to breast cancer.

In addition to *BRCA* gene mutations, we have identified many other abnormal genes that increase a person's risk of developing breast cancer. These include the genes that normally suppress tumor growth, including *PALB2* (which partners with *BRCA* to suppress tumor growth), *TP53*, *CHEK2*, *PTEN*. Other genes that may be abnormal include *ATM* and *NBM* (help repair damaged DNA), *CDH1* (makes a protein to bind cells together), and *STK11* (provides instructions to make a tumor suppressor enzyme).[12]

Most people (90%) who develop breast cancer do not have an abnormal breast cancer gene or a family history of breast cancer. Their cancer is associated with genetic changes that occurred after they were born (somatic mutations). There is no risk for passing on the mutated gene to children.

Risk Factors for Men

Risk factors for breast cancer in men include estrogen use, hyperestrogenism, a family history of breast cancer, and radiation exposure. Examining the male breast should be a routine part of a physical assessment. Men in *BRCA*-positive families should consider genetic testing. Teach men who test positive for a *BRCA* gene mutation to be aware of how their breasts look and feel and to report any changes to their HCP. They should have a CBE every year starting at age of 35.[13] We do not recommend screening mammography as research shows this to be of no benefit. Men with a history of breast cancer treated with lumpectomy should have an ipsilateral annual mammogram. Men with a history of breast cancer and a genetic mutation with an increased risk of breast cancer should have a contralateral mammogram.[14] These men should begin prostate screening at age 35 as they have an increased risk for prostate cancer.

Prophylactic Oophorectomy and Mastectomy

In women with *BRCA1* or *BRCA2* mutations, prophylactic bilateral oophorectomy can decrease the risk for breast and ovarian cancers. Removing the ovaries lowers the risk for breast cancer because the ovaries are the main source of estrogen in a premenopausal woman.

CHECK YOUR PRACTICE

You are doing a preoperative assessment on a woman who having an elective mastectomy because she has a high risk for breast cancer based on her BRCA testing. You note that she appears nervous. She asks you, "Do you think I'm being too aggressive by having this surgery?"

- How would you respond to her?

Removing the ovaries does not reduce the risk for breast cancer in postmenopausal women because the ovaries are not the main producers of estrogen in these women. Women with *BRCA* mutations also have a higher risk for developing breast cancer in the unaffected (contralateral) breast. They may, as might any woman who has a high risk for developing breast cancer choose, in consultation with her HCP and genetic counselor, to undergo prophylactic bilateral mastectomy.

TABLE 56.4 Classification of Breast Cancer

Based on Tissue Type
- Ductal carcinoma (affects milk ducts)
  - Medullary
  - Tubular
  - Colloid (mucinous)
- Lobular carcinoma (affects milk-producing glands)
- Other
  - Inflammatory
  - Paget disease
  - Phyllodes tumor

Based on Invasiveness

Noninvasive (In situ)
- Ductal carcinoma in situ (DCIS)
- Pure Paget disease

Invasive (Spreading to Other Locations)
- Invasive ductal carcinoma
- Invasive lobular carcinoma

Based on Hormone Receptor and Genetic Status

Estrogen and Progesterone Receptor Status
- Estrogen receptor positive
- Estrogen receptor negative
- Progesterone receptor positive
- Progesterone receptor negative

HER-2 Genetic Status
- HER-2 positive
- HER-2 negative

Pathophysiology

The main components of the breast are lobules (milk-producing glands) and ducts (milk passages that connect the lobules and the nipple). In general, breast cancer arises from the epithelial lining of the ducts *(ductal carcinoma)* or from the epithelium of the lobules *(lobular carcinoma)*. Breast cancers may be in situ (within the duct) or invasive (invading through the duct wall).

Metastatic breast cancer is breast cancer that has spread to other organs. The most common sites are the bone, liver, lung, and brain. Cancer growth rates can range from slow to rapid. Factors that affect cancer prognosis are tumor size, axillary node involvement (the more nodes involved, the worse the prognosis), tumor differentiation, estrogen and progesterone receptor (PR) status, and *human epidermal growth factor receptor 2* (HER-2) status. HER-2 is a protein that helps regulate cell growth.[15]

Types of Breast Cancer

Breast cancer is not just one disease, but a group of diseases characterized by different pathologic findings and clinical behaviors. Breast cancer can be classified as (1) ductal, lobular, or other or (2) noninvasive or invasive (Table 56.4). We can also classify it based on hormonal status and genetic subtypes.

Noninvasive Breast Cancer

Around 20% of breast cancers are noninvasive. Noninvasive cancer stays within the milk ducts or lobules. They do not grow into or invade normal tissues within or beyond the breast. They are sometimes called carcinoma in situ ("in the same place") or pre-cancers. These cancers include *ductal carcinoma in situ* (DCIS) and pure Paget disease.

DCIS tends to be unilateral. It may progress to invasive breast cancer if left untreated. Treatment options include breast-conserving treatment (lumpectomy) with or without radiation therapy, total mastectomy with or without sentinel lymph node biopsy (SLNB), and/or hormone therapy (e.g., tamoxifen) to prevent recurrences.[16]

In the past, *lobular carcinoma in situ* (LCIS) was considered a noninvasive breast cancer. It is now classified as a benign condition that is a risk factor for developing breast cancer. No surgical or radiation treatment is indicated for LCIS. Hormone therapy may be used as a preventive measure to reduce breast cancer risk for some patients.

Invasive Ductal Carcinoma

Invasive (infiltrating) ductal carcinoma is the most common type of breast cancer. It accounts for about 80% of all invasive breast cancers. It starts in the milk ducts and then breaks through the walls of the duct, invading the surrounding tissue. From there, it may metastasize to other parts of the body. Subtypes of invasive ductal carcinoma include medullary, tubular, colloid (mucinous), papillary, and metaplastic.

Invasive Lobular Carcinoma

Invasive (infiltrating) lobular carcinoma begins in the lobules (milk-producing glands) of the breast. It accounts for about 10% to 15% of invasive breast cancers. The cancer cells can break out of the lobule and metastasize to other areas of the body. Invasive lobular carcinoma usually presents as a subtle thickening in the upper outer quadrant of the breast. It is often not detected by mammography.

Other Types of Breast Cancer

Inflammatory breast cancer. *Inflammatory breast cancer* is an aggressive and fast-growing breast cancer with a high risk for metastasis. It accounts for about 1% to 3% of all breast cancers. In the early stages, it is often mistaken for mastitis. However, the inflammatory changes do not improve with antibiotics. Cancer cells block the lymph channels in the skin of the breast. Because of skin involvement, the breast looks red, feels warm, and has a thickened appearance that is often described as looking like an orange peel *(peau d'orange)*. Sometimes, the breast develops ridges and small bumps that look like hives. A breast mass may not be present. Changes may not show up on mammograms, making diagnosis difficult. Inflammatory breast cancer has a worse prognosis as compared to invasive ductal and lobular breast cancers.[17]

Paget disease. **Paget disease** is a rare breast cancer that starts in the breast ducts and spreads to the nipple and areola. It causes about 1% of all breast cancers. It is different from Paget disease of the bone (see Chapter 68). Most women with Paget disease have underlying ductal carcinoma. Only in rare cases is the cancer confined to the nipple (in situ) and not invasive.

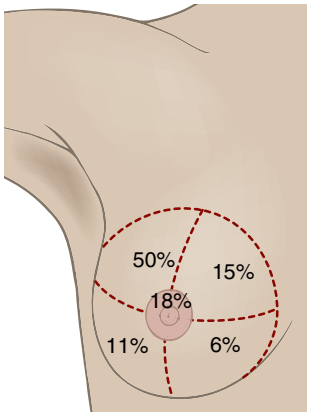

Fig. 56.3 Distribution of where breast cancer occurs.

Itching, burning, bloody nipple discharge with superficial skin erosion and ulceration may be present. A pathologic examination of the lesion confirms the diagnosis. Nipple changes are often diagnosed as an infection or dermatitis, which can lead to treatment delays.

The treatment of Paget disease is surgical removal of the involved tissue by either central lumpectomy or mastectomy with or without sentinel node (SLN) biopsy. Radiation therapy may be used after surgery. The prognosis is good when the cancer is confined to the nipple.

Phyllodes tumor. A phyllodes tumor is a very rare tumor that develops in the connective tissue (stroma) of the breast. The tumors tend to grow quickly, within a period of weeks or months, to a size of 2 to 3 cm or sometimes larger. Although most are benign, some are cancerous. Treatment is usually excision with a wide margin. Axillary surgery is not necessary.

Triple-Negative Breast Cancer

A patient whose breast cancer tests negative for all 3 receptors (estrogen, progesterone, HER-2) has *triple-negative breast cancer.*[18] The incidence of triple-negative breast cancer is higher in Blacks, Hispanics, premenopausal women, and those with a *BRCA1* mutation. These patients tend to have more aggressive tumors with a poorer prognosis. These cancers do not respond to hormone therapy or therapy for HER-2. Chemotherapy is more successful for treating triple-negative breast cancer.

Clinical Manifestations

Breast cancer is usually detected as a lump or thickening in the breast or mammography abnormality. It occurs most often in the upper, outer quadrant of the breast, which is the location of most of the glandular tissue (Fig. 56.3). Breast cancers vary in their growth rate. If palpable, breast cancer is characteristically hard and may be irregularly shaped, poorly delineated, nonmobile, and nontender.

A small number of breast cancers cause nipple discharge. The discharge is usually unilateral. It may be clear or bloody. Nipple retraction may be present. Peau d'orange may occur due to plugging of the dermal lymphatics. In large cancers, infiltration, induration, and dimpling (pulling in) of the overlying skin may occur.

TABLE 56.5 Sites of Breast Cancer Recurrence and Metastasis

Site	Manifestations
Local Recurrence	
Skin, chest wall	Firm, discrete nodules. Sometimes pruritic, usually painless, often in or near a scar
Regional Recurrence	
Lymph nodes	Enlarged nodes in axilla or supraclavicular area, usually nontender
Distant Metastasis	
Bone marrow	Anemia, infection, ↑ bleeding, bruising, petechiae. Weakness, fatigue, mild confusion, lightheadedness, dyspnea
Brain	Headache, unilateral sensory loss, focal muscular weakness, hemiparesis, incoordination (ataxia), nausea and vomiting not related to medication, cognitive changes
Liver	Abdominal distention. Right lower quadrant abdominal pain sometimes radiating to scapular area. Nausea and vomiting, anorexia, weight loss. Weakness and fatigue. Hepatomegaly, ascites, jaundice. Peripheral edema. High liver enzymes
Lung (including lung nodules and pleural effusions)	Shortness of breath, tachypnea, nonproductive cough
Skeletal	Localized pain of gradually increasing intensity, percussion tenderness at involved sites, pathologic fracture caused by involvement of bone cortex
Spinal cord	Progressive back pain, localized and radiating. Change in bladder or bowel function. Loss of sensation in lower extremities

Complications

The main complication of breast cancer is recurrence (Table 56.5). Recurrence may be *local* or *regional* (skin or soft tissue near the mastectomy site, axillary or internal mammary lymph nodes) or distant. Widely disseminated or metastatic disease involves the growth of cancerous breast cells in parts of the body distant from the breast. Most often involved are the bone, lung, brain, and liver. Metastases primarily occur through the lymphatics, usually those of the axilla (Fig. 56.4). However, metastatic disease can occur anywhere.

Diagnostic Studies

In addition to radiologic and biopsy studies used to diagnose breast cancer, we use other tests to predict the risk for local or systemic recurrence. These tests include axillary lymph node analysis, tumor size, estrogen and PR status, cell-proliferative indices (number of cells that are dividing), and genomic assays.

Axillary Lymph Node Analysis

Axillary lymph node involvement is an important prognostic factor in breast cancer. *Axillary lymph nodes* are often examined

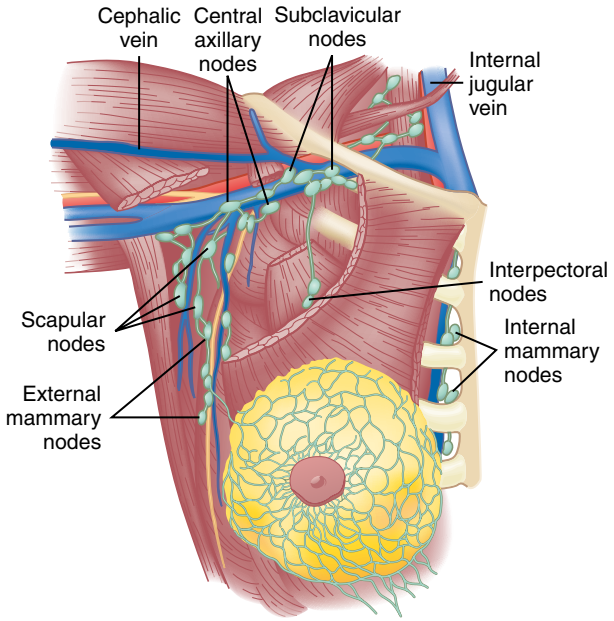

Fig. 56.4 Lymph nodes and drainage in the axilla. The sentinel lymph node is usually found in the external mammary nodes. A complete axillary dissection would remove all nodes. (From Donegan WL, Spratt JS: *Cancer of the breast,* ed 3, Philadelphia, 1988, Saunders.)

to see if cancer has spread to the axilla on the same side of the breast as the cancer (Fig. 56.4). The more nodes involved, the greater the risk for recurrence.

A *sentinel lymph node biopsy* helps to identify the lymph node(s) that drain first from the tumor site. Those nodes are *sentinel node(s)*. In SLNB, a radioisotope and/or blue dye, which will travel the same route as the cancer, is injected into the affected breast. Then, in surgery, the HCP determines if the radioisotope (using radioactive detector) or dye (visually see blue nodes) is found in any SLNs. A local incision is made in the axilla, and the HCP dissects the blue-stained and/or radioactive SLNs. Generally, with SLNB, 1 to 4 axillary lymph nodes are removed. The nodes are sent for pathologic analysis. If the SLNs are negative, no further axillary surgery is needed.

If the SLNs are positive or the SLN cannot be identified, the patient may have a complete *axillary lymph node dissection* (ALND). In an ALND, the HCP will typically remove 12 to 20 lymph nodes. SLNB is less invasive and has a lower mortality rate than ALND.

Tumor Size

Tumor size is a prognostic variable. In general, the larger the tumor, the poorer the prognosis. The wide variety of biologic types of breast cancer explains the variability of disease behavior. In general, the more well differentiated (like the original cell type) the tumor, the less aggressive it is. The cells of poorly differentiated (unlike the original cell type) tumors appear morphologically disorganized, and they are more aggressive.

Estrogen and Progesterone Receptor Status

Estrogen receptor (ER) and progesterone receptor (PR) status is another diagnostic test useful for decisions about treatment and prognosis. Hormone receptor testing is done with any newly diagnosed primary or metastatic breast cancer and on DCIS. Receptor-positive tumors (1) often show histologic evidence of being well differentiated, (2) have a lower chance for recurrence, (3) often have a *diploid* (more normal) DNA content and low proliferative indices, and (4) are often hormone dependent and responsive to hormone therapy. Receptor-negative tumors (1) are often poorly differentiated histologically, (2) often recur, (3) have a high incidence of *aneuploidy* (abnormally high or low DNA content) and higher proliferative indices, and (4) are usually unresponsive to hormone therapy. Ploidy status (number of chromosomes in a cell) correlates with tumor aggressiveness. Diploid tumors have a much lower risk for recurrence than aneuploid tumors.

Genomic Assay

An important *genomic assay* is to determine HER-2, which is a prognostic indicator. Overexpression of HER-2 is associated with unusually aggressive tumor growth, a greater risk for recurrence, and a poorer prognosis. It is overexpressed in 10% to 20% of patients with breast cancer. The presence of HER-2 helps in the selection and sequence of drug therapy and predicts the patient's response to treatment. HER-2 testing is done with any newly diagnosed primary or metastatic breast cancer.

A *gene expression assay* test uses a sample of the breast cancer tissue to analyze the activity of a group of genes that can affect how a cancer is likely to behave and respond to treatment. Knowing whether certain genes are present or absent, or overly active or not active enough, can provide information about the risk for recurrence and the expected benefit of chemotherapy or hormone therapy. The 21-gene recurrence (OncotypeDX) test is the most often used genomic test.[19] Other genomic tests are MammaPrint, PAM50 (Prosigna), EndoPredict, and the Breast Cancer Index.

Cell-Proliferative Indices

Cell-proliferative indices indirectly measure the rate of tumor cell proliferation. The number of tumor cells in the synthesis (S) phase of the cell cycle (see Fig. 16.1) is another important prognostic indicator. Although cell-proliferative indices are not a routine part of the cancer pathology evaluation, patients with cells that have high S-phase fractions have a higher risk for recurrence and earlier cancer death.

Interprofessional Care

A wide range of treatment options is available (Table 56.6). The treatment plan is often determined by prognostic factors, the clinical stage, and biology of the cancer.

Breast Cancer Staging

The most widely accepted staging method for breast cancer is the TNM system. This system uses anatomic factors of tumor size (T), nodal involvement (N), and presence of metastasis (M) to determine the stage of disease (Table 56.7). The stages range from 0 to IV, with stage 0 being in situ cancer with no lymph node involvement and no metastasis. Stage IV indicates metastatic spread, regardless of tumor size or lymph node involvement. This system is used worldwide to communicate

TABLE 56.6 Interprofessional Care

Breast Cancer

Diagnostic Assessment

Prediagnosis

- Health history, including risk factors
- Physical assessment, including breast and lymph nodes
- Mammography
- Ultrasound (if indicated)
- Breast MRI (if indicated)
- Biopsy

Postdiagnosis

- Lymph node analysis
- Estrogen and progesterone receptor status
- Cell-proliferative indices
- HER-2 marker
- Genetic assays (e.g., MammaPrint, Oncotype DX)

Staging

- Complete blood count
- Liver function tests
- Chest x-ray (if indicated)
- CT scan of chest, abdomen, pelvis (if indicated)
- PET/CT, MRI, bone scans (if indicated)

Management

Surgical Therapy

- Breast-conserving surgery (lumpectomy) with SLNB and/or axillary lymph node dissection
- Simple (total) mastectomy with SLNB and/or axillary lymph node dissection
- Modified radical mastectomy
- Reconstructive surgery

Radiation Therapy

- External radiation
- Brachytherapy
- Palliative radiation therapy

Drug Therapy (Table 56.9)

- Chemotherapy
- Hormone therapy
- Immunotherapy
- Targeted therapy

TABLE 56.7 Staging of Breast Cancer

Stage	Tumor Size	Lymph Node Involvement	Metastasis
0	TIS (tumor in situ)	No	No
I			
A	<2 cm	No	No
B	<2 cm	<2 mm	No
II			
A	No evidence of tumor ranging to 5 cm	No, or 1–3 axillary nodes and/or internal mammary nodes	No
B	Ranging from ≤2 to >5 cm	No, or 1–3 axillary nodes and/or internal mammary nodes	No
III			
A	Ranging ≤2 to >5 cm	Yes, 1–9 axillary nodes and/or internal mammary nodes	No
B	Any size with extension to chest wall or skin	No, or 1–9 axillary nodes and/or internal mammary nodes	No
C	Any size	Yes, ≥10 axillary nodes, internal mammary nodes, or infraclavicular nodes	No
IV	Any size	Any type of nodal involvement	Yes

the size of a breast cancer and the extent to which it has spread. It provides an accurate prediction of the outcome of a group of patients.

The latest cancer staging guidelines add biologic factors in making the final determination of the stage. These enable more accurate determination of prognosis and appropriate systemic therapy. These factors include tumor grade, hormone receptor expression, HER-2 overexpression and/or amplification, and genomic panels.

For example, some larger tumors are considered stage I instead of stage II based on their biology. For patients with hormone receptor–positive, HER2-negative, lymph node–negative tumors, and a low-risk gene recurrence score, regardless of T size, place into the same prognostic category as T1a-T1b N0 M0. Patients with triple-negative tumors have survival equal to that of patients with disease 1 TNM stage higher who have ER, PR, or HER2-positive expressing tumors.

Surgical Therapy

Surgery is the main treatment for breast cancer. Table 56.8 describes the most common procedures used to treat breast cancer. The most common options for operable breast cancer are (1) breast conservation surgery (lumpectomy [segmental mastectomy]) and (2) mastectomy with or without reconstruction. Most women diagnosed with early-stage breast cancer (tumors smaller than 5 cm) are candidates for either surgery. The overall survival rate with lumpectomy and radiation is the same as with mastectomy.[15]

Breast reconstruction is an option for any woman having surgery for breast cancer. Women having a mastectomy can have breast reconstruction at the time of the surgery or months or even years later. Some women choose to not have reconstruction and use a breast prosthesis instead.

Breast-conserving surgery. Breast-conserving surgery, or **lumpectomy**, involves removing the entire tumor along with a margin of normal surrounding tissue (Fig. 56.5A). In some cases, it may take 2 or 3 more surgeries to remove all the cancer from the margins. After surgery, radiation therapy is usually delivered to the entire breast, ending with a boost to the tumor bed. If the risk for recurrence is high, the patient may receive chemotherapy before starting radiation.

TABLE 56.8 Surgical Procedures for Breast Cancer

Procedure	Side Effects	Complications	Patient Issues
Breast-Conserving Surgery (Lumpectomy) With Radiation Therapy			
Excision of tumor with no tumor at margins, sentinel lymph node biopsy (SLNB) and/or axillary lymph node dissection (ALND) Radiation therapy	Arm swelling Breast edema Breast soreness Sensory changes in breast and arm Skin reactions	*Short-term:* moist desquamation[a] hematoma, seroma, infection *Long-term:* fibrosis,[a] lymphedema,[b] myositis, pneumonitis,[a] rib fractures[a]	Impaired arm mobility[b] Prolonged treatment[a] Texture and sensitivity changes in breast
Mastectomy			
Simple Mastectomy Removal of breast, preservation of pectoralis muscle, SLNB may be done at same time ***Modified Radical Mastectomy*** Removal of breast with ALND, pectoralis muscle is spared	Chest wall tightness, scar Impaired range of motion Lymphedema Phantom breast sensations Sensory changes	*Short-term:* skin flap necrosis, seroma, hematoma, infection *Long-term:* sensory loss, muscle weakness, lymphedema	Body image Impaired arm mobility Incision Loss of breast Need for prosthesis
Breast Implants and Tissue Expansion			
Expander used to slowly stretch tissue. Saline gradually injected into reservoir over weeks to months Insertion of implant under musculofascial layer of chest wall Fat grafting can sometimes replace implant	Chest wall tightness Pain	*Short-term:* skin flap necrosis, wound separation, seroma, hematoma, infection *Long-term:* capsular contractions, displacement of implant	Body image HCP visits to expand implants Potential added surgeries for nipple construction, symmetry
Breast Reconstruction Tissue Flap Procedures[c]			
Transverse Rectus Abdominis Musculocutaneous (TRAM) Flap Musculocutaneous flap (muscle, skin, fat, blood supply) is transposed from abdomen to the mastectomy site May be done concurrently with mastectomy	Pain related to 2 surgical sites and extensive surgery	*Short-term:* delayed wound healing, infection, skin flap necrosis, abdominal hernia, hematoma	Longer postoperative recovery
Deep Inferior Epigastric Artery Perforator (DIEP) Flap Free flap that transfers skin and fat from the abdomen to the chest. Differs from TRAM flap because no muscle is moved	More time in surgery than pedicle TRAM flap Pain related to 2 surgical sites	Needs close monitoring first 24–48 hr after surgery. If flap fails, patient needs surgery	Less pain and impaired movement than with a pedicle TRAM flap

[a]Specific to radiation therapy.
[b]If ALND (less likely with SLNB).
[c]This list is not inclusive; other breast reconstruction options are available.

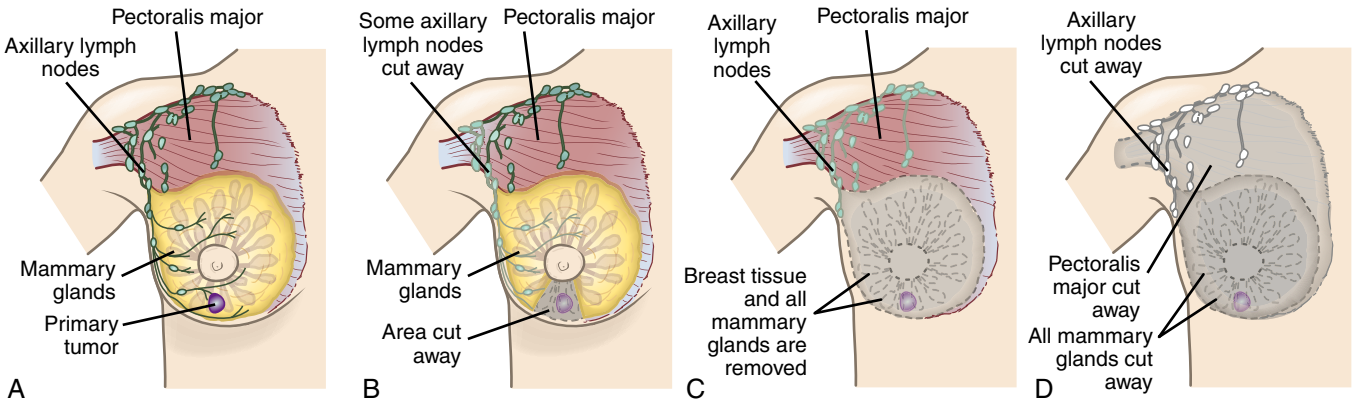

Fig. 56.5 Breast cancer surgery. (A) Preoperative. (B) Lumpectomy. (C) Simple mastectomy. (D) Modified radical mastectomy.

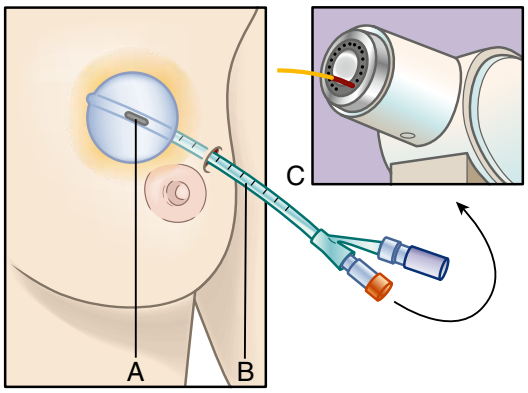

Fig. 56.6 High-dose brachytherapy for breast cancer. The MammoSite system involves the insertion of a single small balloon catheter *(B)* at the time of the lumpectomy or shortly thereafter into the tumor resection cavity (the space that is left after the HCP removes the tumor). A tiny radioactive seed *(A)* is inserted into the balloon, connected to an afterloader *(C),* and delivers the radiation therapy.

Not everyone is a candidate for breast conservation surgery. Contraindications include breast size too small in relation to the tumor size to yield an acceptable cosmetic result, multifocal masses and calcifications, multicentric masses (in more than 1 quadrant), diffuse calcifications in more than 1 quadrant, or prior radiation therapy. Because of the time commitment (5 to 7 weeks of daily radiation therapy treatments) and travel distances to access radiation therapy treatment centers, some patients may choose mastectomy over breast conservation surgery.

Mastectomy. A *total* or *simple mastectomy* removes the entire breast. A *modified radical mastectomy* includes removal of the breast and axillary lymph nodes. It preserves the pectoralis major muscle (Fig. 56.5B). For women desiring breast reconstruction, a skin-sparing mastectomy provides the best cosmetic result and does not increase the chance of the cancer recurring. In a *nipple-sparing mastectomy,* the nipple and/or areola are left in place and the breast tissue under them is removed. Women who have a small, low-grade cancer near the outer part of the breast, with no signs of cancer in the skin or near the nipple, may be able to have nipple-sparing surgery.

For women who have a mastectomy, breast reconstruction can be done with the mastectomy or it can be delayed. Some women choose not to have reconstruction. There are 2 main types of breast reconstruction procedures: implant reconstruction or procedures that use autologous tissue transplantation (pedicled or microsurgical flaps from the abdomen, back, buttocks or thigh, and/or fat grafting) (Table 56.8).

Radiation Therapy

Radiation therapy is one *adjuvant (additional)* therapy that can be used after surgery. It is used for breast cancer to (1) prevent local breast cancer recurrences after breast-conserving surgery; (2) prevent local and lymph node recurrences after mastectomy; or (3) relieve pain caused by local, regional, or distant cancer spread.

External radiation therapy. When radiation therapy is a primary treatment, it is usually done after surgery. The decision to use radiation after mastectomy is based on the chance that local, residual cancer cells are present. Radiation of the axilla and/or supraclavicular nodes may be done when lymph nodes are involved to decrease the risk for axillary recurrence. Radiating a localized area does not prevent distant metastasis.

With traditional whole breast, and in some cases regional lymph node, treatment, the area is radiated 5 days per week over the course of about 5 to 7 weeks. An external beam of radiation delivers daily fractions to a total dose of 46 to 50 Gy (4500 to 5000 cGy). Patients who have had breast-conserving surgery may receive a "boost" dose of radiation to the area where the original tumor was located. It is given by external beam and adds 4 to 8 more treatments to the total number given.[15]

Newer and preferred regimens use a type of accelerated external beam radiation called hypofractionation. This type of radiation has a shortened schedule, daily for 3 to 4 weeks, with a total dose of 40 to 42.5 Gy.[15]

Fatigue, skin changes, and breast edema are temporary side effects of external radiation therapy. Nursing care of the patient receiving radiation therapy is discussed in Chapter 16.

Brachytherapy. *Brachytherapy* (internal radiation) is used for partial-breast radiation. It is an alternative to traditional external radiation treatment for some patients with early-stage breast cancer.[15] This method has the same chance for local recurrence as whole breast radiation. However, the cosmetic results may not be as good.

Brachytherapy is minimally invasive. The radiation is delivered directly into the cavity left after a tumor is surgically removed by a lumpectomy. Because the radiation is concentrated and focused on the area with the highest risk for tumor recurrence, it only requires 5 treatments. Therapy is delivered using a multicatheter method or balloon-catheter system.

In the *multicatheter method* (e.g., SAVI) many small catheters are placed in the breast at the site of the tumor. The SAVI is inserted through a small incision, and the catheter bundle expands uniformly. The ends of the catheters stick out through little holes in the skin. Small radioactive seeds are placed in the catheters. The seeds are left in place just long enough to deliver the radiation dose (e.g., 5 to 10 minutes) and then removed. The radiation does not stay in the body between treatments or after the last treatment is over.

In the *balloon-catheter system*, a balloon is placed where the tumor was located. The balloon is filled with fluid, to keep it in place, then radioactive seeds are inserted (Fig. 56.6). Radiation is emitted by a tiny radioactive seed attached by a wire to an afterloader, a computer-controlled machine. The seed travels through the MammoSite applicator into the inflated balloon. As with the multicatheter system, the radiation does not stay in the body between treatments or after the last treatment is over. After the last session, the balloon is deflated, and the system is removed.

Palliative radiation therapy. Reducing the primary tumor mass with radiation often results in a decrease in pain. Radiation is a treatment option for symptomatic metastatic lesions in such sites as bone, soft tissue organs, brain, and chest. It often relieves pain and is successful in controlling recurrent or metastatic disease.

Drug Therapy

Drug therapy includes chemotherapy, hormone therapy, immunotherapy, and targeted therapy. When drug therapy is given before surgery, we call it *neoadjuvant therapy.* Neoadjuvant therapy is given to shrink the size of the tumor enough to make surgical removal possible or allow for breast-conserving surgery in women who would have been recommended to have a mastectomy. It also allows time for genetic testing to occur (if appropriate) so a patient can make more informed treatment decisions. It provides evidence whether the tumor is responsive to the selected agent(s).

Drug therapy after surgery is called *adjuvant therapy*. Drug therapy can decrease the rate of recurrence and increase the length of survival. Because of the risk for recurrent disease, nearly all patients with evidence of node involvement, particularly those who are hormone receptor negative, will have some type of drug therapy. Some patients, especially those with a more aggressive tumor, have a higher risk for recurrent or metastatic disease. They may receive drug therapy even when there is no evidence of node involvement. Weighing the risks and benefits of drug therapy is a complex process.

Chemotherapy. Chemotherapy is the use of cytotoxic drugs to destroy cancer cells. A combination of drugs is usually better than using a single drug. Combination treatment is best because the drugs have different mechanisms of action and work at different parts of the cell cycle. When used in the neoadjuvant and adjuvant setting, chemotherapy is usually given for 3 to 6 months. However, a patient with metastasis may receive chemotherapy for the rest of their life.

Common combination-therapy protocols in the adjuvant and neoadjuvant setting are (1) CMF: cyclophosphamide, methotrexate, and fluorouracil; (2) AC: doxorubicin and cyclophosphamide, with or without the addition of a taxane, such as paclitaxel (Taxol) or docetaxel (Taxotere); or (3) CEF or CAF: cyclophosphamide, epirubicin (Ellence) or doxorubicin, and fluorouracil.

DRUG ALERT

Doxorubicin

- Monitor for signs of cardiotoxicity and heart failure (e.g., shortness of breath, pedal edema, decreased activity tolerance, dysrhythmias, ECG changes).
- Tell the patient not to have immunizations without the HCP's approval.

Teach patients to avoid contact with those who recently received live virus vaccines and those with infections. Because chemotherapy affects healthy cells, many side effects accompany chemotherapy. The incidence and severity of common side effects are related to specific drug combinations, drug schedule, and dosage. The most common side effects involve rapidly dividing cells in the gastrointestinal tract (nausea, anorexia, weight loss), bone marrow (anemia), and hair follicles (hair loss).

Cognitive changes during and after treatment can occur. We often call this *"chemo brain."* These changes include problems with memory, focus, and attention. Cognitive changes in cancer are discussed in Chapter 16.

Hormone therapy. Estrogen can promote the growth of breast cancer cells if the cells are ER positive. Hormone therapy promotes tumor regression by either (1) blocking ERs or (2) suppressing estrogen synthesis by inhibiting aromatase, an enzyme needed for estrogen synthesis (Table 56.9).

ER and PR status assays can identify women whose breast cancers are likely to respond to hormone therapy. These assays predict whether hormone therapy is a treatment option. Chances of tumor regression are much higher in women whose tumors have estrogen and PRs. The 21-gene recurrence score (OncotypeDX) can identify which women with hormone-positive breast cancer can be treated with hormone therapy alone and do not need chemotherapy.

Premenopausal women with ER-positive breast cancers may benefit from the removal or suppression of their ovaries. Ovarian ablation can be done surgically or by using luteinizing hormone-releasing hormone (LHRH) analogs, such as goserelin (Zoladex) or leuprolide (Lupron).

Estrogen receptor blockers. ER blockers include tamoxifen, toremifene (Fareston), and fulvestrant (Faslodex). Tamoxifen has been the hormone therapy of choice in ER-positive women at all stages of breast cancer for the past 30 years. It also may be used in high-risk women to prevent breast cancer. Common side effects include hot flashes, mood swings, vaginal discharge and dryness, and other effects associated with decreased estrogen. It increases the risk for blood clots, cataracts, stroke, and endometrial cancer in postmenopausal women.

DRUG ALERT

Tamoxifen

- Irregular vaginal bleeding or spotting may occur.
- Decreased visual acuity, corneal opacity, and retinopathy can occur in women receiving high doses (240–320 mg/day for >17 months). These problems may not be reversible.
- Teach the patient to immediately report any vision changes.
- Monitor for signs of VTE and stroke, including shortness of breath, leg cramps, and weakness.

Aromatase inhibitors. Aromatase inhibitors lower estrogen levels by stopping aromatase, an enzyme in fat tissue, from changing other hormones into estrogen. These drugs include anastrozole (Arimedex), letrozole (Femara), and exemestane (Aromasin). They do not stop the ovaries from making estrogen. Thus, they are of little benefit and may be harmful in premenopausal women. They are used to treat breast cancer in postmenopausal women.

Because they block estrogen production in postmenopausal women, osteoporosis and bone fractures may occur. Side effects include night sweats, nausea, and joint and muscle pain.

Estrogen receptor modulators. Raloxifene (Evista) is a selective ER modulator that has both estrogen-agonistic effects on bone and estrogen-antagonistic effects on breast tissue (see Chapter 68).

TABLE 56.9 Drug Therapy

Breast Cancer

Drug Class	Mechanism of Action	Indications
Hormone Therapy		
Aromatase Inhibitors		
anastrozole (Arimidex) exemestane (Aromasin) letrozole (Femara)	Prevents estrogen production by inhibiting aromatase	ER-positive breast cancer in postmenopausal women only
Estrogen Receptor (ER) Blockers		
fulvestrant (Faslodex)	Blocks ERs and increases their degradation	ER-positive breast cancer in postmenopausal women only
tamoxifen	Selectively blocks ERs	ER-positive breast cancer in premenopausal and postmenopausal women Used as a preventive measure in high-risk premenopausal and postmenopausal women
toremifene (Fareston)	Blocks ERs	ER-positive breast cancer in postmenopausal women only
Estrogen Receptor Modulator		
raloxifene (Evista)	In breast, blocks the effect of estrogen. In bone, promotes effect of estrogen and prevents bone loss	Postmenopausal women
Targeted Therapy		
HER-2 Inhibitors		
lapatinib (Tykerb)	Blocks the function of HER-2 related kinases inside the cell	HER-2-positive breast cancer
margetuximab-cmkb (Margenza) pertuzumab (Perjeta) trastuzumab (Herceptin) trastuzumab-pkrb (Herzuma) trastuzumab-qyyp (Trazimera)	Blocks HER-2 receptor	HER-2-positive breast cancer
ado-trastuzumab emtansine (Kadcyla)	Trastuzumab with a chemotherapy drug called DM1	HER-2-positive breast cancer
fam-trastuzumab deruxtecan-nxki (Enhertu)	HER-2 directed antibody and a topoisomerase inhibitor	Advance or metastatic HER-2 positive breast cancer after 2 other HER-2 therapies
Kinase Inhibitors		
abemaciclib (Verzenio) palbociclib (Ibrance) ribociclib (Kisqali)	CDK4/6 Kinase inhibitors	ER-positive, HER-2-negative breast cancer in postmenopausal women
neratinib (Nerlynx) tucatinib (Tukysa)	Tyrosine kinase inhibitor	Advance or metastatic HER-2 positive breast cancer after 1 other HER-2 therapy, includes patients with brain metastasis
alpelisib (Piqray)	P13 kinase inhibitor	PIK3CA mutated, HER-2 negative advanced breast cancer
everolimus (Afinitor)	mTOR inhibitor suppressing T cell activation and proliferation	ER-positive, HER-2-negative breast cancer in postmenopausal women
olaparib (Lynparza) talazoparib (Talzenna)	PARP inhibitors	Patients with metastatic breast cancer positive for BRCA mutations
entrectinib (Rozlytrek) larotrectinib (Vitrakvi)	NTRK inhibitors	In NTRK + breast cancers (very rare) when no other options exist
Immunomodulators		
atezolizumab (Tecentriq)	PD-1 inhibitor	PD-L1 positive triple negative advanced or metastatic breast cancer
pembrolizumab (Keytruda)	PD-'1 inhibitor	Any MSI-H breast cancer when no other options exist
sacituzumab govitecan-hziy (Trodelvy)	Monoclonal antibody that targets Trop-2 protein and a topoisomerase 1 inhibitor	Metastatic triple negative disease after 2 other therapies

Targeted Therapy

As we learn more about genetic changes in breast cancer, we have developed drugs that specifically target cells that have altered gene expression. One of these genetic changes is the overexpression of HER-2. Tumors that overexpress the HER-2 protein tend to be more aggressive and are more likely to recur.

HER-2 inhibitors work by attaching to the HER-2 receptors on the surface of the breast cancer cells and blocking them from receiving signals that tell them to proliferate. Trastuzumab

(Herceptin) is one HER-2 inhibitor. It can be used alone or in combination with chemotherapy agents. The most common side effects are flu-like symptoms (fever, chills, myalgia), nausea and vomiting, diarrhea, and infusion reactions. A possible, but more serious, side effect is heart damage. Trastuzumab-qyyp (Trazimera) and trastuzumab-pkrb (Herzuma) are biosimilars of trastuzumab.

DRUG ALERT

Trastuzumab (Herceptin)

- Use with caution in women with preexisting heart disease.
- Monitor for signs of heart failure.

Other drugs that target HER-2 include pertuzumab (Perjeta), ado-trastuzumab emtansine (Kadcyla), and lapatinib (Tykerb). Neratinib (Nerlynx) is an option for extended adjuvant therapy for some high-risk women. Using 2 of these agents together for neoadjuvant therapy can increase the number of tumors that become undetectable. Survival improves when used for adjuvant therapy.

Kinase inhibitors prevent cells from dividing, thus slowing cancer growth. Drugs in this class include palbociclib (Ibrance), ribociclib (Kisqali), and abemaciclib (Verzenio). They are used for ER-positive, HER-2-negative cancer in postmenopausal women

Other targeted drugs include everolimus (Afinitor). It works by blocking mTOR, a protein that normally promotes cell growth and division. The PARP inhibitors olaparib (Lynparza) and talazoparib (Talzenna) are used in patients with metastatic breast cancer positive for BRCA mutations. Alpelisib (Piqray) a PI3K inhibitor, is used for patients with advanced or metastatic disease with a PIK3CA-mutation. For the rare breast cancers that test positive for NTRK fusion genes, the NTRK inhibitors larotrectinib (Vitrakvi) and entrectinib (Rozlytrek) may be tried after other treatments are exhausted. Immunotherapy and targeted therapy are discussed in Chapter 16.

Immunotherapy

Atezolizumab (Tecentriq), an immune checkpoint inhibitor, is the first FDA-approved immunotherapy agent. It is used with chemotherapy to treat locally advanced triple-negative breast cancer in patients with a PD-L1 (programmed death ligand 1) positive biomarker. Adding pembrolizumab (Keytruda) to chemotherapy as part of neoadjuvant therapy for triple-negative breast cancer increased the chance of a complete response (disappearance of the tumor) regardless of PD-L1 status. Pembrolizumab is an option with advanced breast cancer that tests MSI-H (microsatellite instability-high) when no other therapies are available.

Culturally Competent Care: Breast Cancer

Differences exist among racial and ethnic groups in the incidence, mortality rate, and care related to breast cancer (Box 56.2). In addition, cultural differences may involve gender roles, health beliefs, religion, family structure, socioeconomic factors

BOX 56.2 PROMOTING HEALTH EQUITY

Breast Cancer

- White and Black women have the highest incidence of breast cancer.
- Black women have lower survival rates from breast cancer than White women, even when diagnosed at an early stage.
- Hispanic and Black women are more likely to be diagnosed at a later stage of breast cancer than white women.
- Triple-negative breast cancer has a higher incidence in Black and Hispanic women.
- Mortality rates are lower among Hispanic and Asian/Pacific Islander women.
- Breast cancer is the most commonly diagnosed cancer among Hispanic women.
- Indian/Alaskan native women have the lowest rate of breast cancer screening of any ethnic group.

(e.g., poverty), and lack of health insurance. Lack of education may influence disparities related to access to health care and having recommended surveillance examinations.[20]

Cultural values strongly influence how a person responds to and copes with breast cancer and treatment. Diverse cultural norms influence health beliefs and behaviors. Cultural values and meanings (body image, sexuality, modesty, motherhood) associated with the breasts affect breast cancer screening, diagnosis, and treatment. Women may delay screening or treatment for varying reasons, including an acceptance of disease as inevitable fate or "God's will," a mistrust of Western medicine, lack of health care benefits, fear, or the stigma of a cancer diagnosis.

NURSING MANAGEMENT: BREAST CANCER

Assessment

You must consider many factors when assessing a patient with a breast problem. The history helps establish a diagnosis. Investigate the presence of nipple discharge, pain, rate of growth of the lump, breast asymmetry, and correlation with the menstrual cycle.

Carefully record the size and location of the lump(s). Assess the lesion, including consistency, mobility, and shape. If nipple discharge is present, note the color and consistency. Does it occur from 1 or both breasts?

Subjective and objective data to obtain from a person suspected of having or diagnosed with breast cancer are outlined in Table 56.10.

Clinical Problems

Clinical problems for the care of a patient diagnosed with breast cancer vary. After diagnosis and before a treatment plan has been selected, the following would apply:

- Difficulty coping
- Deficient knowledge
- Negative self-image

If surgery is planned, the nursing diagnoses and interventions may include those in eNursing Care Plan 56.1 (available on the website for this chapter).

TABLE 56.10 NURSING ASSESSMENT

Breast Cancer

Subjective Data

Important Health Information

Health history: Benign breast disease with atypical changes. Previous unilateral breast cancer. Menstrual history (early menarche with late menopause), pregnancy history (nulliparity or first full-term pregnancy after age 30). Endometrial, ovarian, or colon cancer. Hyperestrogenism and testicular atrophy (in men)

Medicines: Hormones, especially as postmenopausal hormone therapy and in oral contraceptives. Infertility treatments

Surgery or other treatments: Exposure to therapeutic radiation (e.g., Hodgkin lymphoma or thyroid radiation)

Functional Health Patterns

Health perception–health management: Family history of breast cancer (young age at diagnosis). History of abnormal mammogram or atypical prior biopsy. Palpable change found on BSE. Known *BRCA* mutation carrier, first-degree relative of *BRCA* carrier (but untested)

Nutritional-metabolic: Obesity; unexplained severe weight loss (may indicate metastasis)

Activity-exercise: Level of usual activity

Cognitive-perceptual: Changes in cognition, headache, bone pain (may indicate metastasis)

Sexuality-reproductive: Unilateral nipple discharge (clear, milky, bloody). Change in breast contour, size, or symmetry

Coping–stress tolerance: Psychologic stress

Self-perception–self-concept: Anxiety about threat to self-esteem

Objective Data

General

Axillary and supraclavicular lymphadenopathy

GI

Hepatomegaly, jaundice, ascites (may indicate liver metastasis)

Respiratory

Pleural effusions (may indicate metastasis)

Skin

Hard, irregular, nonmobile breast lump most often in upper, outer sector, possibly fixated to fascia or chest wall. Thickening of breast. Nipple inversion or retraction, erosion. Edema ("peau d'orange"), redness, induration, infiltration, or dimpling (in later stages). Firm, discrete nodules at mastectomy site (may indicate local recurrence). Peripheral edema (may indicate metastasis)

Possible Diagnostic Findings

Finding of mass or change in tissue on breast examination. Abnormal mammogram, ultrasound, or breast MRI. Positive results of FNA or surgical biopsy; similar results with a needle biopsy

Planning

The overall goals are that the patient with breast cancer will (1) take part in decision-making related to treatment, (2) adhere to the therapeutic plan, (3) communicate about and manage the side effects of therapy, (4) be supported by significant others and the health care team, and (5) adhere to recommended follow-up and surveillance after treatment.

Implementation

Health Promotion

Review the risk factors in Table 56.3. Maintaining a healthy weight, exercising regularly, limiting alcohol, eating nutritious food, and never smoking (or quitting if currently smoking) are ways to reduce risk.

Encourage women to adhere to the breast cancer screening guidelines shown in Table 56.1. Those at high risk need a personalized plan with the HCP. Early detection can decrease mortality from breast cancer.

Along with these lifestyle choices, there are other risk-reduction options for those at high risk. Genetic testing for *BRCA* and other gene mutations is available. People with a personal history of breast cancer, especially those diagnosed at age 45 or earlier; those older with unknown family history; those with a second breast cancer at any age; those of Ashkenazi Jewish ancestry; males of any age: and anyone with 1 or more close relatives with breast, ovarian, pancreatic, or high-grade prostate cancers should be tested. If testing was done in the past and was negative, a conversation about repeat testing with a genetic counselor is worthwhile as newer tests examine a much wider range of genes.

Prophylactic surgery decisions require a great deal of thought, patience, and discussion with the HCP, genetic counselor, and family. In women with an abnormal *BRCA1* or *BRCA2* gene, prophylactic oophorectomy may reduce their risk of developing breast and ovarian cancer. In deciding whether and when to undergo this surgery, women should receive counseling about the risks and benefits of prophylactic oophorectomy, including fertility issues.

Patients need to consider the options and make decisions with which they feel comfortable. Removing both breasts and ovaries does not eliminate the risk for breast cancer. A small risk exists that cancer can develop in the areas where the breasts used to be. Close follow-up is necessary even after prophylactic surgery.

Acute Care

The times of waiting for the initial biopsy results and waiting for the HCP to make treatment recommendations are difficult for patients and their families. Even after the HCP has discussed treatment options, the patient often relies on you to clarify and expand on these options. During this stressful time, the patient may not be coping effectively. Explore the patient's usual decision-making processes, help them evaluate the advantages and disadvantages of the options, and provide information relevant to the decision. Clarify any unresolved issues with the HCP. Provide support to the patient and family after they make decisions (Box 56.3).

Provide the patient with enough information to ensure informed consent. Some patients seek extensive, detailed information to maintain a sense of control. Others avoid information to decrease anxiety and fear. Be sensitive to the person's need for and preferred type of information. These include (1) instructions on pain control and what to expect after surgery (e.g., dressing and drain care, turning, coughing, deep breathing), (2) a review of mobility restrictions and postoperative exercises, and (3) an explanation of the recovery period.

BOX 56.3 EVIDENCE-BASED PRACTICE

Breast Cancer Treatment

C.P. is a 56-year-old woman who was diagnosed with stage IIIA breast cancer. Her treatment plan is to receive neoadjuvant chemotherapy and then have surgery and radiation. C.P. tells you that she will have surgery and radiation but does not want chemotherapy because she is afraid of the side effects.

Making Clinical Decisions

Best Available Evidence

The use of chemotherapy before surgery reduces the size and extent of the tumor, thus making the surgery more likely to succeed. It reduces the chance more extensive treatment will be needed.

Clinician Expertise

Neoadjuvant chemotherapy is usually recommended for stage IIIA breast cancer. The common side effects (e.g., nausea, vomiting, fatigue) can be managed with appropriate treatment.

Patient Preferences and Values

C.P. does not want chemotherapy and prefers to take her chances. If the cancer comes back, she will have chemotherapy.

Implications for Nursing Practice

1. Why is it important to discuss with C.P. the reason chemotherapy is recommended?
2. What information would you share with her about treatment side effects and how they can be managed?
3. You note her spouse appears attentive and supportive. How will you involve him in C.P.'s care?

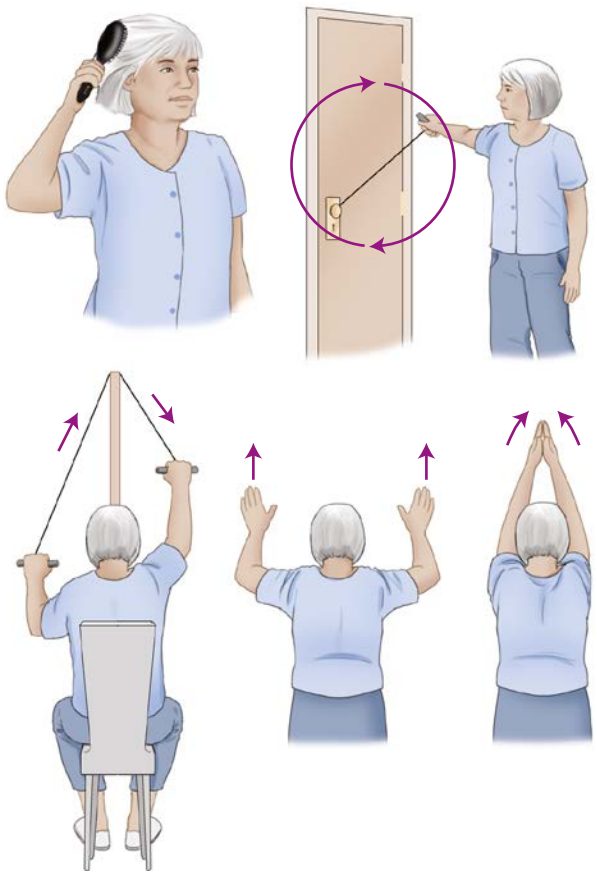

Fig. 56.7 Postoperative exercises for the patient with a mastectomy or lumpectomy with axillary lymph node sampling and/or dissection.

The woman who has breast-conserving surgery usually has an uncomplicated postoperative course with variable pain intensity. Pain depends primarily on the extent of the lymph node sampling procedure. If an ALND has been done or if the patient had a mastectomy, drains are generally left in place and patients are discharged home with them. Teach the patient and family how to manage the drains at home.

Most patients are discharged from the hospital 24 to 48 hours after a mastectomy, depending on if reconstructive surgery was done. Restoring arm function on the affected side after breast cancer surgery is a key nursing goal. Arm and shoulder exercises, which are started gradually, may begin prior to discharge (Fig. 56.7). These exercises aim to prevent contractures and muscle shortening, maintain muscle tone, and improve lymph and blood circulation. The difficulty and pain encountered in performing what used to be simple tasks may cause frustration and depression. The goal of all exercise is a gradual return to full range of motion.

Minimize discomfort by giving analgesics regularly when the patient is in pain and about 30 minutes before starting exercises. When the patient can shower, the warm water on the involved shoulder often relaxes the muscle and reduces joint stiffness.

Explain the specific follow-up plan to the patient and emphasize the importance of ongoing monitoring and self-care. After surgery, teach the patient to report symptoms, such as fever, inflammation at the surgical site, redness, and unusual swelling. Other changes to report are new back pain, weakness, shortness of breath, and change in mental status, including confusion.

For women who have had a mastectomy without breast reconstruction, a variety of products are available. Your role is to present the choices and resources. Options include garments such as camisoles with soft breast prosthetic inserts or a fitted prosthesis with a bra. Should the woman choose a breast prosthesis, a certified fitter can help her choose a comfortable, more permanent weighted prosthesis and bra. This is generally done 4 to 8 weeks after surgery.

Lymphedema. **Lymphedema** is an accumulation of lymph in soft tissue. It can occur because of the lymph node sampling procedure or radiation therapy (Fig. 56.8). When the axillary nodes cannot return lymph fluid to the central circulation, the fluid accumulates in the arm, hand, or breast, causing obstructive pressure on the veins and venous return. The patient may have heaviness, impaired motor function in the arm, and numbness and paresthesia of the fingers. Cellulitis and progressive fibrosis of the skin can result from untreated lymphedema.

Upper extremity lymphedema can occur at any point after treatment for breast cancer. Teach the patient ways to prevent and reduce lymphedema. These include no BP readings, venipunctures, or injections on the affected arm, if possible. The affected arm should not be dependent for long periods. Caution

Fig. 56.8 Lymphedema. Accumulation of fluid in the tissue after excision of lymph nodes. (From Pappalardo M, Cheng M: *Principles and practice of lymphedema surgery*, 6:39, St Louis, 2022, Elsevier.)

should be used to prevent infection, burns, or compromised circulation on the affected side. Encourage exercise and maintaining a normal weight.

If trauma to the arm occurs, teach the patient to thoroughly wash the area with soap and water and observe. A topical antibiotic ointment and a bandage or other sterile dressing may be needed.

With acute lymphedema, we usually start complete decongestive therapy. Specially trained professionals perform this therapy. It consists of a massage-like technique to mobilize the subcutaneous accumulation of fluid. This may be followed by the use of compression bandaging and an intermittent pneumatic compression sleeve. The sleeve applies mechanical massage to the arm and helps move lymph drainage up toward the heart. Elevating the arm so that it is level with the heart and performing isometric exercises reduce the fluid in the arm. To maintain maximum volume reduction, the patient may need to wear a fitted compression sleeve during waking hours and preventively during air travel.

Post–breast therapy pain syndrome. *Post–breast therapy pain syndrome* (PBTPS) occurs in some people who have had procedures for breast cancer. It is often caused by injury to nerves during surgery. However, it also can be due to chemotherapy and radiation therapy. The most common theory is that PBTPS results from injury to intercostobrachial nerves. These are sensory nerves that exit the chest wall muscles and provide sensation to the shoulder and upper arm.

Because of its multiple causes, PBTPS symptoms can range from mild to debilitating. Common symptoms include chest and upper arm pain, tingling down the arm, continuous aching and burning, numbness, shooting or pricking pain, and unbearable itching that persists beyond the normal 3-month healing time. Edema may be present.

Treatment includes nonsteroidal antiinflammatory drugs (NSAIDs), low-dose antidepressants, topical anesthetics (e.g., EMLA [lidocaine and prilocaine]), and antiseizure drugs (e.g., gabapentin). Other treatments include biofeedback, physical therapy to prevent "frozen shoulder" syndrome from inadequate movement, guided imagery, and psychologic counseling with a therapist trained in the management of chronic pain syndromes.

Phantom breast pain. *Phantom breast pain* is feeling pain in the breast after the breast was removed with mastectomy. It occurs for the same reasons phantom limb sensation occurs after limb amputations. The brain continues to send signals to nerves in the breast area that were cut during surgery, even though the breast is no longer physically there.

CHECK YOUR PRACTICE

You are working in the breast clinic and doing a postoperative assessment on a 56-year-old woman who had a right radical mastectomy 6 weeks ago. She is reporting sharp, prickly feelings in her right arm. She tells you, "I feel pain in the breast that was removed. Am I going crazy? That breast is not even attached to my body anymore!"

- How would you respond and what follow-up would you provide?

Psychosocial support. Throughout history, the female breast has been a symbol of beauty, femininity, sexuality, and motherhood. The potential loss of a breast, or part of a breast, may be devastating for many women because of the significant psychologic, social, sexual, and body image implications associated with it. In some cases, psychosocial concerns may increase the physical effects of cancer, such as pain, fatigue, sleep problems, fear of recurrence, and cognitive changes. Men diagnosed with breast cancer may feel isolation and embarrassment related to the diagnosis. You must be aware of resources for men (https://malebreastcancercoalition.org).

Screening all cancer patients for psychosocial distress is a Commission on Cancer accreditation requirement.[21] From the time of diagnosis through treatment, survivorship, or metastatic disease, the patient may have signs of distress or tension (e.g., tachycardia, muscle tension, sleep problems, restlessness, changes in appetite or mood). Assess the patient's body language and affect during periods of high stress and indecision so that you can begin appropriate interventions.

Be sensitive to the psychologic impact that a cancer diagnosis and breast surgery can have on patients and their families. With an accepting attitude and the offer of resources, you can help the patient cope with feelings of fear, anger, anxiety, and depression (Table 56.11).

Refer patients to support resources, such as Breastcancer.org (www.Breastcancer.org), American Cancer Society (www.cancer.org), Living Beyond Breast Cancer (www.lbbc.org), Susan G. Komen for the Cure (ww5.komen.org), the Cancer Support Community, or local breast cancer organizations. The National Cancer Institute provides materials to help you meet the special needs of patients with breast cancer. In addition to in-person and online support programs, free smart phone applications are available through national cancer

TABLE 56.11 NURSING MANAGEMENT

Managing Distress in Breast Cancer

- Screen all patients for distress.
- Provide a safe environment for expressing feelings.
- Identify sources of support and strength, such as the partner, family, and spiritual or religious practices.
- Encourage the patient to identify and learn personal coping strengths.
- Promote communication among the patient, family, and friends.
- Assess the willingness, availability, and resilience of family and friends to serve as supportive caregivers.
- Provide teaching and answer questions about the disease, treatment options, and reproductive, fertility, or lactation issues (if appropriate).
- Make resources available for mental health counseling.
- Offer information about local and national community resources.

organizations that provide reliable and current information for the patient and family.

Many HCPs do not adequately address sexual concerns. If you are comfortable, begin a discussion of sexuality by inviting questions about relationships or intimacy concerns. Often, the patient's partner and/or family members need help dealing with their emotional reactions to the diagnosis and surgery before they can provide effective support for the patient. There are no physical reasons why a mastectomy would prevent sexual satisfaction. A woman taking hormone therapy may have a decreased sexual drive or vaginal dryness. She may need to use lubrication to prevent pain during intercourse. If difficulty adjusting or other problems develop, single or couples counseling may be useful to deal with the emotional side of a cancer diagnosis.

Depression and anxiety may occur with the continued stress and uncertainty of a cancer diagnosis. A patient's self-esteem and identity may be threatened. The support of family and friends and taking part in a cancer support group and/or counseling are important aspects of care that may improve the patient's quality of life.

Survivorship. Almost 3 million breast cancer survivors are alive in the United States, making this population the largest group of cancer survivors. We expect this number to grow due to an aging population and improved methods for early detection and treatment. After treatment for breast cancer, the patient will have ongoing survivorship care.[22]

A history and physical assessment is recommended 1 to 4 times per year as clinically appropriate for 5 years, then annually thereafter. Teach breast cancer survivors to perform monthly BSE and chest wall self-examination and report any changes to their HCP. Local recurrence of breast cancer is usually at the surgical site. Breast cancer survivors should have an annual mammogram. Other breast imaging studies, such as a breast ultrasound or breast MRI, should be done only as an adjunct to mammography and not for annual routine surveillance. Cancer survivorship is discussed in Chapter 16.

Evaluation

Expected outcomes are that the patient after breast cancer surgery will:

- Identify activities that can reduce postoperative edema and improve mobility
- Show effective use of coping strategies
- Discuss feelings about and the meaning of changes in physical appearance
- Identify community and online resources, personal counseling resources, and support groups

Gerontologic Considerations: Breast Cancer

A major risk for breast cancer is increasing age. More than half of all breast cancers occur in women who are age 55 or older. Older women are less likely to have mammograms. Screening and treatment decisions should be based on a woman's general health status rather than biologic age since health status has a greater influence on tolerance to treatment and long-term prognosis. In addition to comorbidities and life expectancy, treatment decisions for the older woman with breast cancer should be based on nutrition and functional status; vision, gait, and balance; and the presence of dementia or depression.

Breast cancer treatment is similar for older patients, including the use of surgery, radiation therapy, and drug therapy. For healthy older women, breast cancer survival rates are similar to those of younger women when matched by cancer stage.

MAMMOPLASTY

Mammoplasty is the surgical change in the size or shape of the breast. It may be done electively for cosmetic purposes to either enlarge or reduce the size of the breasts. It also may be done to reconstruct the breast after a mastectomy.

A professional, nonjudgmental attitude and clear information about surgical breast options are most useful for women engaged in decision making about mammoplasty. The desire to change the appearance of the breasts has special significance for each woman as she attempts to change or recreate her body image. Be aware of the cultural value that the woman places on the breast. Help the patient set realistic expectations about what mammoplasty can achieve and possible complications (e.g., hematoma formation, hemorrhage, infection). If an implant is involved, capsular contracture and loss of the implant are possible.

Breast Reconstruction

Breast reconstructive surgery is a type of surgery for women who have had all or part of a breast removed. It can achieve symmetry and restore or preserve body image. It may be done simultaneously with a mastectomy or some time afterward. The timing of reconstructive surgery is based on the patient's physical and psychologic needs.[23]

Indications

The main indications for breast reconstruction are to improve self-image, regain a sense of normalcy, and assist in coping with the loss of the breast. It restores the contour of the breast without the use of an external prosthesis. Reconstruction techniques cannot restore lactation, nipple sensation, or erectility. Although the breast will not fully resemble its premastectomy appearance,

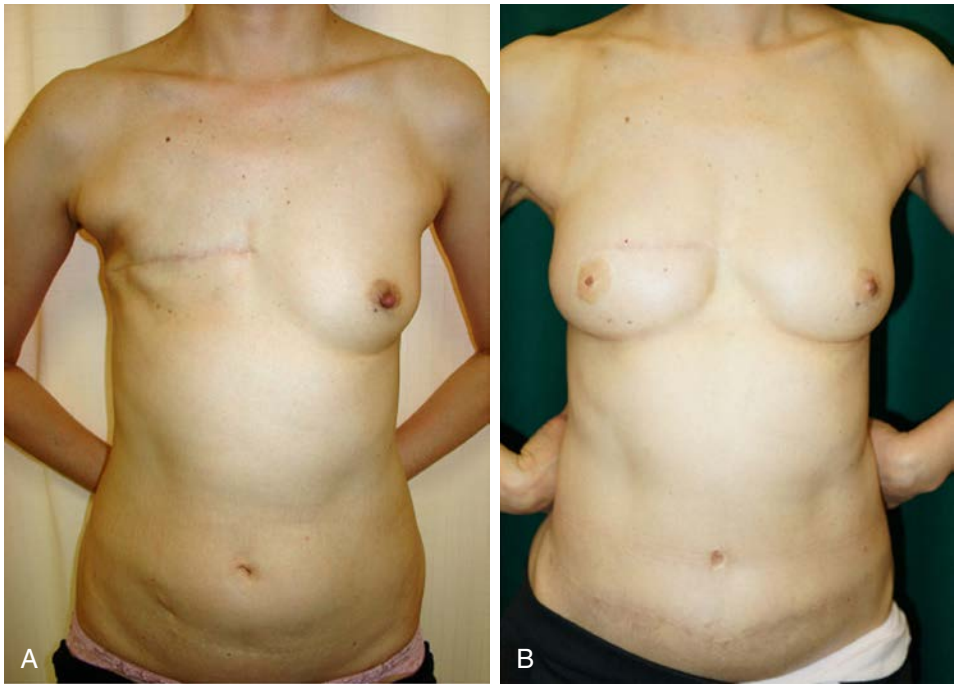

Fig. 56.9 (A) Appearance of chest after right modified mastectomy. (B) Breast reconstruction after nipple-areolar reconstruction. (From Satake T, Muto M, Kou S, et al.: Contralateral unaffected breast augmentation using zone IV as a SIEA flap during unilateral DIEP flap breast reconstruction, *J Plast Reconstr Aesthet Surg* 72:1537, 2019.)

the reconstructed appearance usually is an improvement over the mastectomy scar (Fig. 56.9).

Types of Reconstruction

Breast implants and tissue expansion. Implants have a silicone shell filled with either silicone gel or saline.[24] Some newer types use a cohesive gel, which is a thicker silicone gel. Implant surgery can be done in 1 or 2 stages. In the 1-stage procedure, the implant is placed at the same time as the mastectomy. The implant is usually placed under the pectoralis muscle.

In the 2-stage procedure, a tissue expander is inserted after the mastectomy. The expander stretches the skin and muscle at the mastectomy site before inserting permanent implants (Fig. 56.10). It is placed in a pocket under the pectoralis muscle, which protects the implant and provides soft tissue coverage. The expander is minimally inflated, then gradually filled by weekly injections of sterile saline solution. This procedure stretches the skin and muscle and can be painful. A small magnet embedded in most expanders helps locate the port where the fluid is injected. A woman should not have an MRI with a magnet in place.

The expander can be (1) surgically removed and a permanent implant is inserted or (2) remain in place to become the implant, thus eliminating the need for a second surgery. Tissue expansion does not work well in those with extensive scar tissue from surgery or radiation therapy.

The body's natural response to the presence of a foreign substance is the formation of a fibrous capsule around the implant. If excessive capsular formation occurs because of infection, hematoma, trauma, or reaction to a foreign body, a contracture can develop, resulting in deformity. Although HCPs differ in their approaches to the prevention of contracture formation, gentle manual massage around the implant is routine. Other adverse outcomes include wrinkling, scarring, asymmetry, pain, and infection at the incision site. There is a small chance of anaplastic large cell lymphoma. This has mostly occurred with textured implants.

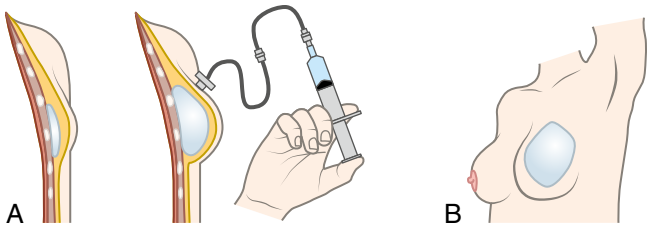

Fig. 56.10 (A) Tissue expander with gradual expansion. (B) Tissue expander in place after mastectomy.

Tissue flap procedures. We can use autologous (person's own) tissue to recreate a breast mound. In autologous reconstruction, tissue from the abdomen, back, thighs, or buttocks is used to create a reconstructed breast. The most common types of tissue flap procedures are *transverse rectus abdominis musculocutaneous (TRAM) flap, deep inferior epigastric artery perforator (DIEP) flap,* and *latissimus dorsi flap.*

The TRAM flap is a common flap surgery. The rectus abdominis muscles are paired flat muscles running from the rib cage down to the pubic bone. Arteries running inside the muscles provide branches at many levels, and these branches supply the fat and skin across a large expanse of the abdomen.

There are 2 different types of TRAM flaps: pedicle and free. In a pedicle flap, the tissue stays attached to the rectus muscle and is tunneled under the skin to the patient's chest (Fig. 56.11).

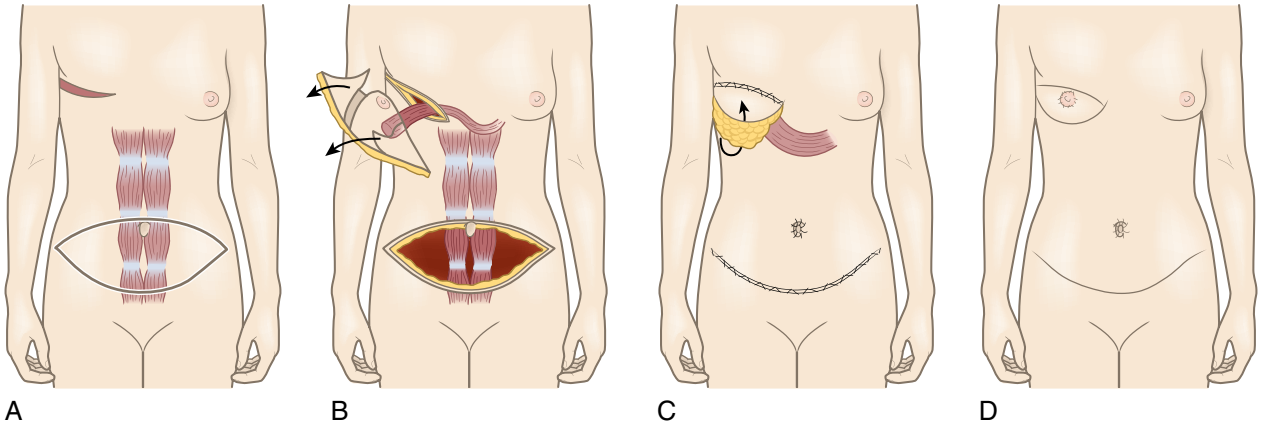

Fig. 56.11 Transverse rectus abdominis musculocutaneous (TRAM) flap. (A) TRAM flap is planned. (B) The abdominal tissue, while attached to the rectus muscle, nerve, and blood supply, is tunneled through the abdomen to the chest. (C) The flap is trimmed to shape the breast. The lower abdominal incision is closed. (D) Nipple and areola are reconstructed after the breast is healed.

In a free flap, the tissue is completely separated from the muscle and its blood supply and moved to the new place on the patient's chest. The tissue is molded and fashioned to form a breast. The abdominal incision is closed, giving the patient a result that is similar to having an abdominoplasty ("tummy tuck"). The procedure can last 6 to 8 hours with recovery taking 6 to 8 weeks. Some patients have report pain and fatigue for up to 3 months. Complications include bleeding, seroma, hernia, infection, and low back pain.

Perforator flaps are a type of free flap (a perforator artery connects a superficial artery with a deep one) that do not use muscle tissue. A *DIEP flap* is the type done most often. With the DIEP flap, only the skin and fat are taken from the same lower abdominal area as the TRAM flap. Patients may have less pain and impaired movement with this procedure. The *superficial inferior epigastric artery perforator (SIEAP)* is another option using the abdominal area.

The *latissimus dorsi flap* is a pedicle flap. In this type of flap, a block of skin and muscle from the patient's back replaces tissue removed during mastectomy. A small implant may be needed under the flap to gain reasonable breast shape and size. A disadvantage of this technique is a scar on the back.

Less often, flaps are taken from the buttocks, hips, or thighs. The transverse upper gracilis flap, or inner thigh flap, is one type of free flap. Tissue, including the gracilis muscle, is taken from the bottom fold of the buttock extending into the inner thigh. The inferior or superior gluteal artery perforators are used for flaps taken from the buttocks.

Nipple-areolar reconstruction. Many patients undergoing breast reconstruction also have nipple-areolar reconstruction. Nipple reconstruction gives the reconstructed breast a much more natural appearance (Fig. 56.9C). Nipple-areolar reconstruction is usually done a few months after breast reconstruction. Tissue to construct a nipple may be taken from the opposite breast or from a small flap of tissue on the reconstructed breast mound. Most often, the areola is tattooed with a permanent pigmented dye. Improved techniques allow skilled tattoo artists to create a complete 3D nipple-areola complex. Polyurethane removable nipples are also available.

Breast Augmentation

In *augmentation mammoplasty* (procedure to enlarge the breasts), an implant is placed in a surgically created pocket between the capsule of the breast and pectoral fascia or ideally under the pectoralis muscle.

Breast Reduction

For some women, large breasts can be a source of physical and psychologic discomfort. They can interfere with normal daily activities, such as walking, using a computer, and driving a car. The weight of large breasts can lead to back, shoulder, and neck problems, including degenerative nerve changes. Overly large breasts can interfere with self-esteem, self-image, and comfort in wearing some clothing. Reducing breast size can have positive effects on the patient's psychologic and physical health.

Reduction mammoplasty is done by resecting wedges of tissue from the upper and lower quadrants of the breast. The excess skin is removed. The areola and nipple are relocated on the breast. Lactation usually can still occur if massive amounts of tissue are not removed, and the nipples are left connected during surgery.

Breast Lift

A breast lift, or mastopexy, is a surgical procedure that changes the shape of the breasts. During a breast lift, excess skin is removed, and the tissue reshaped to raise the breast. Most women who have this procedure do so to lift sagging breasts. A breast lift does not change the size of the breast. It is often done with breast augmentation or reduction.

❖ NURSING MANAGEMENT: BREAST AUGMENTATION AND REDUCTION

Breast augmentation and breast reduction may be done in the outpatient surgical area or involve overnight hospitalization. General anesthesia is used. Drains are generally placed in the surgical site to prevent hematoma formation and then removed when drainage is under 20 to 30 mL/day. Assess drainage for color and odor to detect infection or hemorrhage. Monitor

the temperature. Change dressings as needed using sterile technique.

After surgery, assure the woman that the breast's appearance will improve when healing is complete. Depending on HCP preference, the patient may wear a bra that provides good support continuously for 2 or 3 days after breast reduction or augmentation. Depending on the extent of the surgery, most women resume normal activities within 2 to 3 weeks. They must avoid strenuous exercise for several weeks.

Case Study

Breast Cancer

(© XiXinXing/iStock/Thinkstock.)

Patient Profile

A.K., a 62-year-old married Asian American woman, was diagnosed with a 1.3 cm estrogen- and progesterone-positive, HER-2–negative breast cancer. She had a lumpectomy and sentinel lymph node biopsy (SLNB) with possible axillary node dissection.

Interprofessional Care

Preoperative

- When she is seen in the clinic 1 week before surgery, she was crying uncontrollably and said, "My husband does not want to look at me anymore. He is afraid of what I am going to look like with a flat chest."
- "I cannot sleep, and I just pace the floor at night."
- "My mother died of breast cancer when she was 60, and my sister got it when she was 40."
- Expresses concern that her 2 daughters (34 and 32) and their daughters are going to get "this horrible disease."
- Appointment made with genetic counselor

Operative Procedure

- Lumpectomy and SLNB; 4 lymph nodes removed
- Tumor was removed with clear margins
- No cancer cells in the sentinel lymph nodes
- Tissue specimen sent for a 21-gene recurrence score genomic test

Postoperative

- Does not want to leave hospital and refuses to get out of bed
- Swelling and restricted range of motion in right arm
- Pain not controlled well with pain medication
- Oncology social worker and physical therapy to see patient

Follow-Up Findings and Treatment

- Scheduled for external radiation and a consult with medical oncologist to discuss hormone therapy
- 21-Gene recurrence score is 11, low risk; genetic panel negative
- A.K. joined support group for cancer patient and husband joined support group for caregivers

Discussion Questions

1. ***Recognize***: What in A.K.'s breast cancer experience with her family members may influence her coping response?
2. ***Analyze***: What complication did she develop after surgery?
3. ***Plan:*** How will you include cultural preferences in A.K.'s plan of care?
4. ***Plan:*** Which exercises will A.K. need to perform after surgery?
5. ***Prioritize:*** What is the most important information you would provide A.K. about radiation treatment and hormone therapy?
6. ***Act:*** What information would you provide A.K. about her surgery and why the 21-gene recurrence test was done?
7. ***Act:*** What information would you provide A.K. and her daughters? What early detection measures are important for them to know?
8. ***Act:*** What types of referrals may be indicated for A.K.?
9. ***Evaluate:*** What outcomes would indicate nursing interventions were successful for A.K.?

Answers and a corresponding conceptual care map available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A nurse planning a community program on breast cancer screening guideline would include which recommendation about screening in average risk women?
   - **a.** Women over age 55 should discontinue screening.
   - **b.** Women 40 to 45 should receive a clinical breast exam.
   - **c.** Women aged 45 to 54 years should get annual mammograms.
   - **d.** Women should have the option of beginning annual screening at age 35.
2. Which intervention would the nurse include in the plan of care for a young woman with preductal mastitis?
   - **a.** Administer antibiotics as ordered.
   - **b.** Teach the woman about a breast biopsy.
   - **c.** Counsel her on the need for genetic breast cancer screening.
   - **d.** Explain the role of radiation therapy as a treatment alternative.
3. Which are considered risk factors for breast cancer in women? (*select all that apply*)
   - **a.** Having menarche at age 17
   - **b.** Being a woman over age 60
   - **c.** Previous history of ovarian cancer
   - **d.** Having a brother with breast cancer
   - **e.** Stopping oral contraceptives 15 years ago
4. A patient with breast cancer has a lumpectomy with sentinel lymph node biopsy that is positive for cancer. You explain that, of the other tests done to determine the risk for cancer recurrence or spread, the results that support the more favorable prognosis are *(select all that apply)*
   - **a.** well-differentiated tumor.
   - **b.** estrogen receptor-positive tumor.
   - **c.** overexpression of HER-2 cell marker.
   - **d.** involvement of 2 to 4 axillary nodes.
   - **e.** aneuploidy status from cell proliferation studies.

5. The nurse teaches a patient starting immune based therapy for breast cancer that this treatment works by
   a. blocking HER-2 receptors.
   b. increasing estrogen production.
   c. increasing the number of macrophages.
   d. preventing the production of aromatase.
6. A priority in providing care for a patient who underwent mastectomy includes
   a. teaching the patient to shower with cool water.
   b. measuring blood pressures in both upper extremities.
   c. instructing the patient to limit movement to promote healing.
   d. encouraging exercises to restore arm function on the affected side.
7. A patient with breast cancer who underwent mastectomy is asking about reconstructive surgery. Which information would the nurse provide?
   a. It can restore lactation.
   b. Nipple sensation may not return.
   c. The triceps muscle is used as a tissue flap for breast reconstruction.
   d. Patients must wait 3 months after mastectomy before reconstruction can begin.

1. c; 2. a; 3. b, c, d; 4. a, b; 5. a; 6. d; 7. b

Sexually Transmitted Infections

Daniel P. Worrall

http://evolve.elsevier.com/Lewis/medsurg/

CONCEPTUAL FOCUS

Infection
Pain
Reproduction
Sexuality

LEARNING OUTCOMES

1. Identify factors contributing to sexually transmitted infections (STIs) in the United States.
2. Describe the etiology, clinical manifestations, complications, and diagnostic studies for chlamydia, gonorrhea, trichomoniasis, genital herpes, genital warts, and syphilis.
3. Compare and contrast primary genital herpes with recurrent genital herpes.
4. Explain the interprofessional care and treatment of chlamydia, gonorrhea, trichomoniasis, genital herpes, genital warts, and syphilis.
5. Discuss the assessment for patients who have an STI.
6. Describe the nursing management of patients with STIs.
7. Summarize the nursing role in the prevention and control of STIs.

KEY TERMS

chlamydial infections
genital herpes
genital warts
gonorrhea
sexually transmitted infections (STIs)
syphilis
trichomoniasis

Sexually transmitted infections (STIs) are infectious diseases that spread through sexual contact with the penis, vagina, anus, mouth, or sexual fluids of an infected person. Many do not view STIs as a serious health threat because most are easily treated. However, complications of STIs are serious. They can include infertility and cancer. Having an STI can affect a person's well-being, their relationships, and their sexual lives. Patient education, counseling, and referrals are essential nursing roles for promoting health and optimal sexual well-being.

Mucosal tissues in the genitals (urethra in men, vagina in women), rectum, and mouth are especially susceptible to the bacteria and viruses that cause STIs. A list of common STIs is shown in Table 57.1. Some STIs, such as human papillomavirus (HPV), can spread from direct skin-to-skin contact with an infected person. Other STIs, such as human immunodeficiency virus (HIV), may be contracted via blood products, semen, or vaginal secretions or be transmitted from mother to baby during pregnancy or labor and delivery. Some STIs can spread through *autoinoculation* (spread of infection by touching or scratching an infected area and transferring it to another part of the body). STIs cannot typically be transmitted from casual contact or inanimate objects.

FACTORS AFFECTING INCIDENCE OF STIs

Rates of STIs in the United States are at an all-time high. According to recent data, 26 million new infections are diagnosed in the United States each year. STIs affect 1 in 5 adults and result in $16 billion in health care costs.[1] Although all sexually active persons are at risk, some populations have a greater burden of infection. Socioeconomic factors, decreased condom use, and cuts to STD programs across the country are contributors.[2] Having one STI can increase the risk for getting another. It is also possible for a person to have more than one STI at a time.

All STIs have an *incubation period*. It is the time from initial infection to the time when symptoms first appear or screening tests for the infection are positive. This can lead to the transmission of disease from an asymptomatic (but infected)

TABLE 57.1 Causes of STIs

STI	Cause
Bacterial Infections	
Chlamydial	*Chlamydia trachomatis*
Gonorrhea	*Neisseria gonorrhoeae*
Syphilis	*Treponema pallidum*
Viral Infections	
Genital herpes	Herpes simplex virus (HSV 1 or 2)
Genital warts (condylomata acuminata)	Human papillomavirus (HPV)
Human immunodeficiency virus infection (HIV)	Human immunodeficiency virus (HIV) (see Chapter 15)
Hepatitis B and C	Hepatitis B and C viruses (see Chapter 48)
Molluscum	*Molluscum contagiosum*
Parasitic/Protozoan Infection	
Trichomoniasis	*Trichomonas vaginalis*

person to another person, even before any signs or symptoms begin.

In the United States, all cases of gonorrhea, chlamydia, and syphilis must be reported to public health authorities for surveillance purposes for federally funded control programs and partner notification. Surveillance and partner notification are a major part of the effort to prevent and control the spread of STIs. Nurses and other HCPs play a vital role. They are mandated to report STIs to public health authorities. Despite this requirement, only a small number of infections are reported. This means that the cases of gonorrhea, chlamydia, and syphilis reported in the United States annually do not represent the actual number of infections.

Many factors contribute to the high rate of STIs.[2] Earlier reproductive maturity and increased longevity make for a longer sexual life span. Other factors include greater sexual freedom, individual sexual behaviors, the media's increasing emphasis on sexuality without mentioning safer sex, and sexual network characteristics. Alcohol and substance use can further contribute to unsafe sexual practices by impairing judgment. Risk factors for STIs are outlined in Table 57.2.

STIs affect certain groups of people disproportionately (Box 57.1). This includes youth and young adults under age 25, men having sex with men (MSM), transgender women, and those who are socially and economically disadvantaged.[3] Many minority groups have rates of STIs greater than that of Whites, including Asians, Native American Indian/Alaskan Native, and Native Hawaiian/Other Pacific Islanders.[4]

Trends in methods of contraceptive use affect the rate of STIs. The male condom is the best form of protection (other than abstinence) against STIs. While condom use has increased in the United States, many people do not use condoms. Most women use hormonal (e.g., oral contraceptive pills, patch, injectables) or long-acting reversible contraceptives (e.g., intrauterine devices). These do not provide barrier protection against STIs.

This chapter covers the most common STIs. HIV infection is covered in Chapter 15. Anyone who contracts an STI may also be at risk for HIV infection. HIV pre-exposure prophylaxis

TABLE 57.2 Risk Factors for STIs

High-Risk Behaviors
- Alcohol or substance use (inhibits judgment)
- Having new sexual partners
- Having more than 1 sexual partner
- Having sexual partners who have/have had multiple partners
- Inconsistent or incorrect use of condoms or other barrier methods
- Exchanging sex for money, shelter, or other needs

High-Risk Medical History
- Having 1 STI is a risk factor for getting another
- Not being vaccinated for STIs or other infections that may be transmitted through some forms of sexual activity (HPV, hepatitis A and B)
- Receiving multiple courses of non-occupational postexposure prophylaxis to prevent HIV infection

High-Risk Populations
- Adolescents and young adults (under age 25)
- Ethnicity/race (e.g., Black, American Indian/Alaskan Native, Native Hawaiian/Other Pacific Islander, Hispanic)
- MSM
- Persons in correctional facilities
- Transgender women
- Victims of sexual assault
- Women

BOX 57.1 PROMOTING HEALTH EQUITY

STIs

Incidence of STIs
- Depending on their age and gender, Black persons have
  - The highest number of chlamydial infections
  - More than 50% of cases of gonorrhea
  - Nearly 35% of cases of syphilis
  - More than 40.4% of congenital syphilis cases
  - A higher seroprevalence of herpes simplex type 2
- Hispanic persons
  - Infected with chlamydia and gonorrhea at a higher rate than Whites
  - 23% of all syphilis cases
  - 32.6% of all congenital syphilis cases
- Men who have sex with men (MSM)
  - Have the largest proportion of gonorrhea infections
  - Are more likely to test positive for antimicrobial resistant strains of gonorrhea
  - 64% of all syphilis cases
  - Are at increased risk for HIV, hepatitisC, and HSV-2

Factors Influencing Disparities
- Social and economic disadvantages can make it hard for people to care for their overall health, including their sexual health.
- People who cannot afford basic necessities may have trouble accessing and affording quality sexual health services.
- Fear and distrust of HCPs and institutions can negatively affect racial and ethnic minorities from seeking health care.
- In communities where is a higher prevalence of STIs, it may be hard to reduce the risk for infection because a person faces a higher chance of having an infected partner than in those communities with a lower prevalence.

(PrEP) or non-occupational postexposure prophylaxis (nPEP) may be appropriate for these persons. See Chapter 15 for more about PrEP and nPEP.

STIs CHARACTERIZED BY DISCHARGE, CERVICITIS, OR URETHRITIS

CHLAMYDIAL INFECTIONS

Chlamydia is the most common reportable STI in the United States. Nearly 2 million cases are reported annually. Incidence is on the rise.[2] As many infections are asymptomatic, we believe the actual number of cases is significantly higher, around 4 million.[1]

Etiology and Pathophysiology

Chlamydial infections are caused by *Chlamydia trachomatis,* a gram-negative bacterium and intracellular pathogen. *Chlamydia* is transmitted through vaginal, anal, or oral sex. Ejaculation does not have to occur for transmission. The incubation period for chlamydia is 1 to 3 weeks. Prior infection with *Chlamydia* does not provide protection from reinfection. This means that people who were treated for chlamydia can always be reinfected.

The most common site for infection in men is the urethra. Infection in the male urethra is called *urethritis*. The most common site for infection for women is the cervix. Infection of the female cervix is called *cervicitis*. Men and women can get chlamydia of the rectum from receptive anal sex or the oropharynx from giving oral sex. Because the vagina acts as a natural reservoir for infectious secretions, STI transmission is more efficient from men to women than it is from women to men.

There are many serotypes of *C. trachomatis*. The more common are the cause of nongonococcal urethritis (NGU) in men or cervicitis in women. There is a small subset of serotypes that can cause another STI, lymphogranuloma venereum (LGV), when spread to the rectum. Although rare, this is more common in MSM.

Clinical Manifestations

Patients with chlamydia often have no symptoms. If symptoms develop in men, they may have pain with urination (dysuria) or urethral discharge. Rarely, men have testicular pain or swelling caused by infection of the epididymis (Fig. 57.1). In women, symptoms include mucopurulent vaginal discharge (mucus with pus), abnormal vaginal bleeding, dysuria, and pain with intercourse. Symptoms of rectal chlamydia include anorectal pain, discharge or bleeding, anal pruritus, tenesmus, mucus-coated stools, or painful bowel movements. Most patients with chlamydia in the throat will have no symptoms. A few may have a sore throat.

Complications

Complications often develop from poorly managed, inaccurately diagnosed, or undiagnosed chlamydia. Although men rarely have long-term complications from infection, epididymitis can result in male infertility. More often, chlamydia can affect a woman's reproductive tract, resulting in *pelvic inflammatory disease* (PID).[5] PID can damage fallopian tubes and increase a woman's risk for an ectopic pregnancy, infertility, and chronic pelvic pain. The risk for developing PID increases with repeated infection. The more episodes of PID, the more likely a woman will experience infertility. Although rare, patients can develop reactive arthritis, an autoimmune response to infection with *C. trachomatis*.

Fig. 57.1 Unilateral testicular swelling from chlamydial epididymitis. (From Jordan S, Geisler W: *Infectious diseases,* St. Louis, 2017, Elsevier.)

TABLE 57.3 Interprofessional Care

Chlamydial Infections

Diagnostic Assessment

- History and physical assessment
- Nucleic acid amplification test (NAAT)
- Testing for other STIs (gonorrhea, HIV, syphilis)

Management

- Doxycycline
- Alternative regimen: azithromycin or levofloxacin
- Teach to abstain from sexual contact for 7 days after completing treatment
- Treat all sexual partners, who must also wait 7 days before resuming sexual contact

Diagnostic Studies

Diagnosis of an STI requires an accurate sexual history, a physical assessment, and laboratory tests specific to each infection. The preferred method for diagnosing chlamydia is a nucleic acid amplification test (NAAT) (Table 57.3). NAAT is used to identify small amounts of DNA or RNA in test samples. NAAT can be done on urine, rectal, and oropharyngeal swabs; endocervical or vaginal swabs from women; and urethral swabs from men.

Interprofessional Care

The preferred treatment is doxycycline (Vibramycin) twice a day for 7 days (Table 57.3).[6] All sexual contacts within 60 days

should be evaluated and treated to prevent reinfection and further transmission. Teach patients to abstain from sexual contact for 7 days after treatment or until all partners have been treated and have also abstained from sexual contact for 7 days. Review ways to reduce risk of reinfection or infection with another STI in the future. Anyone diagnosed and treated for chlamydia should return for repeat testing 3 months after treatment to ensure cure or detect reinfection. Tell patients to return sooner if symptoms persist or recur.

DRUG ALERT

Doxycycline (Vibramycin)

- Take doses on an empty stomach either 1 h before eating or 2 h after eating.
- Avoid taking with antacids, iron products, or dairy products.
- Remain upright for at least 30 min after taking a dose.
- Patients should avoid prolonged or excessive exposure to sunlight.
- Pregnant women should not take doxycycline.

Unfortunately, there is a high rate of recurrence. This often occurs when the sexual partners of infected people are not treated. This "ping-pong" effect (treatment, reexposure, reinfection) can end only when both partners are treated appropriately. Because of this issue, we recommend *expedited partner therapy* (EPT).[7] With EPT, HCPs give drugs or prescriptions to patients with STIs to give to partners without their examining the partner. EPT varies from state to state, but few states prohibit EPT. EPT is often not recommended for partners of MSM because of a higher risk for coexisting infections, especially undiagnosed syphilis or HIV. It is not recommended for female partners who are symptomatic because of the risk for PID.

CHECK YOUR PRACTICE

You are caring for a 28-year-old woman who is being treated for pelvic inflammatory disease (PID). This is the second time in 2 months that she has been diagnosed with an STI. The patient says she has not been with anyone else except her regular partner. She says, "I don't know why I have this again. The doctor gave me the pills, and I took them."

- How would you respond?
- What do you think is causing her symptoms?

GONOCOCCAL INFECTIONS

Gonorrhea is the second most common reportable STI in the United States. Like chlamydia, incidence is on the rise. There are nearly 600,000 cases reported each year. We think the actual number of cases is around 1.6 million.[2]

Etiology and Pathophysiology

Gonorrhea is caused by *Neisseria gonorrhoeae,* a gram-negative, diplococcus bacterium. Gonorrhea can be transmitted by exposure to sexual fluids during vaginal, anal, or oral sex. Ejaculation does not have to occur for it to be transmitted. The incubation period ranges from 1 to 14 days. Prior infection does not provide protection from reinfection. The most common site for infection for men is the urethra and for women, the cervix.

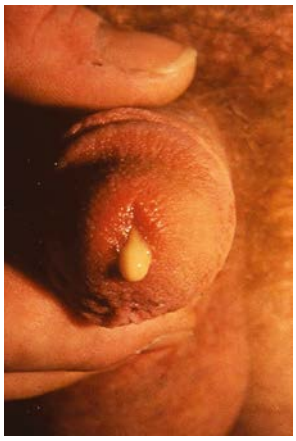

Fig. 57.2 Profuse, purulent drainage in a patient with gonorrhea. (From Marx J, Walls R, Hockberger R: *Rosen's emergency medicine: concepts and clinical practice,* ed 7, St Louis, 2010, Mosby.)

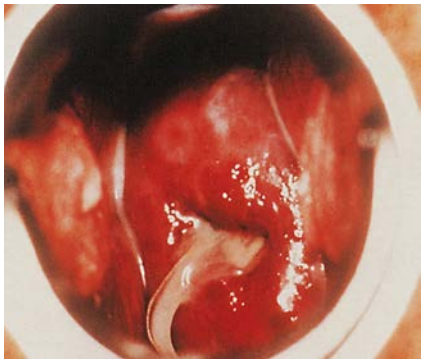

Fig. 57.3 Endocervical gonorrhea. Cervical redness and edema with discharge. (From Morse S, Moreland A, Holmes K: *Atlas of sexually transmitted diseases and AIDS,* London, 1996, Mosby-Wolfe.)

Clinical Manifestations

The initial site of infection in men is usually the urethra. Most men will be symptomatic within a few days of infection. The most common symptoms of gonococcal urethritis are dysuria, purulent urethral discharge (Fig. 57.2), or epididymitis. Most women are asymptomatic or have minor symptoms that they often overlook. In women, common symptoms are increased vaginal discharge, dysuria, frequency, or bleeding after sex. Often, redness and swelling occur at the cervix or urethra along with a purulent exudate (Fig. 57.3).

Anyone can contract rectal gonorrhea during anal intercourse or oropharyngeal gonorrhea during oral sex. Symptoms of rectal infection include mucopurulent rectal discharge or bleeding, anorectal pain, anal pruritus, tenesmus, mucus-coated stools, or painful bowel movements. Most patients with gonorrhea in the throat have no symptoms. A few may have a sore throat (Box 57.2).

Complications

Because men are more often symptomatic and seek treatment earlier, they are less likely to develop serious complications.

BOX 57.2 BIOLOGIC SEX CONSIDERATIONS

STIs

Men

- Syphilis and gonorrhea more common, especially in MSM
- More likely to have symptoms of genital infection
- Genital infection results in fewer complications
- Easier to diagnose because of less complex anatomy
- Less likely to seek medical care unless symptomatic

Women

- Anatomy increases risk for STIs
- Less likely to show early signs of genital infection
- Trichomoniasis and herpes simplex type 2 more common
- Are screened for and therefore more likely to be diagnosed with HPV
- Have more frequent and serious complications related to STIs (e.g., PID, infertility)

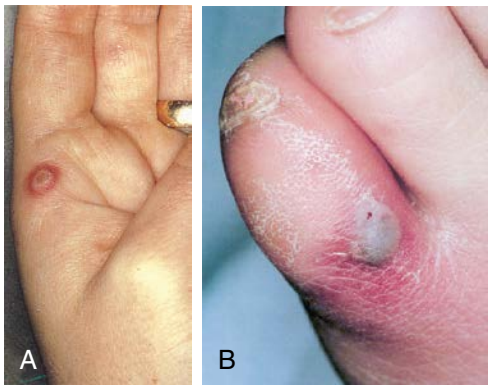

Fig. 57.4 Skin lesions with disseminated gonococcal infection. (A) On the hand. (B) On the fifth toe. (A, From Cohen J, Powderly WG: *Infectious diseases,* ed 2, St Louis, 2004, Mosby. B, From Mandell GL, Bennett JE, Dolin R: *Mandell, Douglas, and Bennett's principles and practice of infectious diseases,* ed 7, Philadelphia, 2010, Churchill Livingstone.)

Those who do can develop epididymitis, a progression of the infection to the testes. It can cause infertility.

Because women are more likely to be asymptomatic and therefore seldom seek early treatment, serious complications are more common. Untreated gonorrhea can cause an infection in the Bartholin glands or Skene glands or result in PID. PID increases risk for ectopic pregnancy, infertility, and chronic pelvic pain.

Although rare, patients can develop disseminated gonococcal infection (DGI). DGI can cause skin lesions, fever, arthralgia, arthritis, and/or endocarditis (Fig. 57.4).

Neonates can develop gonococcal conjunctivitis *(ophthalmia neonatorum)* from exposure to an infected mother during delivery that can result in permanent blindness. Almost all states have laws or health department regulations requiring the use of prophylactic eye treatment of all newborns to prevent such infections. Because of improved prenatal screening for gonorrhea and prophylactic treatment plans, *ophthalmia neonatorum* caused by gonorrhea is rare.

Diagnostic Studies

For men, a presumptive diagnosis of gonorrhea is made if there is a history of sexual contact with a new or infected partner followed within a few days by the development of urethral discharge. For women, making a diagnosis based on symptoms is difficult. Most women are asymptomatic or have symptoms that may be confused with other conditions, such as a urinary tract infection.

The preferred method for diagnosing gonorrhea is through an NAAT (Table 57.4). This can be done on endocervical or vaginal swabs from women, urethral swabs from men, and urine, rectal, and oropharyngeal swabs. A culture may be used to diagnose infection. Gram stains of urethral secretions can be used, but the sensitivity is not as good as other methods.

TABLE 57.4 Interprofessional Care

Gonococcal Infections

Diagnostic Assessment

- History and physical assessment
- Gram-stained smears of urethral or endocervical exudate
- Culture for *N. gonorrhoeae* with antibiotic sensitivity testing if available
- Nucleic acid amplification test (NAAT) to detect *N. gonorrhoeae*
- Testing for other STIs (syphilis, HIV, chlamydial infection)

Management

- Uncomplicated gonorrhea: high-dose ceftriaxone IM
- Gonorrhea with chlamydia coinfection: high-dose ceftriaxone IM plus doxycycline
- Treatment of sexual contacts
- Teach to abstain from sexual contact for 7 days after treatment
- Treat all sexual partners, who must also wait 7 days before resuming sexual contact
- Reexamination if symptoms persist or recur after treatment

Interprofessional Care

Because of a short incubation period and high infectivity, we often start treatment without waiting for positive test results. Over the years, *N. gonorrhoeae* has developed resistance to many classes of antibiotics, including fluoroquinolones (e.g., ciprofloxacin, levofloxacin), tetracyclines (e.g., doxycycline), and macrolides (e.g., azithromycin). First-line treatment is now high-dose IM ceftriaxone (Table 57.4).[8] Patients who persistently test positive after treatment should have culture of the infected site with antibiotic sensitivity testing to check for resistance.

As with chlamydia, all sexual contacts within 60 days should be evaluated and treated to prevent reinfection and further transmission. Teach patients to abstain from sexual contact for 7 days after treatment, or until all partners have been treated and have also abstained from sexual contact for 7 days. Anyone diagnosed and treated for gonorrhea should return for repeat testing 3 months after treatment to ensure cure or detect reinfection.

TRICHOMONIASIS

Trichomoniasis ("trich") is an STI caused by the protozoan parasite *Trichomonas vaginalis*. It is another common STI in the United

States, affecting around 3.7 million people.[6] It is much more common among women than men, especially among women with HIV. This infection is often overlooked compared with other STIs. However, better testing methods have improved detection.

Etiology and Pathophysiology

Trichomonas can be transmitted by exposure to sexual fluids during vaginal, anal, or oral sex, even if ejaculation does not occur. The incubation period is usually 1 week to 1 month but can be much longer. Prior infection does not provide protection from reinfection.

The most common site for infection in men is the urethra and in women is the cervix. It is uncommon for *Trichomonas* to infect the rectum. It is not known to infect the oropharynx. Routine screening should be considered for women in high-risk populations, those receiving care in high-risk settings, and women seeking care for vaginal discharge.[5,6]

Clinical Manifestations

Most people do not have symptoms. Men may have burning with urination, ejaculation, or urethral discharge. Women may have painful urination, vaginal itching, painful intercourse, bleeding after sex, or a yellow-green discharge with a foul odor. The cervix can have a "strawberry" appearance.

Complications

The main complications of untreated infection are related to the inflammation and irritation that it causes in the genital tract. Inflammation makes an infected person more likely to contract or transmit another STI, particularly HIV. Trichomoniasis is associated with PID in women with HIV.

Diagnostic Studies

The preferred method of diagnosing trichomoniasis is by NAAT testing of vaginal or endocervical secretions or urine. Other methods include culture, point-of-care testing, or direct visualization of trichomonads under the microscope. Identifying motile trichomonads in vaginal secretions confirms infection. Tests can be done on liquid-based cervical Pap samples. In men, NAAT testing is recommended.[6]

Interprofessional Care

Patients and their partners should be treated with either metronidazole (Flagyl) or tinidazole (Tindamax). Teach patients to abstain from sexual contact for 7 days after treatment or until all sexual partners have completed a full course of treatment and abstained from sexual contact for 7 days. Tell patients to return if symptoms persist or recur. Any sexual partner within the preceding 60 days should be treated. Teach patients to use condoms or other barrier methods with every sexual contact. Because of a high rate of recurrence, recommend repeat testing 3 months after treatment.

STIs CHARACTERIZED BY GENITAL LESIONS OR ULCERS

GENITAL HERPES INFECTIONS

Genital herpes is a common, lifelong, incurable but treatable infection. There are 2 strains of herpes: herpes simplex virus type 1 (HSV-1) and herpes simplex virus type 2 (HSV-2). Around 18.6 million people in the United States have HSV-2.[1] Most new infections are transmitted by someone who does not know they are infected. The rate of new genital HSV-2 infections is twice as high among women compared with men. Hispanic and Black persons are more likely to be infected.[3,4]

Fig. 57.5 Herpes simplex virus (HSV). (© iStock.com/zeleno.)

Etiology and Pathophysiology

The virus enters through the mucous membranes or breaks in the skin during contact with an infected person. The virus reproduces inside the cell and spreads to the surrounding cells. Then the virus enters the peripheral or autonomic nerve endings and ascends to the sensory or autonomic nerve ganglion near the infection site. There, it often becomes dormant. Viral reactivation (recurrence or "outbreak") occurs when the virus descends to that initial site of infection, either the mucous membranes or skin.

When a person is infected with HSV-1 or HSV-2, the virus persists within the person for life. Transmission of either strain of HSV to others occurs easiest through direct contact with skin or mucous membranes when an infected person is symptomatic. However, both can be transmitted without any apparent symptoms, called *asymptomatic viral shedding*. It is impossible to predict when asymptomatic shedding will occur or for how long. HSV-2 is more likely to shed than HSV-1.

HSV-1 was mainly associated with oral lesions, known as "cold sores" or "fever blisters" (Fig. 57.5), and HSV-2 with anogenital disease.[9] We now know that HSV-1 or HSV-2 can cause genital, anal, or orolabial infections, though it is rare to have HSV-2 infection of the mouth. In most cases, HSV-1 infections are more common "above the waist," involving the gingivae, dermis, upper respiratory tract, and rarely the central nervous system (CNS). HSV-2 almost always infects sites "below the

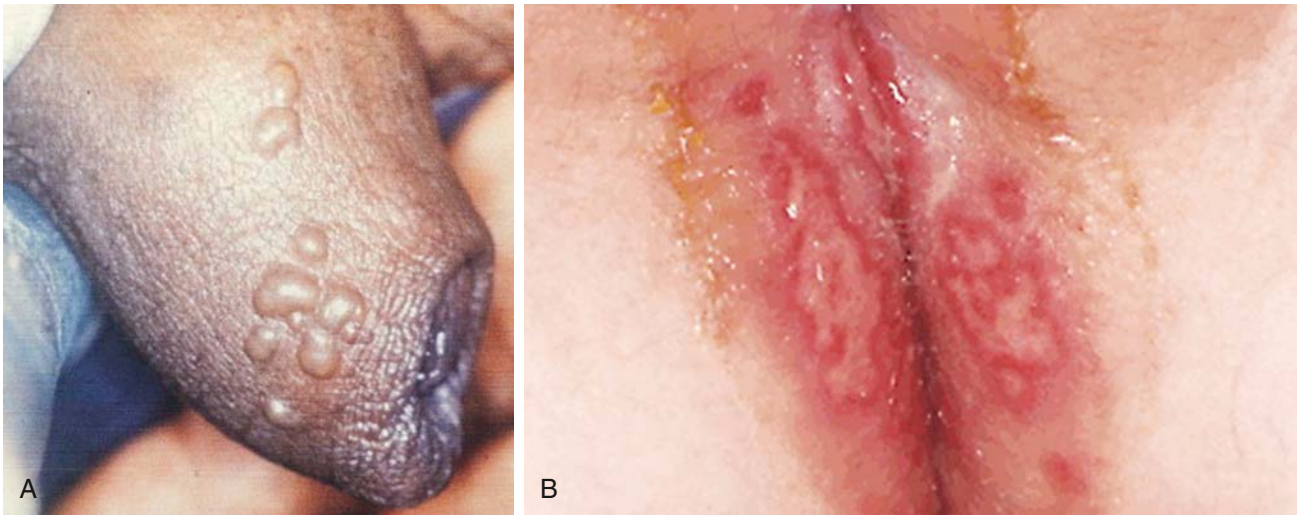

Fig. 57.6 Herpes simplex virus type 2. (A) Vesicular stage. Clear, grouped vesicles on the penis. (B) Ulcerative stage. Vesicles and ulceration of vulvar area. (From Elsevier Point of Care, St. Louis, 2020, Elsevier Health Sciences.)

waist," or the genital tract, perineum, or anus. Having 1 type does not protect against getting the other.

Clinical Manifestations

Primary Episode

A *primary (initial) episode* of genital herpes has an incubation of 2 to 12 days. Most people do not have any recognizable symptoms of primary HSV genital infection. If symptoms do occur, they follow a series of stages. During the *prodromal stage*, the period before lesions appear, the patient may have burning, itching, or tingling at the site of inoculation. In the *vesicular stage*, few to multiple small, often painful vesicles (blisters) may appear on the buttock, inner thigh, penis, scrotum, vulva, perineum, perianal region, vagina, or cervix. The vesicles have large quantities of infectious viral particles (Fig. 57.6). Next, in the *ulcerative stage,* the lesions rupture and form shallow, moist ulcerations. In the *final stage,* spontaneous crusting and epithelialization of the erosions occur.

Regional (inguinal node) lymphadenopathy and systemic flu-like symptoms, including fever, headache, malaise, and myalgia, may occur with the primary episode. Urination may be painful from the urine touching active lesions. The whole process from prodrome to healing varies. It may take up to 3 weeks. Autoinoculation can occur if active lesions are touched or scratched, causing additional and potentially recurrent infection at extragenital sites.

Recurrent Episodes

Recurrent genital herpes occurs in many people during the year after the primary episode. The symptoms of recurrent episodes are less severe. The lesions usually heal more quickly. HSV-1 genital infections recur less often than HSV-2 genital infections. Over time, both decrease in frequency.

Common triggers of recurrence include stress, fatigue, sunburn, general illness, immunosuppression, menses, or local trauma at the site of infection. Many patients can predict a recurrence by noticing the prodromal symptoms of tingling, burning, and itching at the site where the lesions will recur. The greatest risk for transmitting infection exists when active lesions are present. However, it is possible to transmit the virus when no visible lesions or symptoms are present. Most HSV transmission occurs during these asymptomatic periods.[9]

Complications

Both HSV-1 and HSV-2 can cause rare but serious complications, including blindness, encephalitis, and aseptic meningitis. Autoinoculation can result in extragenital lesions in the buttocks, groin, thighs, fingers, and eyes. Genital ulcers increase the risk for contracting HIV. HSV lesions can be more severe and more persistent in HIV-infected patients.

Pregnant women with HSV can transmit the virus to the baby, especially if the virus is shed while the infant passes through the birth canal. Women with a primary episode of HSV near the time of delivery have the highest risk for transmitting genital herpes to the neonate. The virus can infect the neonate's skin, eyes, mouth, or the CNS or become widespread and cause significant mortality. An active genital lesion at the time of delivery is an indication for cesarean delivery.

One of the most profound consequences for people with genital herpes is the overall impact it can have on their psychologic well-being, relationships, and sexual lives. Help teach patients to understand how to talk to sexual partners about HSV. Refer patients who need counseling. Teach patients with herpes that it is a common, manageable, non–life-threatening condition. Help them to understand their treatment options.

Diagnostic Studies

Diagnosis is often based on the patient's reported symptoms, then confirmed by visual examination. Viral culture or PCR from open skin eruptions can be used to diagnose HSV and distinguish between HSV-1 and HSV-2. Highly accurate blood tests for antibodies are available for HSV-1 and HSV-2. Antibodies usually appear by 12 weeks after exposure. These tests do not show the location of the infection.

Interprofessional Care

There is no cure for HSV infection. Antiviral drugs can shorten the duration of HSV viral shedding, shorten the healing time of eruptions, and reduce the frequency of outbreaks by up to 80%.[9] Treatment of HSV should start before diagnostic results are available because early treatment reduces the duration of the ulcers and risk for transmission (Table 57.5).

Three antiviral agents are available for treating HSV: acyclovir (Zovirax), famciclovir (Famvir), and valaciclovir (Valtrex). These drugs inhibit herpetic viral replication (see Table 15.10). They are prescribed for both primary and recurrent infections. Taken daily at a lower dose, they can be used as suppressive therapy to decrease frequency and severity of anogenital recurrences. They reduce, but not eliminate, the risk of transmission to others. IV acyclovir is reserved for severe or life-threatening infections in which hospitalization is needed to treat eye or widespread infections, CNS infections (e.g., meningitis), or pneumonitis.

Teach patients with active outbreaks to maintain good hygiene, wear loose-fitting cotton undergarments, and avoid sexual contact until the outbreak has completely healed.

The main goal is to keep eruptions clean and dry. Ways to reduce pain with urination include pouring water onto the perineal area while voiding to dilute the urine or voiding in the shower. The patient may need a local anesthetic, such as lidocaine gel, or analgesics, such as ibuprofen, acetaminophen, or acetaminophen with codeine. Ice packs to the affected area can give some relief.

TABLE 57.5 Interprofessional Care

Genital Herpes

Diagnostic Assessment
- History and physical assessment
- Antibody assay for HSV type
- Viral isolation by culture, PCR testing

Management
- Identify triggering factors
- Abstain from sexual contact while lesions are present and until fully healed
- Symptomatic care
- Confidential counseling and testing for HIV

Primary (Initial) Infection (see Table 15.10)
- Acyclovir, valacyclovir, or famciclovir

Recurrent Episodic Infection
- Acyclovir, valacyclovir, or famciclovir for shorter duration

Suppressive Therapy
- Acyclovir, valacyclovir, or famciclovir daily at a lower dose

Severe Infection
- IV acyclovir until clinical improvement, followed by oral antiviral therapy

GENITAL WARTS

Genital warts *(condylomata acuminata)* are caused by HPV. There are around 150 types of HPV. At least 40 strains are sexually transmitted.[6,9] "Low-risk" strains of the virus can cause warts on the skin. "High-risk" strains can lead to cancers of the genital tract, anus, or oropharynx. HPV types 6 and 11 cause about 90% of genital and anal warts. HPV types 16 and 18 cause about 70% of cervical cancer, as well as most anal and some throat cancers. Around 16 million people in the United States have HPV.[1] Many sexually active people will be infected with some type of HPV at some point in their lives. In most states, HPV is not a reportable infection. Cervical HPV infection is discussed in Chapter 58.

Etiology and Pathophysiology

HPV is transmitted by skin-to-skin contact, most often during vaginal or anal sex. It can also be transmitted during nonpenetrating sexual activity. The basal epithelial cells infected with HPV undergo transformation and proliferation to form a warty growth (Fig. 57.7). The incubation period can range from weeks

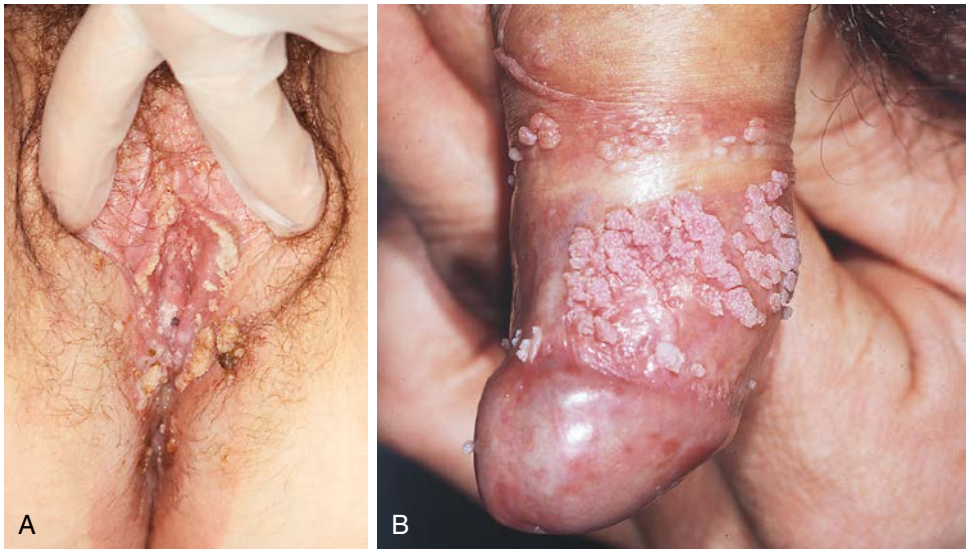

Fig. 57.7 Genital warts. (A) Vulvar warts. (B) Multiple warts on the penis. (From Habif TP: *Clinical dermatology,* ed 6, St Louis, 2015, Mosby.)

to months to years. Infection with 1 type of HPV does not prevent infection with another type.

In most people, HPV is transient (virus is "cleared" or resolves spontaneously after 1 to 2 years). However, it can persist even when the warts themselves are not visible after treatment. We do not know whether removing visible warts helps a person to clear the virus, cures the virus, or reduces their ability to transmit the virus.[10]

Clinical Manifestations

Most people with HPV do not know that they are infected because they have no symptoms. Genital or anal warts are discrete single or multiple papillary growths. They may grow and coalesce to form large, cauliflower-like masses, although most patients will have few lesions. Growths may be pink, pink-flesh colored, or hyperpigmented depending on the skin type.

In men, warts occur on the penis and scrotum, in or around the anus, or in the urethra. In women, warts occur on the inner thighs, vulva, vagina, or cervix, perineum, or internal or external anus (Fig. 57.7). There are usually no other signs or symptoms. Itching may occur with anogenital warts. Bleeding on defecation may occur with anal warts.

Diagnostic Studies

Most early lesions caused by HPV are undetectable by visual examination. A diagnosis of genital warts can be made based on the characteristic appearance of the lesions (Fig. 57.7). Warts may be confused with *condylomata lata* of secondary syphilis, cancer, or benign growths. Testing should be done to rule out other conditions. At present, the only definitive diagnostic procedure is biopsy of any questionable growth. Testing for cervical HPV is discussed in Chapter 58.

Complications

Genital and anal warts have few long-term complications. The HPV strains that cause warts do not cause cancer. For some people, HPV lesions can cause psychosocial burden due to the cosmetic appearance of lesions or the need for long courses of HPV-related treatment. During pregnancy, warts tend to grow rapidly and increase in size. Infection with "high-risk" strains of HPV (especially types 16 and 18) can lead to cancers of the cervix, vagina, vulva, penis, anus, and oropharynx.

Interprofessional Care

HPV Vaccine

It may be possible to eradicate some HPV types over the next few decades, especially if all youth are vaccinated. A 9-valent vaccine (Gardasil 9) is the only vaccine available in the United States. It protects against HPV types 6, 11, 16, 18, and 5 other high-risk HPV types.[11] The vaccine is given in 2 or 3 IM doses over a 6-month period. There are few side effects. The CDC recommends that all children, male and female, be vaccinated at age 11 to 12. Vaccination can be started as early as age 9. Routine vaccination is recommended up to age 26 (Box 57.3). Gardasil 9 is also approved for use in those ages 27 through 45 who may be at risk.[12]

BOX 57.3 EVIDENCE-BASED PRACTICE

HPV Vaccine and Young Males

T.N. is a 19-year-old man who is being seen in the health care center for a urinary tract infection. After reviewing his health history, you learn he has not yet received the HPV vaccine. When asked, he tells you "I am not at risk because HPV really only affects girls."

Making Clinical Decisions

Best Available Evidence

Males ages 9 to 26 can be vaccinated with 9-valent/9vHPV (Gardasil 9) to reduce the incidence of HPV infections and HPV-related cancers (e.g., penile, anal, throat). The vaccine protects against the 2 HPV types (6 and 11) that cause 90% of anogenital warts. Vaccination rates for HPV lag all other vaccinations for young people.

Clinician Expertise

You know younger men may not be aware of the recommendations for the HPV vaccine. The vaccine was first approved to prevent cervical, vulvar, and vaginal cancer in females ages 9 through 26. Since there is no routine screening for HPV-related cancers except cervical cancer, a vaccine that prevents most of these cancers is critical. You know that T.N. will need the 3-dose series (0, 1 to 2, 6 months) to complete his immunization.

Patient Preferences and Values

T.N. states he never has unprotected sex and does not like injections.

Implications for Nursing Practice

1. Why is it important to discuss the risks and benefits of the vaccine to T.N.?
2. How would you respond to T.N., who has heard that only females need the vaccine?
3. How can you address T.N.'s concerns about his dislike of injections?

Reference for Evidence

CDC: Human papillomavirus vaccination and cancer prevention. Retrieved from https://www.cdc.gov/vaccines/vpd/hpv/index.html.

HPV vaccine offers protection against strains causing 90% of anogenital warts and cervical cancers. This protection extends to other HPV-related cancers, including penile, anal, and throat cancers. Remember that the vaccine does not treat active HPV infection. Ideally persons should receive the vaccine before the start of sexual activity or before the potential for infection.

Drug Therapy

Treatment of genital or anal warts is hampered by the high proportion of asymptomatic and undiagnosed infections and lack of curative treatment. The primary goal of treatment is the removal of symptomatic warts.

In-office treatment consists of chemical or ablative (removal with laser or electrocautery) methods. A common treatment is the use of trichloroacetic acid (TCA) or bichloroacetic acid (BCA) applied directly to the wart surface. Petroleum jelly applied with a cotton swab to the surrounding normal skin can minimize irritation. A sharp, stinging pain is often felt with initial acid contact, but this quickly subsides.

Patient-applied treatments are also available. Podofilox liquid and gel are available by prescription (Condylox, Condylox Gel). The patient applies the solution or gel for 3 successive days. Treatment can be repeated for up to 4 weeks or until

Fig. 57.8 Primary syphilis chancre. (From Morse S, Holmes K, Ballard R: *Atlas of sexually transmitted diseases and AIDS,* ed 4, London, 2010, Saunders.)

resolution of the lesions. Imiquimod cream (Aldara, Zyclara) is an immune response modifier applied at bedtime, either 3 times per week (Aldara) or nightly for up to 16 weeks (Zyclara). Sinecatechin ointment (Veregen) is a green tea derivative that has antioxidant properties. It is applied 3 times daily for up to 16 weeks.

Treatment of warts may not decrease infectivity because the HPV-causing warts may still be present. Anogenital warts are hard to treat and often need more than 1 treatment or modality. Therapy should be modified if a patient has not improved or cannot tolerate the side effects of certain treatments.

If the warts do not resolve with topical therapies, treatments such as cryotherapy with liquid nitrogen, electrocautery, laser therapy, local α-interferon injections, or surgical excision may be done. Teach patients that, because treatment does not destroy the virus (merely the infected tissue), recurrence and reinfection are possible. Long-term follow-up is needed.

SYPHILIS

Syphilis is a sexually transmitted bacterial infection that can cause serious long-term complications if not identified and treated appropriately. Over 130,000 cases of syphilis are reported each year in the United States. As with other infections, we think this number is much higher.[1] Incidence is sharply on the rise. The population most affected by syphilis is MSM, with the highest rates among MSM of color.[3,4]

Etiology and Pathophysiology

Syphilis is caused by *Treponema pallidum,* a bacterial spirochete. It is transmitted by direct contact with a syphilitic ulcer called a *chancre* or through the mucosal membranes of an infected person. A chancre can occur externally on the genitals, anus, or lips or internally in the vagina, rectum, or mouth or tongue (Fig. 57.8). Transmission can occur during vaginal, anal, or oral sex. The incubation period can range from 10 to 90 days (average 21 days). Having the infection does not provide protection from reinfection, even after successful treatment. An infected pregnant woman can transmit syphilis to her fetus during her pregnancy. There is a high risk for stillbirth or having babies who develop complications after birth, including seizures and death. Unfortunately, the incidence of congenital syphilis in the United States has risen 185% since 2014.[1]

TABLE 57.6 Stages of Syphilis

Primary
- *Infectivity:* Highly infectious
- *Duration of stage:* 3–6 weeks
- Single or multiple chancres (painless indurated lesions) of penis, vulva, lips, mouth, vagina, and rectum) (Fig. 57.8). Occurs 10–90 days after inoculation
- Regional lymphadenopathy (microorganisms drain into the lymph nodes)
- Exudate and blood from chancre are highly infectious

Secondary
- *Infectivity:* Highly infectious
- *Duration of stage:* Occurs a few weeks after primary chancre heals, lasts 1–2 years
- Flu-like symptoms: malaise, fever, sore throat, headaches, fatigue, arthralgia, generalized adenopathy
- Mucous patches in mouth (Fig. 57.9), tongue, or cervix
- Symmetric, nonpruritic rash bilaterally that appears on trunk, palms, and/or soles (Fig. 57.10)
- *Condylomata lata* (moist, weeping warts) in the anogenital area
- Weight loss, alopecia

Latent
- *Infectivity:* Early (<1 year)—infectious; late (≥1 year)—noninfectious
- *Duration of stage:* Throughout life or progression to late stage
- No signs or symptoms
- Diagnosis based on positive specific treponemal antibody test together with normal CSF and absence of clinical manifestations

Late
- *Infectivity:* Noninfectious
- *Duration of stage:* Chronic (without treatment), occurs 1–20 years after initial infection
- Gummas (chronic, destructive lesions affecting any organ of body, especially skin, bone, liver, mucous membranes) (Fig. 57.11)
- Cardiovascular: Aneurysms, heart valve insufficiency, heart failure, aortitis
- Neurosyphilis: Can occur at any stage of syphilis
- General paresis: Personality changes from minor to psychotic, tremors, physical and mental deterioration
- Tabes dorsalis (ataxia, areflexia, paresthesias, lightning pains, damaged joints)

Clinical Manifestations

Syphilis is called "*The Great Imitator*" because it can present with a variety of signs and symptoms that mimic other diseases. Compared with other STIs, syphilis is harder to recognize, which can delay treatment. If it is not diagnosed and treated, specific clinical stages occur with the progression of the disease (Table 57.6).

The primary stage is the development of a chancre at the site of transmission. This can appear days to months following infection. In most patients, it occurs by 3 weeks. Chancres can

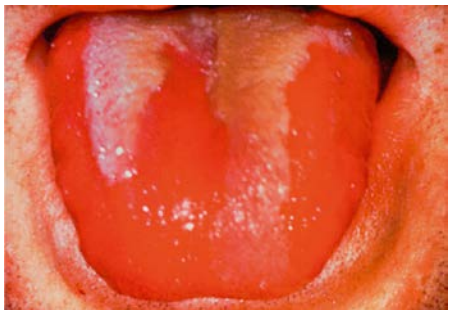

Fig. 57.9 Secondary syphilis. Mucous patch in the mouth. (From Mandell GL, Bennett JE, Dolin R: *Mandell, Douglas, and Bennett's principles and practice of infectious diseases,* ed 7, Philadelphia, 2010, Churchill Livingstone.)

Fig. 57.10 Secondary syphilis. Palmar rash. (From Centers for Disease Control and Prevention Public Health Image Library. Courtesy Robert Sumpter.)

Fig. 57.11 Destructive skin gummas from tertiary syphilis. (From Gawkrodger D, Ardern-Jones M: *Dermatology,* ed 6, St Louis, 2016, Mosby.)

be found on the genitals but often go unnoticed when inside the mouth, vagina, or anus. As the chancre begins to heal or shortly after, patients will progress to the secondary stage of infection if untreated. This stage is usually characterized by a maculopapular rash. The classic rash appears as round, reddish "spots" on the palms of the hands or soles of the feet. It may involve the trunk or extremities. Without treatment, the rash will resolve, but the patient still has syphilis and is infectious for some time. There may be other systemic symptoms at this stage.

Tertiary, or late syphilis, is the final stage. Patients will not have obvious symptoms. During this stage, the organism is silently causing organ damage over many years. The formation of *gummas*, an inflammatory tumor-like response to syphilis, can lead to serious complications.

Complications

Gummas may cause irreparable damage to skin, bone, or liver. In cardiovascular syphilis, the resulting aneurysm may press on structures such as the intercostal nerves, causing pain. The risk for rupture exists as the aneurysm increases in size. Scarring of the aortic valve can cause aortic valve insufficiency and heart failure.

Neurosyphilis occurs when *T. pallidum* invades the CNS. It can occur at any stage of syphilis. Visual impairment, *tabes dorsalis* (progressive locomotor ataxia), and dementia are rare, extreme manifestations.

Chancres on or inside the genitalia or anus enhance HIV transmission. Patients with HIV and syphilis are at greatest risk for significant CNS involvement. They may need more intensive treatment than other patients with syphilis.

Diagnostic Studies

Blood tests can diagnose syphilis. We classify tests for syphilis as those done for screening and those done that help to stage the infection and ensure an infected person was effectively treated. The fluorescent treponemal antibody absorption (FTA-Abs) test, *T. pallidum* particle agglutination (TP-PA) test, and syphilis qualitative enzyme-linked immunoassay (EIA) treponemal tests detect antibodies to *T. pallidum.* They are positive if a patient has ever been infected with syphilis. They remain positive even after treatment, so another test is used to ensure cure and determine when someone has been reinfected.

Nontreponemal tests detect antibodies that are not specific for syphilis. These include the Venereal Disease Research Laboratory (VDRL) test and the rapid plasma reagin (RPR) test. These tests usually become positive 10 to 14 days after the appearance of a chancre. When positive or "reactive," the test will read as a titer and will increase exponentially (e.g., 1:1, 1:2, 1:4, 1:8). This titer will continue to climb, reaching levels of up to 1:2048 during the primary and secondary stages of infection. Following treatment, this titer will fall back to "nonreactive" or negative. It will take time for this to happen, usually several months. If the titer does not return to nonreactive or continues to elevate, this could indicate treatment failure or reinfection.

False-negative and false-positive test results can occur with the nontreponemal tests (VDRL, RPR). A false-negative result may occur with primary syphilis if the test is done before the person has had time to make these nonspecific antibodies. A false-positive may occur in patients who have other diseases or inflammatory conditions that produce these nonspecific antibodies. In addition, if treatment with antibiotics is started early in suspected cases of syphilis, the serologic nontreponemal test may not react or elevate.

Interprofessional Care

Because of the serious complications of untreated syphilis, screening programs for high-risk groups are important for

TABLE 57.7 Interprofessional Care

Syphilis

Diagnostic Assessment
- History and physical assessment
- Treponemal and/or nontreponemal serologic testing
- Testing for other STIs (HIV, gonorrhea, chlamydial infection)

Management
- Antibiotic therapy:
  - Penicillin G benzathine
  - Doxycycline or tetracycline (if penicillin contraindicated)
- Confidential counseling and testing for HIV infection
- Surveillance
- Repeat of nontreponemal tests at 6 and 12 months
- Cerebrospinal fluid examination at 1 year if treatment involves alternative antibiotics or treatment failure has occurred

reducing morbidity and mortality. The evaluation of all patients with syphilis should include HIV testing. The CDC recommends annual syphilis testing for HIV patients (Table 57.7).[6]

Drug Therapy

Management is aimed at starting treatment early. Penicillin G benzathine is the recommended treatment for all stages (Table 57.7). When penicillin is contraindicated, doxycycline or tetracycline may be used with close follow-up. Aqueous procaine penicillin G is the treatment of choice for neurosyphilis. Treatment cannot reverse damage that is already present in the later stages of the disease. All sexual contacts from the preceding 90 days should be treated. Reexamination and follow-up testing are recommended every 6 months for up to 2 years to ensure cure. Repeat HIV testing should be done on all HIV-negative patients diagnosed with primary or secondary syphilis given the higher risk for HIV transmission during these stages.

❖ NURSING MANAGEMENT: STIs

◆ Assessment

Subjective and objective data that you should obtain from a person with an STI are outlined in Table 57.8. Screen patients based on risk history and sexual behaviors. Assess the patient's risk for contracting an STI. Questions to ask include the number of sexual partners (in the last month, year), gender of partners ("Do you have sex with men, women, or both? Transgender, nonbinary?"), type of birth control used (if applicable), use of condoms or other barrier methods, and history of an STI. Do they use social media or other networking apps to meet partners? Do they use drugs and alcohol or exchange sex for drugs or money? Are there violence and personal safety concerns?[13] Plan teaching based on the patient's responses.

Interpersonal skills needed for this interview include respect, compassion, and a nonjudgmental attitude. Tailor counseling to the patient and protect their privacy. Sexual practices are deeply personal. Interview patients alone, without parents or partners present whom they may not want to disclose all activities in front of. Provide a safe space to encourage honest discussion.

TABLE 57.8 NURSING ASSESSMENT

STIs

Subjective Data

Important Health Information

Sexual health history: Sexual activity, history of STIs, number of sexual partners, unsafe sexual practices, alcohol and substance use, social media apps

Medications: Allergy to antibiotics

Functional Health Patterns

Health perception–health management: Unsafe sexual practices, drug and/or alcohol use

Nutritional-metabolic: Nausea, vomiting, anorexia. Pharyngitis, oral lesions, chills. Alopecia

Elimination: Dysuria, urinary frequency, urethral discharge, pain with bowel movements

Cognitive-perceptual: Arthralgia, headache, painful, burning lesions, itching or irritation at infected site

Sexuality-reproductive: Dyspareunia, vaginal or penile discharge, bleeding with sex, genital or perianal lesions

Objective Data

General

Fever, lymphadenopathy (generalized or inguinal)

GI

Rectal discharge, rectal lesions

Reproductive

Cervical mucopurulent discharge, cervical erythema, cervical bleeding; penile purulent discharge, epididymitis, proctitis, genital lesions

Skin

Syphilis: Primary: Painless, indurated genital, oral, or perianal lesions

Secondary: Bilateral, symmetric rash on palms, soles, or entire body. Mucous patches on mouth or tongue; alopecia; condylomata lata

Genital herpes: Painful genital or anal vesicular lesions

Genital warts: Single or multiple, flesh-colored, hyperpigmented, genital or anal warts

Urinary

Urethral discharge, erythema

Possible Diagnostic Findings

Chlamydia: Positive NAAT cervical, urethral, anal, oropharyngeal, or urine samples

Gonorrhea: Positive cultures or NAAT from cervical, urethral, anal, oropharyngeal, or urine samples

Genital herpes: Positive HSV-1 or HSV-2 serum antibody test. Positive viral culture or PCR from an active lesion indicating HSV-1 or HSV-2

Syphilis: Positive findings on fluorescent treponemal antibody absorption (FTA-Abs) test, *T. pallidum* particle agglutination (TP-PA) test, or syphilis qualitative enzyme-linked immunoassay (EIA) test and/or a reactive VDRL or RPR test with elevated titer

Trichomoniasis: ↑ pH and positive motile protozoa on wet preparation of discharge. Positive FDA-approved rapid test or liquid-based Pap positive for trichomoniasis

Start by asking patients how they define themselves, including their gender identity and sexual preferences. Finally, do not assume that older people are not at risk. Sex and sexuality are dynamic across the life cycle. Sexually active older adults can be at risk for STIs.[13]

BOX 57.4 PROMOTING POPULATION HEALTH

Preventing STIs

- Follow "safer" sex practices every time you have sexual contact and be responsible for your own protection.
- Have sexual activity only in an established, monogamous relationship, and limit the number of sexual partners otherwise.
- Obtain vaccinations to help prevent some types of HPV.
- Know your sex partners. Be comfortable saying "no" to sexual activity.
- Limit alcohol use to moderate levels, and avoid substance use.
- If you are sexually active and at risk, obtain testing regularly and encourage partners to do the same.

CHECK YOUR PRACTICE

You are working on the medicine unit caring for a 68-year-old man admitted for IV penicillin for neurosyphilis. The nurse whom you are working with says, "I can't believe a man that old got syphilis."

- How would you respond?
- What should you discuss with your colleague?

Clinical Problems

Clinical problems for the patient with an STI include:

- Impaired sexual functioning
- Infection
- Deficient knowledge

Planning

The overall goals are that the patient with an STI will (1) understand the mode of transmission of STIs and the risks related to STIs, (2) complete treatment and return for appropriate follow-up, (3) notify or assist in notifying sexual contacts about their need for testing and treatment, (4) abstain from sexual contact until the infection is resolved and all partners have been treated, and (5) show knowledge of safer sex practices.

Implementation

Health Promotion

Many approaches to stopping the spread of STIs have had varying degrees of success (Box 57.4). Be prepared to discuss "safer" sex practices and harm reduction with all patients, not only those you perceive to be at risk. These practices include abstinence, monogamy, avoiding high-risk sexual behaviors, and correctly using condoms and other barriers with every sexual act. Sexual abstinence is the only certain method of avoiding all STIs, but few people consider this option. Limiting sexual contacts to an established, monogamous relationship in which both partners have been tested for STIs can reduce the risk. Addressing issues related to drug and alcohol use is important for promoting healthy sexual behavior.

Be prepared to teach special populations about their risks, including people of different racial and ethnic backgrounds, men having sex with men (MSM), and transgender persons (Table 57.9). Encourage routine testing in people who are at higher risk so STIs can be identified early. This will help to decrease the potential for complications and reduce transmission to others.

TABLE 57.9 Working With Special Populations

When working with the following populations at risk for STIs, consider cultural, behavioral, social networking, and other factors that may place them at increased risk.

Racial and Ethnic Minorities

- When approaching patients of different backgrounds, be sensitive to their culture, religion, and social norms.
- Remember that there may be limited access to care, varying education levels, and lower health literacy among certain populations.
- Use an interpreter when communicating with non–English-speaking patients.
- Acknowledge that some communities may not be open to talking about sex or sexual practices for religious or cultural reasons.
- Be aware that some men in the Black, Hispanic, or Middle Eastern communities may not be comfortable disclosing that they are having sex with other men. They may be in a relationship with a female partner due to cultural or community pressures.

Men Who Have Sex With Men

- Assess risk for STIs. Be comfortable asking questions about sexual identity and practices, including insertive and receptive anal sex. Do not assume all MSM engage in the same sexual activities.
- Ask about social media and networking apps used to connect with other men for casual dating and sex. These have been traced to outbreaks of STIs.
- Counsel HIV-uninfected MSM with an STI about options for HIV prevention, including pre-exposure prophylaxis (PrEP) and non-occupational postexposure prophylaxis (nPEP) (see Chapter 15).

Transgender Persons

- *Transgender man* is a term used to describe a person assigned as female at birth but who identifies as male. *Transgender woman* is a term used to describe a person assigned as male at birth but who identifies as female.
- Not all transgender persons have had gender reassignment surgery and may still have the anatomy present at birth. Screen these persons for STIs based on both risk history and site of exposure. For example, a transgender man may still have a vagina and cervix, requiring a vaginal exam and testing for trichomoniasis.

A teaching guide for the patient with an STI is shown in Table 57.10.

Measures to prevent infection. Help patients to be aware of specific signs and symptoms of infection. Encourage patients to take notice of a sexual partner's genitalia before sex. They should note any discharge, sores, blisters, lesions, or rashes. This can help them to make good decisions about whether to continue sexual activity with safer-sex modifications or to choose not to have sexual contact at all. Remind patients that most STIs may have no symptoms but can still be transmitted. Emphasize that when they have sex, they are exposed to the infections of everyone with whom their partner has ever had sex.

Proper condom use is a highly effective mechanical barrier to infections that may be transmitted by or to a penis. Partners should openly discuss any objections to condom use, such as interference with spontaneity and the presence of a barrier. Information about the mechanics of sexual arousal and incorporating a condom into sex can help to overcome resistance to

TABLE 57.10 PATIENT & CAREGIVER TEACHING

STIs

When teaching a patient with an STI:

1. Explain precautions to take, such as
   - Using condoms and other barrier methods with every sexual encounter
   - When being monogamous, defining what monogamy means with your partner
   - Limiting the number of sexual partners
   - Asking potential partners about their sexual history
   - Asking potential partners if they have been tested for STIs
   - Avoiding sex with partners who have visible oral, inguinal, genital, perineal, or anal lesions or those who use IV drugs
   - Voiding and washing genitalia and surrounding area after sex to flush out/wash away organisms to reduce potential for transmitting infection
2. Explain the importance of taking all antibiotics or antiviral agents as prescribed. Symptoms will improve after 1–2 days of treatment, but organisms may still be present.
3. Teach patients diagnosed with gonorrhea, chlamydia, syphilis, or trichomoniasis that all sexual partners need treatment to prevent transmission and reinfection.
4. Teach patients to abstain from sexual contact during and for 7 days after treatment. Review the use of condoms or other barrier methods when sexual activity is resumed to prevent spread of infection and reinfection.
5. Explain the importance of follow-up examination and retesting at least once after treatment (if appropriate) to confirm complete cure.
6. Allow patients and partners to voice their concerns and clarify areas that need explanation.
7. Teach patients about the signs and symptoms of complications and need to report problems to their HCP to ensure proper follow-up and early treatment of reinfection.
8. Tell patients of the infectious nature of these infections to avoid a false sense of security, which may result in careless sexual practices or poor personal hygiene.
9. Tell patients about health department requirements for anonymously reporting certain STIs.

its use. Refusing sexual activity with any partner who will not use a condom is a safe and legitimate option.

The *female condom,* a lubricated polyurethane sheath designed for vaginal use, is an option for some women. Teach patients to avoid the spermicide nonoxynol 9 (N-9), which can be used alone to prevent pregnancy or as a condom lubricant. N-9 is one of the least effective methods of birth control when used alone. It can be irritating to the vagina and rectum, increasing the risk for acquiring an STI.

Screening programs. Screening programs are a way to identify, treat, prevent, and control the spread of STIs. At present, there are CDC-recommended screening programs for certain populations, including young people, MSM, pregnant women, and anyone at increased risk for exposure to an STI (e.g., new partners, multiple relationships, not using condoms).[6]

Case finding. Interviewing and case finding are other methods used to control the spread of STIs. These activities are directed toward finding and examining all sexual contacts of patients with reportable STIs so that they receive treatment. Public health professionals, often nurses, are aware of the social implications of STIs and the need for discretion in finding partners. Sexual contacts are not told about the origin of the information naming them as a contact or the timing of exposure to ensure patient privacy mandates.

Partner notification and treatment impose a heavy burden on public health departments. As a result, notification often becomes the responsibility of the infected partner. The infected partner may choose not to tell sexual partners, and the partners may choose not to seek treatment. Unfortunately, this perpetuates the disease.

Educational programs. Actively encourage your community to provide better education about STIs for its citizens. High-risk populations (e.g., young people under age 25) should be a prime target for such programs. STI rates are rising in older adults.[2] Older adults are less likely to use condoms and often have a hard time starting discussions about sexual health issues.

Knowledge and understanding can decrease the incidence of STIs. Encourage the HPV vaccine before the start of sexual activity. Accurate and current information may help reduce parental fears related to the vaccine. Consider stressing the prevention of cancer as a reason for the vaccine. This may be more productive and less controversial, thus making the parent and adolescent more receptive.

◆ Acute Care

Psychologic support. The diagnosis of an STI may be met with a variety of emotions, such as embarrassment, shame, guilt, anger, or even a desire for vengeance. Encourage the patient to voice feelings. Couples in marital or committed relationships have an added problem when an STI is diagnosed if they must face the implication of sexual activity outside the relationship. The STI raises other concerns about their relationship and may serve as an incentive for further problem solving. A referral for professional counseling to explore the impact of the STI on their relationship may be needed.

A patient with genital herpes is faced with the fact that future outbreaks will occur and that no cure is available. This can be frustrating and disruptive to the patient's physical, emotional, social, and sexual life. Help the patient identify and avoid any factors that may precipitate outbreaks, such as stress, local trauma, or sun exposure. Tell the patient that the frequency and severity of recurrences will decrease over time. Stress that herpes is a common, manageable condition and does not pose a risk to their overall health.

Genital or anal warts involve a prolonged course of treatment. Clearing the virus takes time and is not always possible. Patients can become frustrated and distressed due to frequent office visits, associated costs, potential for unpleasant treatment side effects, and effects of the infection on future health and sexual relationships. Support and a willingness to listen to the patient's concerns are needed. Local or online support groups are available for almost all STIs. Help patients to connect with support groups.

Follow-up. If you work in public health facilities, clinics, or other outpatient settings, you are more likely to care for a patient with an STI than if you work in a hospital setting. Whatever the setting, as a nurse, you can teach about treatment measures, such as the purpose and side effects of prescribed drugs, and the need for follow-up care (Table 57.10).

BOX 57.5 ETHICAL/LEGAL DILEMMAS

Confidentiality and HIPAA

Situation

D.G. is a 25-year-old male who recently tested positive for chlamydia. You tell him to tell his sexual partners of the infection so they may be treated. He refuses to tell her girlfriend because she will then know that he had sex with someone else. You later learn that a nursing student who was in the clinic that day is a friend of his girlfriend and told her that the girlfriend is likely infected and should have STI testing.

Ethical/Legal Points for Consideration

- Each state has requirements for reporting communicable diseases and other health-related data. Inform the patient of the reporting requirements for communicable diseases.
- Nurses and other HCPs have both a legal and an ethical obligation to maintain confidentiality of patient information. The Health Insurance Portability and Accountability Act (HIPAA) ensures the privacy of personal health information.
- The duty to maintain confidentiality is not absolute and may be limited, as needed, to protect the patient or other parties, or by law or regulation, such as mandated reporting for safety or public health reasons.
- Your main obligation is to the patient seeking care. Teaching is one way to establish a partnership with this patient. Share information about the effects of the disease, the consequences of reinfection, and the effect of the disease on others who may not know that they are infected. Then encourage the patient to tell his partners of the diagnosis and discuss the option of EPT where applicable.

Discussion Questions

1. What are your state's requirements for reportable conditions?
2. In your opinion, what is the best way to balance the needs of an individual patient with those of the public?
3. What are the risks to agencies for the breach of confidentiality and HIPAA?

Reference

Code of Ethics for Nurses. Retrieved from https://www.nursingworld.org/practice-policy/nursing-excellence/ethics/code-of-ethics-for-nurses/.

Single-dose treatment for gonorrhea, chlamydia, and syphilis helps prevent problems from nonadherence with drug therapy. Stress to the patient receiving multiple-dose therapy the need to complete the prescribed treatment. Teach the patient about problems resulting from nonadherence. All patients should return to the treatment center for repeat testing of the infected sites or for serologic testing at designated times to determine the effectiveness of the treatment. Explaining to the patient that they may not be cured with the first treatment can reinforce the need for a follow-up visit. Tell the patient to inform sexual partners of the need for testing and treatment as a contact, regardless of whether they are free of or have symptoms (Box 57.5).

Hygiene measures. Emphasize the importance of certain hygiene measures, such as frequent hand washing. Tell the patient not to scratch infection sites, to avoid autoinoculation of STIs that can be spread to other parts of the body. Washing with soap and water and voiding after sex may have some benefit in decreasing the exposure to STIs but does not give adequate protection against transmission. Teach patients not to douche after sex. It can push bacteria higher into the reproductive tract or undermine local immune responses.

Sexual activity. Sexual abstinence is needed during the communicable phase of any STI. Long-term precautions must be taken with those STIs that are chronic or recurrent. Emphasize that even single-dose treatments can take up to 1 week to clear the infection. Thus the patient is infectious during this period and should avoid all sexual contact. Remind patients that all partners must be treated as contacts to prevent reinfection. Emphasize the importance of using condoms or other barrier methods to help prevent the spread of infection and reinfection after all have been treated. Remind patients that complications can follow if sexual activity occurs before treatment completion or if all partners are not treated appropriately. Patients need to discuss re-treatment or continued treatment with an HCP. During treatment, the patient can choose to relate to a partner in an intimate way that avoids penetrative, oral-genital contact, or skin-to-skin contact.

◆ Ambulatory Care

Because many STIs are cured with a single dose or short course of antibiotic therapy, many patients are casual about the outcome. The consequences of this attitude can include delays in treatment, nonadherence with instructions, treatment failure, reinfection, and complications. Complications are serious and costly and can include future infertility.

Patients with infection-related complications may need prolonged treatment and surgery. Major surgery, such as resection of an aneurysm or aortic valve replacement, may be needed to treat cardiovascular problems caused by syphilis. Pelvic surgery and procedures to correct fertility problems from an STI may be needed. If not successful, patients may need assisted reproductive technologies to achieve future pregnancy. Because young people ages 15 to 24 represent about 50% of new STIs annually, almost every state and the District of Columbia have laws that allow minors to consent to STI services without parental involvement. However, the minimum age does vary by state.

◆ Evaluation

Expected outcomes for the patient with an STI are that the patient will:

- Understand the course, modes of transmission, and treatment options for the STI
- Relate the potential long-term complications of untreated infection
- Adhere to treatment plan and the follow-up protocol
- Understand the importance of partner notification and treatment
- Practice STI risk-reducing behaviors

Case Study

Gonococcal Infection

(© ajr_images/iStock.com.)

Patient Profile

B.D. is a 24-year-old MSM seen in the outpatient clinic with dysuria and yellow penile discharge for the past 2 days. He is sexually active with a new partner. B.D. reports having had oral and unprotected anal sex as the insertive partner 1 week ago. He was treated in the past for chlamydia.

Subjective Data

- He and his partner used condoms at the beginning of their relationship but stopped recently
- His partner has no symptoms
- Appears worried

Objective Data

- Penis: Meatus is red
- Moderate amount of yellowish penile discharge
- Testicles are nontender, no local lymph adenopathy
- Urine NAAT is positive for *N. gonorrhoeae*

Interprofessional Care

- ceftriaxone 500 mg IM × 1 dose

Discussion Questions

1. ***Recognize:*** What are B.D.'s risk factors for acquiring gonorrhea?
2. ***Analyze:*** What complications could occur if B.D.'s infection is not treated?
3. ***Plan:*** What impact is the diagnosis likely to have on B.D.'s self-image? On his relationship with his sexual partner?
4. ***Prioritize:*** What is the priority of care for B.D.?
5. ***Act:*** B.D. mentions he and his partner are on pre-exposure prophylaxis (PrEP) for protection against HIV. How would you advise him on STI prevention?
6. ***Act:*** What instructions should B.D. receive to ensure successful treatment? To prevent reinfection? To prevent further transmission?
7. ***Safety:*** B.D. tells you he is worried about how his partner will react when he discloses this information. What assistance in notifying his partner should you consider?

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. The nurse planning a prevention program for sexually transmitted infections (STIs) notes which factors are associated with the increased incidence of STIs? *(select all that apply)*
   - **a.** Alcohol and drug use
   - **b.** Asymptomatic infections
   - **c.** Being upper middle class
   - **d.** Use of long-acting contraceptives
   - **e.** Being placed in a correctional facility
2. The nurse is reviewing treatment orders for a pregnant woman diagnosed with chlamydia. What is *most* important to consider?
   - **a.** Infection may involve the throat or anus.
   - **b.** Doxycycline should not be used as treatment.
   - **c.** Symptoms of chlamydia are often absent in women.
   - **d.** Repeat testing is needed 3 months after treatment to ensure cure.
3. The nurse plans to include in the teaching plan for a patient with herpes who is prescribed an antiviral agent that daily use of the medication
   - **a.** cures the infection over time.
   - **b.** masks the symptoms of other STIs.
   - **c.** eliminates the risk of transmission to others.
   - **d.** reduces the frequency and severity of recurrent episodes.
4. Which laboratory tests would the nurse evaluate to confirm suspected syphilis in a patient who denies a prior history of syphilis?
   - **a.** Antibiotic resistance testing to select an appropriate treatment
   - **b.** Treponemal-specific test with an antinuclear antibody (ANA)
   - **c.** Complete blood count (CBC) to assess for a shift in white blood cells
   - **d.** Treponemal-specific test, and a follow-up rapid plasma reagin (RPR) if positive
5. Which STIs can be asymptomatic? *(Select all that apply.)*
   - **a.** Syphilis
   - **b.** Chlamydia
   - **c.** Genital warts
   - **d.** Genital herpes
   - **e.** Gonorrhea of the throat
6. When educating patients about preventing STIs, the nurse should highlight *(select all that apply)*
   - **a.** the appropriate use of oral contraceptives.
   - **b.** how alcohol and substance use may increase risk.
   - **c.** sexual positions that can be used to avoid infection.
   - **d.** the need for annual Pap tests for women with HPV.
   - **e.** sexual practices that are considered high-risk behaviors.
7. A student nurse is assisting the staff nurse with an admission history for a patient with pelvic inflammatory disease from gonorrhea. Which action by the student nurse requires the nurse to intervene?
   - **a.** Obtains a history of alcohol and substance use
   - **b.** Asks questions considering the patient's ethnic background and education
   - **c.** Reviews sexual activities in a respectful, compassionate, nonjudgmental manner
   - **d.** Interviews the patient with the partner present to determine if the partner is at risk

1. a, b, d, e; 2. b; 3. d; 4. d; 5. a, b, c, d, e; 6. b, e; 7. d.

Female Reproductive Problems

Robyn Schafer

http://evolve.elsevier.com/Lewis/medsurg/

CONCEPTUAL FOCUS

Cellular Regulation
Hormonal Regulation
Infection
Inflammation
Pain
Reproduction
Sexuality

LEARNING OUTCOMES

1. Outline strategies for the diagnosis and treatment of female infertility.
2. Identify risk factors and nursing and interprofessional management of early pregnancy loss and ectopic pregnancy.
3. Describe the etiology and clinical manifestations of menstrual problems, abnormal uterine bleeding, and polycystic ovary syndrome.
4. Describe physiologic changes related to menopause and management of perimenopausal symptoms.
5. Outline the etiology and clinical manifestations of lower genital tract infections and pelvic inflammatory disease.
6. Identify the pathophysiology and appropriate interprofessional and nursing care for benign gynecologic problems.
7. Explain the clinical manifestations, diagnostic studies, and treatment of gynecologic cancers.
8. Discuss the interprofessional and nursing care for victims of sexual assault.

KEY TERMS

abnormal uterine bleeding (AUB)
dilation and curettage (D&C)
dysmenorrhea
early pregnancy loss
ectopic pregnancy
endometriosis
fibroids (leiomyomas)
infertility
menopause
pelvic inflammatory disease (PID)
pelvic organ prolapse
perimenopause
polycystic ovary syndrome (PCOS)
premenstrual syndrome (PMS)
sexual assault
sexual dysfunction
spontaneous abortion

Sexual functioning and satisfaction are important aspects of well-being across the lifespan. Problems with gynecologic and female sexual health profoundly affect health and well-being. This chapter discusses common female reproductive system problems. Care often includes screening and prevention, health teaching and promotion, and assessment and treatment of complications.

While these are referred to as female reproductive system problems, the terms "female" and "woman" may not reflect the gender identity of patients with these problems. These problems may be relevant in transgender, gender-nonconforming, and gender-diverse persons assigned female sex at birth. Use of gendered terms here is not meant to exclude any person who has these problems.

INFERTILITY

Infertility is defined as the inability to conceive after at least 1 year of regular intercourse without contraception.[1] Around 15% of heterosexual couples experience infertility. It is more common with advancing age. The process of assessing and managing infertility is often stressful and emotionally difficult for patients and their partners.

TABLE 58.1 Diagnostic Criteria

Infertility

Infertility is diagnosed after a person has not been able to conceive after:

- 12 months of regular (frequent) intercourse without contraception in those less than 35 years of age; OR
- 6 months of regular (frequent) intercourse without contraception in those 35 years of age and older.

TABLE 58.2 Interprofessional Care

Infertility

Diagnostic Assessment

- History and physical assessment of both partners
  - Detailed menstrual, sexual, reproductive, and gynecologic history
  - Height, weight, and body mass index
  - Pelvic examination
- Laboratory tests (as indicated)
  - CBC
  - Thyroid-stimulating hormone (TSH)
  - STI screening
  - Hormone levels (FSH, LH, antimüllerian hormone, progesterone, prolactin)
- Imaging
  - Transvaginal ultrasound
  - Hysterosalpingogram

Management

- Lifestyle changes
- Drug therapy (Table 58.3)
- Surgery
- Assisted reproductive technologies (ARTs)

TABLE 58.3 Drug Therapy

Infertility

Class	Drugs	Mechanism of Action
Aromatase inhibitor	letrozole (Femara)	↓ Estrogen by preventing the conversion of androgens to estrogens in the ovaries
Biguanide	glucophage (Metformin)	↓ Hyperinsulinemia. May lead to enhanced spontaneous ovulation with PCOS
Gonadotropin	follicle-stimulating hormone (Gonal-f) human chorionic gonadotropin (hCG) human menopausal gonadotropin (Menopur)	Stimulates follicle growth and maturation by mimicking the body's natural hormones
Selective estrogen receptor modulator (SERM)	clomiphene citrate (Clomid)	Stimulates ovulation by binding estrogen receptors in the hypothalamus. Leads to ↑ gonadotropin-releasing hormone (GnRH) production and ↑ LH and FSH secretion in the pituitary

Etiology and Pathophysiology

Infertility affects men and women equally. We describe it as being caused by male or female factors. There may also be a combination of factors. In as many as 30% of cases, no specific cause is identified. Factors that cause male infertility are discussed in Chapter 59. The most common causes of female infertility are hormone imbalances, anatomic or structural problems of the reproductive tract, and other unexplained causes.

Diagnostic Studies

Formal evaluation of infertility is usually done after 12 months of regular, unprotected intercourse (Table 58.1). Earlier evaluation is appropriate in women over the age of 35 or in the presence of known medical or physical problems. Evaluation starts with a history and physical assessment (Table 58.2). Based on the findings, laboratory tests and diagnostic imaging may be done. These explore common causes of infertility, including diminished ovarian reserve, ovulatory dysfunction, and structural problems of the fallopian tubes and uterus.[2] A semen analysis of the male partner is often part of the infertility workup.

❖ Interprofessional and Nursing Management

There are multiple treatment options for infertility. These include lifestyle changes, drug therapy, and surgery. The approach is tailored to the underlying cause. A patient-centered approach to care is essential in treating infertility. Patients and, when appropriate, their partners should be involved in determining the plan of care and weighing the efficacy, safety, and advantages and disadvantages of various treatment options. These procedures may be expensive and stressful. Provide an overview of infertility evaluation, treatments, and alternatives to help reduce stress. Teaching about fertility, ovulation, and intercourse is important. This information often improves conception rates.

Lifestyle changes include weight loss, smoking cessation, and reduced alcohol and caffeine intake. Intercourse is timed around ovulation. Medical treatment for female infertility focuses on stimulating the ovaries (known as *ovulation induction*). Table 58.3 reviews common drugs used in fertility treatment. Surgery may address blockages in the ovarian tubes or uterine problems. Finally, *assisted reproductive technology* (ART) procedures include insemination through intracervical insemination (ICI), intrauterine insemination (IUI), or in vitro fertilization (IVF). The National Infertility Association (RESOLVE) is a useful resource to support patients in exploring treatment options.[3]

PREGNANCY LOSS

Pregnancy loss is the term used to describe the loss of a nonviable pregnancy up to 20 weeks gestation. **Early pregnancy loss** occurs in the first trimester (the first 13 weeks of pregnancy). It is the most common type of pregnancy loss. *Abortion* is another term used to describe the loss of a previable pregnancy or the elective termination of pregnancy at any stage. We classify

TABLE 58.4 Types of Spontaneous Abortion

Type	Description
Complete abortion	All products of conception (POC) are expelled
Incomplete abortion	Passage of some but not all POC through the cervix
Inevitable abortion	Pregnancy loss cannot be prevented due to opening of the cervix or rupture of amniotic membranes
Infected (septic) abortion	Serious maternal infection occurring with any type of abortion
Missed abortion	Nonviable POC remain in the uterus
Threatened abortion	Vaginal bleeding in a pregnancy prior to 20 weeks' gestation in the absence of cervical dilation

abortions as spontaneous or induced. Pregnancy loss can lead to grief and psychological distress.

Spontaneous Abortion

Spontaneous abortion is the natural loss of pregnancy before 20 weeks of gestation. Many refer to this as a "miscarriage." Types of spontaneous abortions are listed in Table 58.4. Around 20% of pregnancies result in spontaneous abortion. Most occur in the first trimester. They are often related to embryonic chromosomal abnormalities. Other common causes include endocrine problems, maternal infection, uterine abnormalities (e.g., uterine fibroids, endometriosis), immune factors, and environment factors. Risk factors for spontaneous abortion include age greater than 35 years, history of prior pregnancy loss, and chronic medical problems such as diabetes, obesity, or thyroid disease. Stress and substance use are also related to an increased risk.

Patients experiencing a spontaneous abortion often present with vaginal bleeding and cramping. Following a history and physical assessment, transvaginal ultrasound imaging is recommended for diagnosis. Bloodwork is done to assess serum human chorionic gonadotropin levels (hCG, also called β-hCG or "beta"). We have few interventions to prevent pregnancy loss. We used to place patients with threatened abortions on bed rest. Research shows this practice has more potential to be harmful than helpful. So, we no longer recommend bed rest.

There are 3 approaches to treatment of spontaneous abortion: (1) expectant management, (2) drug therapy, and (3) surgery.[4] A patient-centered approach should be used to determine the plan of care based on the patient's preferences and values. Provide patients with information about treatment options. Discuss the risks and benefits of each. Involving patients in decision making leads to the best mental health outcomes. Any patients with signs of acute complications such as hemorrhage or infection need emergency care.

Expectant management involves waiting for the pregnancy tissue (also called *products of conception [POC]*) to pass on its own. When appropriate criteria are met, this approach is about 75% effective in the 1st trimester. This option is the least invasive. However, it is not as predictable or effective as other approaches. Patient teaching about warning signs is needed. We need to monitor for complications and have a clear plan for follow-up.

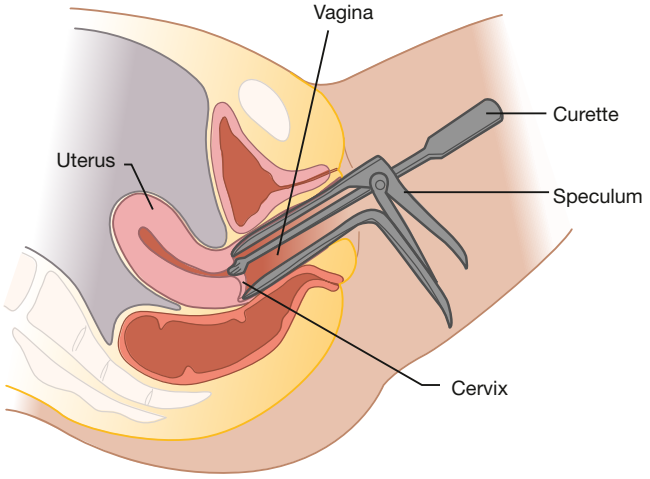

Fig. 58.1 D&C.

Drug therapy involves drugs such as misoprostol (Cytotec) and mifepristone (Mifeprex) to open the cervix and induce passage of the POC from the uterus. This approach offers more predictable timing of the POC than expectant management. It is less invasive than surgery. The ability to prescribe and dispense mifepristone is restricted in the United States.[5] This limits its accessibility in some settings. Teaching about side effects and anticipatory guidance is essential to safety in this approach.

Surgery of an abortion involves **dilation and curettage (D&C)** (Fig. 58.1). With a D&C, the cervix is dilated and the uterine contents removed using either manual vacuum aspiration (MVA) or electric vacuum aspiration (EVA). This approach is the most invasive of spontaneous abortion treatment options. But it is highly effective and offers rapid resolution of pregnancy loss.

Teach patients to call the HCP for heavy vaginal bleeding, fever, foul-smelling vaginal discharge, or severe pain. Discuss the use of pain medications, such as ibuprofen. Give resources or referrals for psychologic support and grief counseling to reduce mental health complications such as depression and anxiety. Review contraceptive options or planning for a subsequent pregnancy. Ovulation can resume within days or weeks after a pregnancy loss. Historically, we told patients to abstain from vaginal intercourse and wait several weeks or months before trying to become pregnant again. However, these practices do not reduce complications like infection or recurrent pregnancy loss and are no longer recommended.

Induced Abortion

Induced abortion is the elective termination of a pregnancy. There are several ways to induce an abortion. In the United States, the most common ways are medical abortion and aspiration (sometimes called surgical) abortion (Table 58.5). The approach used depends on the gestational length of the pregnancy, patient preference, and availability of care. State laws and agency regulations affect abortion care. Cost can be a significant factor since most patients pay out-of-pocket for abortion services. Engage patients in decision making about the risks, benefits, and alternatives to help them make the most appropriate decision. Provide patients information about all available options and referral to a setting that provides safe abortion care.[6]

TABLE 58.5 Comparison of Common Ways to Induce Abortions

Method	Aspiration Abortion	Medication Abortion
Description	Products of conception are removed through medical instruments that are introduced through the cervix and attached to manual or electric vacuum aspirator	Use of a combination of oral or buccal drugs (most often mifepristone and misoprostol) to soften and dilate the cervix and expel the pregnancy tissue
Timing	Up to 14 weeks gestation	Up to 10 weeks gestation
Success rate	High (99%)	High (98%–99%)
Common side effects	Abdominal cramping, vaginal bleeding	GI distress, abdominal cramping, vaginal bleeding
Health care visits	Requires 1 visit (often to an abortion care center)	May require multiple visits. Drugs must be taken in 2 doses 2 days apart. Follow-up care advised to ensure complete passage of tissue

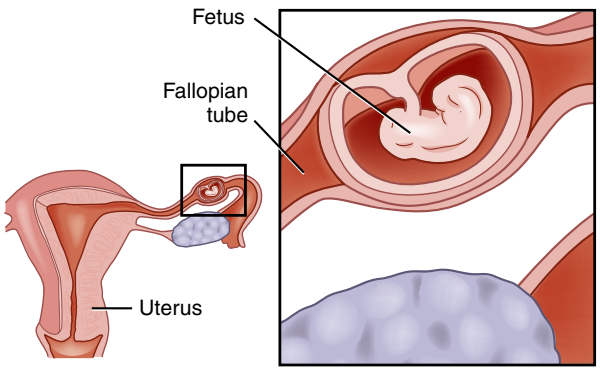

Fig. 58.2 Ectopic pregnancy in the fallopian tube.

Nursing care for induced abortion includes assessment, psychosocial support, and teaching. Patients who are RhD-negative blood type should receive Rho(D) immune globulin (Rhogam) for alloimmunization prevention. While rare, potential complications include infection, hemorrhage, uterine perforation, or incomplete abortion. Teach patients about the warning signs of complications, such as heavy vaginal bleeding, severe abdominal cramping or pain, fever, or foul-smelling vaginal discharge. Induced abortions do not negatively affect future pregnancies. Ovulation can occur within 2 weeks following an induced abortion. Menses often returns within 2 months. Therefore, when pregnancy is not desired, explore contraceptive options.

ECTOPIC PREGNANCY

An **ectopic pregnancy** is the implantation of a fertilized ovum outside the uterus. Almost all ectopic pregnancies occur within the fallopian tube (Fig. 58.2). When this happens, there is a risk that the pregnancy will rupture the fallopian tube. This can lead to excessive intrabdominal blood loss. It is a life-threatening emergency. Early detection of ectopic pregnancy is essential to reduce mortality.

Etiology and Pathophysiology

Tubal complications or blockages from infection, surgery, or deformity increase the chance that implantation will occur in the fallopian tube. While rare, ectopic pregnancies can occur in other sites such as the cervix, ovaries, surgical scar tissue, or abdominal wall. Embryos that implant outside of the uterine lining are unable to develop normally. As the embryo grows, it can cause organ rupture leading to severe internal bleeding and, if untreated, death.

Risk factors include a history of ectopic pregnancy, tubal surgery or deformity, or pelvic infection. Assisted reproduction and previous induced abortion also increase risk. Intrauterine conception greatly reduces the likelihood of intrauterine pregnancy. Therefore, when pregnancy does occur in a person with an intrauterine device (IUD), there is a higher risk of it being an ectopic pregnancy.

Clinical Manifestations

In an ectopic pregnancy, symptoms often occur 6 to 8 weeks after the last (normal) menstrual period (LMP). The main symptoms are abdominal or pelvic pain and unexplained vaginal bleeding. Secondary symptoms include those of early pregnancy, such as absent or late menses, nausea, frequent urination, and breast tenderness. Pain is typically caused by distention of the fallopian tube. This pain is often described as vague, sharp, or unilateral. Some patients do not have any pain. When present, vaginal bleeding can vary in quantity and color from scant brown spotting to bright red, heavy bleeding. In severe cases, patients have severe, sharp, unilateral pelvic or abdominal pain and sudden onset of vaginal bleeding. Any patients who present with severe hemorrhage or symptoms of shock such as hypotension or feeling dizzy or faint should be treated as a medical emergency.

Diagnostic Studies

Physical assessment, diagnostic imaging, and laboratory studies are used to diagnose an ectopic pregnancy. The presence of cervical motion or adnexal tenderness or an adnexal mass on pelvic examination are common findings. Serial transvaginal ultrasound and measurement of serum hCG are useful in confirming or ruling out ectopic pregnancy.

CHECK YOUR PRACTICE

You are working in the ED. Your patient is a 29-year-old woman who presents with acute abdominal pain, scant vaginal bleeding, and a positive home pregnancy test. The HCP suspects an ectopic pregnancy. The patient is crying, "I am going to lose this baby, and we have been trying so hard to have one."

- As her nurse, what are your priorities?
- How would you respond to her?

Interprofessional and Nursing Management

There are 3 ways to treat an ectopic pregnancy: drug therapy, surgery, or expectant management. Drug therapy with methotrexate may be an option if an ectopic pregnancy is diagnosed

early and the patient is stable. Methotrexate stops the growth of rapidly dividing cells, including fetal and early placenta cells, by inhibiting DNA synthesis and disrupting cell multiplication. It is given as a single- or multiple-dose IM injection. The most common side effect is cramping or abdominal pain, which usually occurs during the first 2 to 3 days after treatment. When therapy is ineffective, or a patient has severe symptoms or high risk of rupture, surgery is needed. Surgical options include a *salpingectomy* (removal of the fallopian tube) or *salpingostomy* (surgically opening the tube and removing the pregnancy tissue). Surgery may be done laparoscopically. For a small number of low-risk patients, expectant management with close monitoring may be an option.

Nursing care includes closely monitoring symptoms and vital signs. Assess for signs of shock. Teach patients about ectopic pregnancy and treatment options. Provide emotional support. Prepare patients for diagnostic procedures, drug therapy, or surgery. Follow up with additional laboratory tests or imaging as appropriate based on the treatment approach and symptoms.

PROBLEMS RELATED TO MENSTRUATION

Wide variation exists among normal menstrual cycle length and bleeding duration, quantity, and character (see Table 55.2). The menstrual cycle may be irregular the first few years after *menarche* (first menstruation) and in *perimenopause* (the years preceding menopause). Common perimenstrual problems include premenstrual syndromes (PMS) and painful menses. Patients may have bleeding that is absent or irregular in amount, frequency, duration, or timing. Hyperandrogenic disorders like polycystic ovary syndrome (**PCOS**) can cause menstrual problems. We discuss each of these in the following sections.

PREMENSTRUAL DISORDERS

Most women have physical and emotional symptoms during specific menstrual cycle phases. For example, many have mild bloating, breast tenderness, or mood swings in the premenstrual phase. While often referred to as PMS, these mild symptoms do not meet the criteria for PMS. Clinically, the term **premenstrual syndrome (PMS)** is used in situations in which 1 or more recurrent physical and behavior symptoms cause severe distress or interfere with daily functioning. PMS can affect health, relationships, work performance, or academic performance. *Premenstrual dysphoric disorder* (PMDD) is a severe form of PMS that often includes behavior and affective symptoms.

Etiology and Pathophysiology

We do not know the exact cause of premenstrual disorders. Most likely, they are the result of a combination of hormone and psychosocial factors. Genetics, nutrition, drug therapy, and underlying medical or mental health problems may be contributing factors.

Clinical Manifestations

PMS presents with a wide variety of recurrent, cyclical symptoms. Symptoms may be physical, emotional, behavioral, or cognitive. Onset of symptoms occurs in the luteal phase of the menstrual cycle. Resolution of symptoms occurs within days of onset of menses. Common physical symptoms are breast discomfort, bloating and swelling, headache, and cramping. Emotional symptoms include mood swings, irritability, and feeling anxious or depressed. Changes in behavior such as food cravings or increased appetite are common. Some patients have cognitive symptoms like difficulty concentrating. With PMDD, patients often have irritability, anger, fatigue, anxiety, and depressed mood. PMDD may be superimposed on other psychiatric conditions.

Diagnostic Studies

To diagnose premenstrual disorders, we rule out problems that may present with similar symptoms. Obtain a history, including detailed menstrual and psychiatric histories. Physical and laboratory assessments may be helpful. Evaluation for mood or anxiety disorders, thyroid problems, or perimenopausal symptoms may be appropriate. Use of a symptom diary or calendar can aid the diagnosis.

Interprofessional Care and Nursing Management

Care focuses on symptom management. A holistic approach including lifestyle and behavior interventions, complementary and alternative therapies, and consideration of drug options may best meet the patient's needs.

Health promotion should include guidance and support for improved nutrition, exercise, sleep, and stress management. Behavior interventions such as relaxation techniques may be helpful. Cognitive behavioral therapy may be used to manage moderate to severe symptoms. Drug treatment options include selective serotonin reuptake inhibitors (SSRIs) and/or combined hormonal contraceptives such as an oral contraceptive pill (OCP). Some herbal remedies such as *vitex agnus castus* (chasteberry) and nutrition supplements may help reduce symptoms in some persons.[7]

Nursing care includes teaching about the condition and ways to manage symptoms (Table 58.6). Acknowledging the diagnosis can be therapeutic and validating. Helping patients monitor their symptoms and set realistic goals can improve functioning and quality of life. Patients with PMDD are at increased for suicide. Provide counseling and resources for suicide prevention.

DYSMENORRHEA

Dysmenorrhea is painful menstruation. It is one of the most common gynecologic problems. Although most women have some discomfort during menses, dysmenorrhea is cyclic pain that interferes with activities of daily living. It can be primary or secondary. In *primary dysmenorrhea*, no underlying problem or disease process is causing the symptoms. In *secondary dysmenorrhea*, the symptoms are due to an underlying pathology such as endometriosis or uterine fibroids.

TABLE 58.6 Interprofessional Care

Premenstrual Disorders

Diagnostic Assessment
- Health history including medication, menstrual, psychiatric history
- Symptom diary
- Physical assessment
- Laboratory studies as indicated

Management
- Health promotion (diet, sleep, exercise)
- Stress reduction
- Cognitive behavioral therapy
- Nutrition therapy
- Drug therapy
  - SSRIs
  - Combined hormonal contraceptives

Etiology and Pathophysiology

Primary dysmenorrhea is thought to be caused by excess production of prostaglandin, a hormone secreted by the *endometrium* (uterine lining) during menstruation. Prostaglandin stimulates the uterus to contract. Uterine contractions and constriction of small endometrial blood vessels lead to tissue ischemia and increased sensitization of pain receptors. This results in painful menstrual cramps. As menstruation continues, prostaglandin levels decrease, and menstrual cramping improves. Primary dysmenorrhea is most common in adolescents around the time of menarche.

Secondary dysmenorrhea has similar symptoms of pain during menses but is caused by a uterine pathology. The most common causes of secondary dysmenorrhea are endometriosis, adenomyosis, or uterine fibroids. There may also be an association between dysmenorrhea and chronic pain conditions.

Clinical Manifestations

Both forms of dysmenorrhea present with the same symptoms. Patients have painful uterine cramping with the start of menses. Symptoms often resolve spontaneously within 2 or 3 days after onset. Patients may also have back pain, nausea and vomiting, and symptoms of premenstrual disorders. Dysmenorrhea can impair patients' functioning and quality of life. Severe dysmenorrhea can lead to absenteeism and decreased productivity at work or school. Depending on the cause, secondary dysmenorrhea may be associated with *dyspareunia* (painful intercourse), heavy or irregular vaginal bleeding, or infertility.

Diagnostic Studies

Evaluation begins with the history. Obtain detailed menstrual and sexual histories. Because dysmenorrhea has a genetic component, take a focused family history. Use of a symptom diary may help aid diagnosis. A diagnosis of primary dysmenorrhea can be made based on the presentation of symptoms in the absence of other suspected causes of pain. Pelvic examination may not be necessary for adolescents who are not at risk for sexually transmitted infections (STIs) and present with classic symptoms of primary dysmenorrhea. If we suspect secondary dysmenorrhea, assessment will include a pelvic examination and transvaginal or pelvic ultrasound imaging.

CHECK YOUR PRACTICE

In an outpatient clinic, your 28-year-old patient is reporting symptoms of PMS. She tells you, "Lately, before my period comes, I spend the entire day in bed. I'm in pain. I'm anxious and overwhelmed. I just can't function like this anymore."
- How would you respond?
- What can she do to improve her symptoms?

Interprofessional Care

Treatment for primary dysmenorrhea includes drug and nonpharmacologic therapies. Nonpharmacologic options include use of heat, exercise, and complementary and alternative therapy such as transcutaneous electrical nerve stimulation (TENS) or acupuncture. First-line drug therapy includes nonsteroidal antiinflammatory drugs (NSAIDs). NSAIDs inhibit prostaglandins and decrease pain. If NSAIDs are ineffective or patients want contraception, hormone therapies such as oral conceptive pills may be appropriate.

Treatment of secondary dysmenorrhea depends on the cause. Some patients' symptoms are improved by the same approaches used to treat primary dysmenorrhea. However, management of the underlying problem may be needed to relieve symptoms. Some patients may need surgical treatment. Common surgical treatments for dysmenorrhea include *endometrial ablation* (surgical destruction of the uterine lining) and *hysterectomy* (removal of the uterus) (Table 58.7).

Nursing care includes teaching about the cause, symptoms, and treatment options for dysmenorrhea. Validate the patient's pain and experience. Provide psychosocial support. Teach patients about lifestyle changes and nonpharmacologic options. Regular exercise and good nutrition to improve symptoms. Provide teaching about drug therapy. Follow-up on test results as appropriate. Develop a plan to evaluate the effectiveness of treatment and provide follow-up care.

ABNORMAL UTERINE BLEEDING

Abnormal uterine bleeding (AUB) is any uterine bleeding that is abnormal in quantity, duration, or timing. It is one of the most common gynecologic concerns. AUB can have significant negative effects on quality of life. AUB is defined as either acute or chronic. *Acute AUB* is an episode of uterine bleeding (in a non-pregnant woman of reproductive age) that requires immediate treatment. *Chronic AUB* is abnormal uterine bleeding that has been present for most of the past 6 months. The most common forms of AUB are heavy menstrual bleeding (menses that are heavy or prolonged), intermenstrual bleeding (bleeding between menses), and irregular bleeding (ovulatory dysfunction). Historically, several terms were used to describe AUB. These include dysfunctional uterine bleeding (DUB), menorrhagia, and metrorrhagia. Though their use is no longer recommended, you may still hear them used in some settings.

TABLE 58.7 Common Gynecologic Surgeries

Type of Surgical Procedure	Description
Dilation and Curettage (D&C)	Opening (dilation) of cervix and removal (scraping) of endometrial tissue
Endometrial Ablation	Destroys endometrial lining using heat, cold, or electrical energy
Hysterectomy	Removal of the uterus Several different types: • Vaginal: uterus is removed through an incision in the vagina • Abdominal: uterus is removed through an incision in the abdomen • Laparoscopic: uses a laparoscope and instrument inserted through abdominal incisions • Robotic-assisted laparoscopy: uses a surgical robot to manipulate surgical instruments
Hysteroscopy	Examination of uterine cavity using a hysteroscope (lighted, flexible viewing instrument), inserted through the cervix
Myomectomy	Removal of fibroids from the uterus, leaving the uterus in place
Oophorectomy	Removal of the ovary, can be unilateral or bilateral
Salpingectomy	Removal of the fallopian tube, can be unilateral or bilateral
Uterine artery embolization	Minimally invasive surgery to inject embolic agents into uterine arteries to block blood supply to uterine fibroids
Vaginectomy	Removal of vagina, may be partial or total
Vulvectomy	Removal of part or all the vulva

The absence of menses (*amenorrhea*) is also a common menstrual abnormality. We describe amenorrhea as primary or secondary. *Primary amenorrhea* refers to the failure of menstrual cycles to begin by 16 years of age. *Secondary amenorrhea* occurs when menstrual cycles stop for more than 3 months in women with previously regular menstrual cycles or more than 6 months in those with irregular menses.

Etiology and Pathophysiology

There are many different problems that cause AUB. The most common causes are outlined in the PALM-COEIN classification system for AUB (Fig. 58.3). PALM stands for common structural causes of bleeding: polyps, adenomyosis, leiomyoma, and malignancy or hyperplasia. The COEIN acronym represents common nonstructural causes: coagulopathy, ovulatory dysfunction, endometrial dysfunction, iatrogenic, and not otherwise classified. AUB may also be related to drug therapy such as hormonal contraception. Common causes of amenorrhea are listed in Table 58.8.

Clinical Manifestations

AUB is defined in contrast to normal menstruation. Bleeding that is outside the norms of frequency, duration, volume, and timing is classified as abnormal. For example, normal menstruation occurs every 24 to 38 days, lasts no more than 8 days, and has a blood loss that does not interfere with quality of life. Normal menstruation is discussed in Chapter 55.

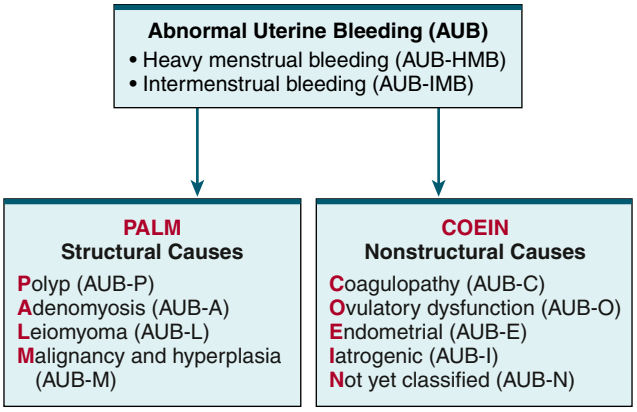

Fig. 58.3 PALM-COIEN classification system for abnormal uterine bleeding. (Used with permission from Munro MG, Critchley HO, Broder MS, et al.: FIGO classification system [PALM–OEIN] for causes of AUB in nongravid women of reproductive age, *Int J Gynecol Obstet* 11:3, 2011.)

TABLE 58.8 Common Causes of Amenorrhea

Anatomic
- Abnormality in müllerian development (e.g., absence of uterus)
- Imperforate hymen
- Intrauterine adhesions (e.g., Asherman syndrome)

Hormone
- Hypothalamic dysfunction
- Ovarian dysfunction (e.g., Turner syndrome)
- PCOS
- Pituitary problems (e.g., pituitary tumors)
- Thyroid problems

Other
- Drug therapy (e.g., hormonal contraceptives)
- Lifestyle (e.g., low body weight, stress, excessive exercise)
- Pregnancy, breastfeeding, menopause

Diagnostic Studies

Evaluation of AUB begins with the history, including detailed menstrual, sexual, gynecologic, and obstetric histories. Physical assessment should determine rule out other (non-uterine) potential sources of bleeding. For example, bleeding could be coming from another site in the urinary, GI, or genital tracts. Pelvic examination is useful to assess for any masses or structural problems. A pregnancy test is appropriate in sexually active patients to rule out pregnancy-related causes of bleeding. Depending on the suspected cause of AUB, laboratory tests to assess for hormone imbalances, coagulation problems, or thyroid problems may be done. HCPs may assess for STIs and anemia. A progesterone challenge test may be done. Other possible diagnostic studies include cervical cancer screening (Pap test), pelvic or transvaginal ultrasound, endometrial biopsy, and hysteroscopy or saline infusion sonohysterography (SIS).

Interprofessional Care

Treatment for AUB depends on the cause (Table 58.9).[8] Treatment goals may be to improve quality of life or prevent

TABLE 58.9 Interprofessional Care

Abnormal Uterine Bleeding

Diagnostic Assessment

- History
  - Detailed menstrual history
  - Bleeding patterns, perceived severity of bleeding (clots, soaking through clothing)
- Physical assessment
  - Inspection of the source of bleeding
  - Pelvic examination
  - Evaluation for obesity/hirsutism (suggestive of PCOS)
- Laboratory tests (as indicated)
  - Pregnancy test
  - CBC
  - Thyroid-stimulating hormone (TSH)
  - STI screening
  - Screening for bleeding disorders
  - Hormone levels (e.g., FSH, LH, prolactin, testosterone)
  - Liver and renal function tests
- Imaging studies and tissue sampling
  - Transvaginal/pelvic ultrasound
  - Saline infusion sonohysterography
  - Endometrial biopsy
  - Hysteroscopy

Management

Based on the cause, may include:

- Hormone therapy
- NSAIDS
- Tranexamic acid (Lysteda)
- Antibiotics
- Surgery
  - D&C
  - Endometrial ablation
  - Uterine artery embolization
  - Hysterectomy

further complications such as cancer and severe anemia. Future fertility goals are important in guiding the treatment plan. Care for *heavy menstrual bleeding (HMB)* focuses on medical or surgical treatments. Drug therapy for HMB includes hormone therapy such as OCPs, NSAIDs, and tranexamic acid (Lysteda). IUDs are another option for HMB. Another approach for HMB is surgical therapy such as D&C, endometrial ablation, uterine artery embolization, or hysterectomy (Table 58.7). There are also medical and surgical treatment options for intermenstrual or irregular bleeding. These options include hormone therapy, antibiotics for suspected infections, and polyp removal (polypectomy).

Nursing care focuses on patient teaching. Teach about the menstrual cycle and characteristics of normal bleeding to help patients identify variations (see Table 55.2). Encourage patients to report excessively heavy bleeding, passing of clots, or bleeding of extended duration. Nutrition teaching is appropriate, especially for adolescents and those at risk for anemia. Ensure that patients understand the cause of their bleeding and the various treatment options. Follow up to assess treatment effectiveness and improvement in symptoms and quality of life.

TABLE 58.10 Diagnostic Criteria

PCOS

A diagnosis of PCOS is made based on the presence of 2 of the 3 following:

1. Menstrual irregularity (infrequent menstruation or anovulation)
2. Signs of hyperandrogenism or elevated serum androgen levels
3. Polycystic ovaries on ultrasound

Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) is an endocrine disorder that affects menstruation and fertility. This syndrome is characterized by menstrual irregularity, ovulatory dysfunction, and hyperandrogenism. It is the most common cause of infertility. The cause of PCOS is not known. We think there are multiple etiologies, including complex genetic and environmental factors. The underlying pathophysiology includes excessive androgen production in the ovaries, often accompanied by insulin resistance. There are numerous long-term health consequences associated with PCOS. Patients with PCOS are at increased risk for diabetes, cardiovascular disease, mood disorders, and endometrial cancer.

Clinical Manifestations

Manifestations include signs of hyperandrogenism such as hirsutism and acne, irregular menstrual cycles, and obesity. Amenorrhea or oligomenorrhea and anovulation are common. Hyperandrogenism may present with acne, hirsutism, or male-pattern hair loss. Signs of insulin resistance, such as metabolic syndrome, may be present.

Diagnostic Studies

Table 58.10 outlines the diagnostic criteria for PCOS. A diagnosis of PCOS should be considered in a female of reproductive age based on the presence of classical manifestations of irregular menstrual cycles with signs of hyperandrogenism, as described above. Laboratory tests and pelvic imaging are not needed to make a diagnosis. However, testing may be useful to identify high androgen levels in the absence of symptoms. These diagnostic studies can also rule out other potential causes of symptoms such as pregnancy or non-classic congenital adrenal hyperplasia. Polycystic ovaries may be visible on ultrasound, although this is not required for diagnosis (Fig. 58.4).

Interprofessional Care

The approach to treating PCOS depends on the symptoms and desire for pregnancy. For overweight patients, weight loss is recommended. Weight loss results in improved ovulatory dysfunction. Hormonal contraceptives are often used to reduce symptoms of hyperandrogenism. Spironolactone (Aldactone), a diuretic, may be prescribed for its antiandrogenic effects. For patients with undesired infertility, an aromatase inhibitor, letrozole (Femara), can induce ovulation. Approaches to reducing hirsutism include cosmetic measures (e.g., waxing, electrolysis, laser hair removal) and topical therapies like depilatory agents or eflornithine hydrochloride (Vaniqa) cream. In some patients, insulin-lowering drugs such as metformin are given to treat PCOS. Resources such as the National PCOS Association's PCOS Challenge may be helpful to provide support and resources to patients with PCOS.[9]

DRUG ALERT

Spironolactone (Aldactone)

- Check for drug interactions.
- Monitor for hypotension and electrolyte imbalances.
- Discuss the importance of a low-potassium diet.

Fig. 58.4 PCOS. (From Kumar V, et al.: *Robbins and Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

MENOPAUSE

Menopause is the cessation of menstruation. *Natural menopause* is the permanent cessation of menstrual periods. It is diagnosed retrospectively after 12 months of amenorrhea without any other suspected cause. The age of natural menopause ranges from 40 to 58 years, with a median age of 52 years. The menopausal transition is known as **perimenopause**. Perimenopause often begins about 4 years before the *final menstrual period (FMP)* but can be much earlier or later. Menopause and perimenopausal symptoms are a major health focus for women during midlife. The Stages of Reproductive Aging Workshop (STRAW) +10 System describes reproductive aging in women (Fig. 58.5). Common menopause terminology is defined in Table 58.11.

Etiology and Pathophysiology

Natural menopause occurs in response to normal physiologic changes of aging in the hypothalamic-pituitary-ovarian axis. Fluctuations in hormone levels cause perimenopausal

Menarche — FMP (0)

Stage	−5	−4	−3b	−3a	−2	−1	+1a	+1b	+1c	+2
Terminology	Reproductive				Menopausal transition		Postmenopause			
	Early	Peak	Late		Early	Late	Early			Late
					Perimenopause					
Duration	*Variable*				*Variable*	1-3 years	2 years (1+1)		3-6 years	*Remaining lifespan*
Principal criteria										
Menstrual cycle	Variable to regular	Regular	Regular	Subtle changes in flow/ length	*Variable length* persistent ≥7-day difference in length of consecutive cycles	Interval of amenorrhea of ≥60 days

Descriptive characteristics										
Symptoms						Vasomotor symptoms *likely*	Vasomotor symptoms *most likely*			*Increasing* symptoms of urogenital atrophy

* Blood draw on cycle days 2–5. ↑ = elevated.

** Approximate expected level based on assays using current international pituitary standard.

Fig. 58.5 Stages of Reproductive Aging Workshop + 10 staging system for reproductive aging in women. (Source: Harlow SD, Gass M, Hall JE, et al.: Executive summary of the Stages of Reproductive Aging Workshop + 10: addressing the unfinished agenda of staging reproductive aging, *J Clin Endocrinol Metab* 2012. © 2012, The Endocrine Society.)

TABLE 58.11 Menopause Terminology

Term	Definition
Final menstrual period (FMP)	Last menstrual period; the point of menopause
Induced menopause	Menopause resulting from medical or surgical intervention
Menopause	A point in time 12 consecutive months after the FMP
Natural menopause	Menopause resulting from normal, spontaneous, physiologic changes
Perimenopause	Period of transition before menopause. Often lasts around 4 years. Associated with fluctuations in hormone levels
Postmenopause	Period of time after menopause. Characterized by symptoms associated with decreased estrogen and progesterone
Primary ovarian insufficiency	Temporary or permanent menopause at <40 years of age. May be called premature menopause

TABLE 58.12 Symptoms Associated With Perimenopause

Changes in menstrual bleeding patterns
Depression
Headache
Joint pain
↓ Libido
Memory loss
Poor concentration
Sexual dysfunction
Sleep problems
Urinary frequency/urgency
Vaginal dryness
Vasomotor symptoms (e.g., hot flashes)

symptoms. Menopause can also be induced. *Induced menopause* occurs after surgical intervention to remove the ovaries or due to side effects of chemotherapy, radiation therapy, or other drugs. *Primary ovarian insufficiency* is permanent or temporary menopause that occurs at less than 40 years of age. Causes include drugs, chromosomal abnormalities, or health problems such as endocrine or autoimmune disorders.

Clinical Manifestations

Perimenopause is characterized by erratic hormone fluctuations and irregular menstrual cycles. Common symptoms of perimenopause are outlined in Table 58.12. The experience of perimenopause varies widely. Many women have vasomotor changes such as hot flashes or hot flushes. These are often experienced as an intense heat sensation. They may be accompanied by profuse sweating. Sleep disruptions, mood changes, and decreased sexual function are common. Some find perimenopausal systems greatly disrupt their quality of life and well-being, while others may report no bothersome symptoms. In postmenopause, estrogen and progesterone deficiency increases the risk for cardiovascular disease, urogenital atrophy, bone mineral density loss, dementia, and various types of cancer.

Diagnostic Studies

Menopause is a retrospective diagnosis. It can only be made after 12 consecutive months of amenorrhea in the absence of other causes. A diagnosis of perimenopause is based on manifestations. We begin with the history, including menstrual and sexual histories and physical assessment. A symptom diary may be useful to aid diagnosis. Laboratory tests are not needed in women over age 45 with typical perimenopausal symptoms. Some HCP measure serum follicle-stimulating hormone (FSH). However, FSH varies widely throughout the menstrual cycle and is therefore not a reliable indicator of perimenopause. HCPs should assess for other potential causes of clinical manifestations such as pregnancy or thyroid disease. Further assessment is needed in women under 40 years of age or those with atypical symptoms. This may include laboratory assessment of hormone levels or diagnostic imaging such as pelvic ultrasound.

Interprofessional Care

Treatment options for menopausal symptoms include options to target specific symptoms and systemic effects. The North American Menopause Society (NAMS) has patient information, tools, and a mobile app to help patients and HCPs engage in patient-centered care around treatment decisions.[10]

Drug therapy centers on hormone therapy. Hormone therapy typically starts with estrogen. There are many different forms of estrogen, including oral pills, transdermal patches, intramuscular injection, transvaginal ring, and topical creams, lotions, and sprays. Patient preference and symptoms often inform which preparation they use. For patients with an intact uterus (e.g., have not had a hysterectomy), progesterone must be given with estrogen to prevent endometrial cancer from estrogen-related endometrial hyperplasia. Progesterone also comes in several different forms and combinations. These include various pills, patches, vaginal administrations (capsule, ring, cream, gel), and an IUD.

A patient-centered approach to treatment is important. We need to address the patient's needs and preferences against the potential risks from hormone therapy. Assess for contraindications to hormone therapy such as a history of breast cancer, coronary heart disease, stroke, thromboembolic disorders, or liver disease. Hormone therapy can greatly reduce bothersome symptoms and improve quality of life. However, this must be balanced against the potential for increased risk of breast and endometrial cancer and cardiovascular disease. For patients who are not candidates for hormone therapy or want alternatives, there are some nonhormone drug treatment options. These include antidepressants (SSRIs or SNRIs), gabapentin, and antihypertensives. Despite their widespread use, there is not a strong body of evidence to support the safety and efficacy of herbal or other complementary and alternative therapies for symptoms.

❖ NURSING MANAGEMENT: MENOPAUSE

Menopause is a time of great physical and psychologic transition. Many women have symptoms for years during the perimenopausal period, while others transition without any difficulty. Menopause may be occurring simultaneously with role

TABLE 58.13 Vaginal Infections Associated With Vaginitis

Infection	Manifestations	Treatment Options
Bacterial vaginosis (bacterial infection)	"Fishy" odor Gray or white vaginal discharge	Oral or vaginal antibiotics • clindamycin (Cleocin) • metronidazole (Flagyl) • tinidazole (Tindamax)
Trichomonas vaginalis (protozoan infection)	Genital itching and inflammation Dysuria Frothy, thin, yellowish-greenish vaginal discharge Deep red or pink cervix and vagina ("strawberry cervix")	Antifungal agents • metronidazole (Flagyl) • tinidazole (Tindamax) Treatment of partner(s)
Vulvovaginal candidiasis (yeast infection)	Vaginal itching Red, swollen vulva Thick, white, curdy vaginal discharge	Oral or vaginal antifungals • butoconazole (Gynazole) • clotrimazole (Gyne-Lotrimin) • fluconazole (Diflucan) • miconazole (Monistat)

changes in personal and professional life. Many patients will not seek treatment for common menopausal symptoms such as hot flashes, sleep disturbances, and mood changes. Asking patients about midlife health issues, including menopausal symptoms during routine health encounters, can help identify concerns.

Teach patients about menopause and common symptoms. Provide support for physical, psychological, and emotional effects of menopause. Discuss lifestyle changes that can improve symptoms and quality of life. These include diet changes, exercise, clothing selection, and sleep hygiene. Support stress reduction and management strategies. Encourage smoking cessation. Recommend increased water intake to reduce dryness and hot flashes. Suggest wearing breathable or moisture-wicking fabrics and layered clothing to improve comfort during hot flashes. Suggest environmental changes such as room temperature, use of fans, or special cooling bedding.

Review the risks, benefits, and alternatives of various treatment options. Other therapies include vaginal lubricants and moisturizers and the intake of soy isoflavones through diet or supplements. Ensure patients are getting adequate intake or supplementation of calcium and vitamin D to reduce risk of bone fractures (see Table 68.16). Encourage health promotion measures such as depression screening, bone density screening, mammography, and ways to reduce risk of cardiovascular disease.

LOWER GENITAL TRACT INFECTIONS

Lower genital tract infections include infections resulting from a disruption in the vaginal microbiome and STIs. The *vaginal microbiome* contains microorganisms like yeast and healthy bacteria that protect against infection by maintaining an acidic environment. Inflammation of the vagina, known as *vaginitis*, can occur from a disruption of the vaginal flora. Vaginal infections associated with vaginitis are shown in Table 58.13. STIs are discussed in Chapter 57. If not treated, lower genital tract infections can lead to long-term health problems.

Etiology and Pathophysiology

Many problems can cause vaginitis. Common problems associated with vaginitis are bacterial vaginosis, vulvovaginal candidiasis, and STIs such as trichomoniasis. Exposure to irritating substances and foreign bodies (such as tampons or condoms) left in the vagina can disrupt the vaginal microbiome and cause lower genital infections.

Bacterial vaginosis is characterized by a disruption in the microbiota shifting away from healthy *Lactobacillus* species towards other organisms such as anaerobic bacteria leading to a rise in vaginal pH. Bacterial vaginosis can be transmitted by sexual activity, especially receptive oral sex. Having other STIs, vaginal douching, and smoking are also risk factors for bacterial vaginosis.

The second most common cause of vaginitis symptoms is vulvovaginal candidiasis. *Vulvovaginal candidiasis* is caused by an overgrowth of *Candida*, a naturally occurring part of the vaginal flora. The cause of the disruption of normal vaginal flora is not always known. Certain drugs (e.g., broad-spectrum antibiotics), behaviors (e.g., vaginal douching), and chronic problems (e.g., diabetes) increase the risk of vulvovaginal candidiasis.

STIs such as *trichomoniasis*, a protozoan infection, can also cause vaginitis. STIs are passed from person to person through sexual contact. They are caused by bacteria, viruses, or parasites. They are transmitted through bodily fluids such as blood, semen, and vaginal fluids. High-risk sexual behaviors such as having multiple sex partners increase the risk for STIs. The most common STIs are chlamydia, trichomoniasis, genital herpes, and human papillomavirus (HPV). Common STIs are listed in Table 58.14 and discussed in Chapter 57.

Clinical Manifestations

The manifestations depend on the type of infection. Many persons are asymptomatic. Others will have specific symptoms such as skin or mucosal lesions, cervical inflammation or tenderness, or enlarged lymph nodes. Vaginal discharge that is abnormal in color, quantity, odor, or consistency is a common symptom. For example, a "fishy" odor is a common symptom of bacterial vaginosis. Discharge that is thick, white, and curdy is characteristic of vulvovaginal candidiasis. Many patients have itching, burning, or irritation. Pain during intercourse or urination is common.

TABLE 58.14 Common STIs

Bacterial vaginosis
Chancroid
Chlamydia
Gonorrhea
Hepatitis
Herpes simplex virus
Human immunodeficiency virus (HIV)
Human papillomavirus (HPV)
Pelvic inflammatory disease (PID)
Pubic lice or crabs
Scabies
Syphilis
Trichomoniasis
Zika virus

❖ Interprofessional and Nursing Management

Assessment for lower genital infections starts with the history, including a sexual history. Routine screening for vaginitis infections is not recommended in asymptomatic persons. For patients with lower genital tract infection symptoms, the physical assessment should include pelvic and speculum examination. Evaluating vaginal secretions by pH testing, microscopic examination, culture, and/or other laboratory tests aid in diagnosis. Treatment options depend on the type of infection (Table 58.13). Options include topical and oral therapies. Screening and treatment for STIs are discussed in Chapter 57. A follow-up visit is often recommended to evaluate treatment effectiveness and teach sexual health and contraception.

Teach patients about behavior and lifestyle measures to reduce the risk for infection. This includes keeping the vulvar area dry and avoiding products like harsh laundry detergents, scented menstrual products, or spermicides that can cause irritation. Discuss how to clean the vulva and vagina to reduce infections by using only gentle and unscented soaps to clean externally and avoiding douching. Review sexual practices to prevent infections, such as inserting only clean objects (like washed hands or sex toys) into the vagina and using water or silicone-based lubricants. Smoking cessation and nutrition teaching may help minimize the risk of infection.

Review symptoms that indicate a problem and help women seek care promptly. Discussing problems that concern the patient's genitalia or sexual intercourse is often hard. Use a nonjudgmental attitude to make women feel more comfortable while empowering them to ask questions.

When a woman is diagnosed with a genital infection, ensure that she fully understands the treatment. Provide information about comfort measures to improve symptoms. If she is using a vaginal medication for the first time, show her the applicator and how to fill it. Teach where and how the applicator should be inserted using visual aids or models. Vaginal creams should be inserted before going to bed so the drug will remain in the vagina for a long period.

Fig. 58.6 Pelvic inflammatory disease (PID). (From Kumar V, et al.: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders.)

PELVIC INFLAMMATORY DISEASE

Pelvic inflammatory disease (PID) is a clinical syndrome that includes a spectrum of infectious and inflammatory diseases of the upper genital tract. Ascending organisms cause inflammation in the endometrium, fallopian tubes, ovaries, and pelvic peritoneum (Fig. 58.6). There are about 1 million cases of PID each year in the United States. PID is most common among sexually active young women.

Etiology and Pathophysiology

PID is caused by an infectious organism ascending from the vagina or upper urogenital tract. Untreated sexually transmitted *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are common causes of PID, as are microbes associated with bacterial vaginosis. Organisms can ascend past the endocervical barrier through normal processes like menstruation or gynecologic procedures (e.g., IUD insertion). Other risk factors include high-risk sexual behaviors, young age, vaginal douching, recent cervical manipulation, and history of PID.

Clinical Manifestations

The classic presentation of acute PID is pelvic or lower abdominal pain with tenderness in the cervix, uterus, or adnexa. Pain varies from mild to severe. The pain often occurs with intercourse and urination. Movement, such as walking, can increase the pain. Spotting after intercourse and purulent cervical or vaginal discharge may occur. Fever and chills may be present.

Complications

If not diagnosed and treated promptly, PID can cause serious complications. These include infertility, ectopic pregnancy, chronic pelvic pain, or tubo-ovarian abscess (TOA). These complications result from scarring, adhesions, or obstruction of the fallopian tubes. TOA or perihepatitis (Fitz-Hugh Curtis Syndrome) are potential immediate and serious risks of untreated PID.

Interprofessional Care

A health and sexual history and physical assessment are important to explore the presenting symptoms and rule out other causes of abdominal or pelvic pain. Physical assessment will

include abdominal, pelvic, and speculum examinations. While no laboratory tests are needed to begin treatment, microscopic examination of vaginal discharge and testing for gonorrhea and chlamydia can support the diagnosis. Testing for other STIs such as HIV is recommended. A pregnancy test is done to rule out a possible ectopic pregnancy. Ultrasound, endometrial biopsy, or laparoscopy may be useful to rule out other potential complications. Some HCPs may order blood tests, such as a complete blood count (CBC), erythrocyte sedimentation rate, or C-reactive protein.

❖ Interprofessional and Nursing Management

Treatment is started promptly, often based on the presentation, without waiting for laboratory results. PID is usually treated on an outpatient basis with a combination of broad-spectrum antibiotics (see Table 15.8). Antibiotic regimens recommended by the Centers for Disease Control and Prevention (CDC) are outlined in Chapter 57. Symptoms should improve within 72 hours of starting treatment. Hospitalization may be needed for patients with suspected PID who do not respond within 48 to 72 hours. Patients who are pregnant or present with severe symptoms such as high fever or nausea and vomiting may be hospitalized. In those instances, IV antibiotics, further tests, or surgery may be needed. Recent sexual partners should be treated presumptively for gonorrhea and chlamydia.

Prevention, early recognition, and prompt treatment can prevent PID and associated complications. Subjective and objective data that you should obtain from the patient with PID are outlined in Table 58.15. For hospitalized patients, you have a key role in implementing drug therapy and monitoring the patient's health status. Record vital signs. Note the character, amount, color, and odor of any vaginal discharge. Assess patient's pain and provide analgesics and supportive measures to decrease pain.

Teaching about PID is important. Provide anticipatory guidance about symptom improvement. Teach patients the importance of completing the prescribed therapy. Advise them to abstain from sexual intercourse until treatment is completed and sexual partners have been treated. Provide teaching about sexual practices and health screening to reduce transmission of STIs in the future.

TABLE 58.15 NURSING ASSESSMENT

PID

Subjective Data

Important Health Information

Health history: Previous STIs or PID. Recent IUD insertion, termination of pregnancy, or gynecologic procedure.

Sexual history: Age of first sexual encounter. Number and sex of sexual partners. Exposure to partner with STIs. Types of sexual activities. Use of condoms and other preventative measures for STIs.

Medications: Hormone agents, including contraception.

Allergies: Allergies to antibiotics or other drugs.

Functional Health Patterns

Health perception–health management: Malaise

Nutritional-metabolic: Nausea, vomiting; chills, fever

Elimination: Urinary frequency, urgency

Cognitive-perceptual: Lower abdominal pain, pelvic pain, low back pain, onset of pain just after a menstrual cycle; dyspareunia, dysuria, vulvar pruritus

Sexuality-reproductive: Abnormal vaginal discharge, unscheduled vaginal bleeding

Objective Data

Reproductive

Mucopurulent cervicitis, vulvar maceration, vaginal discharge (heavy and purulent to thin and mucoid), cervical motion tenderness, uterine or adnexal tenderness. Inflammatory masses on palpation

Possible Diagnostic Findings

White blood cells on wet mount (saline microscopy of vaginal fluid), ↑ erythrocyte sedimentation rate, laboratory confirmation of gonorrheal or chlamydial infection, abscess or inflammation on ultrasonography

BENIGN GYNECOLOGIC PROBLEMS

Many different benign problems affect the female reproductive organs. While they are benign in that they are not life-threatening or cancerous, they can still significantly impact quality of life. Problems that affect the skin, such as vulvar dermatoses, are discussed in Chapter 55. This section focuses on those benign conditions affecting the cervix, uterus, or adnexa.

Some patients with these conditions present with symptoms such as bleeding or pain. Others have no symptoms. They are diagnosed based on findings from a physical assessment or other procedure. Assessment includes a detailed health and sexual history and physical assessment with pelvic and speculum examinations. Diagnostic imaging is often helpful. For many of these conditions, no treatment is necessary. In those instances, care centers on confirming the diagnosis of the benign condition, providing teaching and reassurance, and recommending supportive measures to reduce any bothersome symptoms. In other cases, medical or surgical treatments may improve patients' quality of life.

Cervical Problems

The cervix may have benign growth or lesions such as cervical ectropion, cysts, or polyps. These may be seen with a speculum examination (Fig. 58.7). *Cervical ectropion* occurs when the cervix becomes slightly everted, exposing underlying cells which may be more sensitive or prone to bleeding. This condition is not due to underlying pathology. It is common in adolescents and pregnancy.

Nabothian cysts (mucus or epithelial inclusion cysts) are another common finding on speculum examination. They are caused by mucus-producing cells being covered by epithelial cellular growth. Nabothian cysts do not usually cause symptoms or require treatment. They may resolve spontaneously.

Cervical polyps are another benign growth that may be found during routine speculum examination. Polyps are usually red or purple and small, measuring less than 3 cm in length. Their cause is not known. We believe hormone factors play a role. Polyps may be removed if they are large or cause complications, such as bleeding after intercourse.

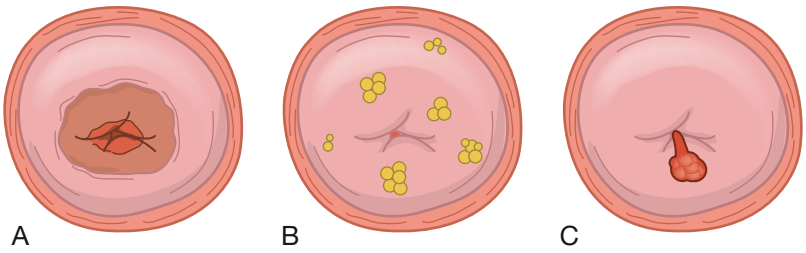

Fig. 58.7 Benign cervical lesions: (A) cervical ectropion. (B) Nabothian cyst. (C) Cervical polyp.

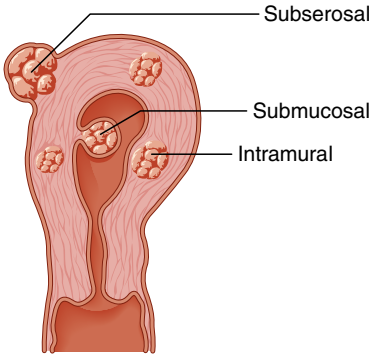

Fig. 58.8 Uterine fibroids. (From McCance KL, Huether SE: *Pathophysiology: the biologic basis for disease in adults and children*, ed 6, St. Louis, 2010, Mosby.)

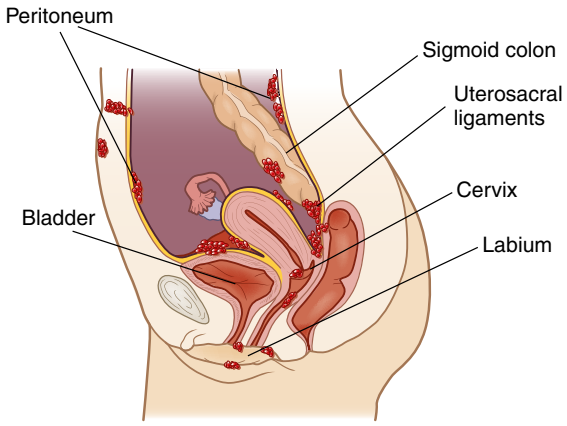

Fig. 58.9 Common sites of endometriosis.

Uterine Problems

The most common benign uterine problems are uterine fibroids, endometriosis, and adenomyosis. Uterine **fibroids** (or leiomyomas, myomas) are non-cancerous smooth-muscle tumors. They appear most often in women of reproductive age. We think they are caused by hormone and genetic factors. We classify fibroids based on their location in the uterus. The most common types are subserosal, intermural, or submucosal (Fig. 58.8).

Many patients with fibroids have no symptoms. Others will have pelvic pain, AUB, or infertility. On physical assessment, the uterus may be enlarged or irregularly shaped. Pelvic ultrasound is used to confirm the diagnosis. The approach to treatment depends on the patient's age, severity of symptoms, and desire for pregnancy. Expectant management may be appropriate since most fibroids reduce in size after menopause. Drug therapy, such as hormonal contraception or gonadotropin-releasing hormone (GnRH) agonists, can reduce HMB and pain. Surgical interventions such as removal of uterine fibroids (myomectomy), hysterectomy, or uterine artery embolization may be used for severe symptoms impacting quality of life or fertility.

Endometriosis is a benign inflammatory condition in which endometrial tissue accumulates outside the endometrium of the uterus.[11] The most frequent sites for endometriosis are in or near the ovaries, uterosacral ligaments, and uterovesical peritoneum (Fig. 58.9). We think endometriosis is caused by a combination of hormone, genetic, and immune factors. Retrograde menstruation (menstrual blood and endometrial tissue flow backward into the pelvis during menses) may be a factor.

Endometriosis may be suspected based on manifestations of infertility, HMB, and pain. Pain may be chronic or occur during menses, intercourse, urination, or defecation. Tenderness or nodules in the pelvic region may be noted on physical assessment. Some patients may not have any symptoms but are diagnosed with endometriosis during fertility treatment or gynecologic surgery. Laparoscopy with biopsy is needed for a definitive diagnosis. Imaging such as ultrasound and MRI may be used to aid in the diagnosis.

Management includes both medical and surgical approaches. The treatment depends on the patient's age, desire for pregnancy, severity of symptoms, and extent and location of the disease. Drug therapy is used to relieve pain, reduce inflammation, and suppress endometrial tissue growth. Common agents include NSAIDs, hormonal contraceptives, aromatase inhibitors, and GnRH analogs (such as leuprolide [Lupron]).

The only cure for endometriosis is surgical removal of all endometrial tissue and adhesions. For women with infertility or who desire pregnancy, efforts are made to restore pelvic anatomy to allow the ovaries and fallopian tubes to work better. Therapy may involve removing implants blocking the fallopian tube. Adhesions are removed from the tubes, ovaries, and pelvic structures.

DRUG ALERT

Leuprolide (Lupron)

- Assess for pregnancy before starting therapy.
- Monitor for dysrhythmias, palpitations.
- Teach patient to use nonhormonal contraceptive measures during therapy.

Adenomyosis is the benign growth of endometrial tissue in the myometrium of the uterus. It is most common in middle-aged women. We do not know the cause. We describe

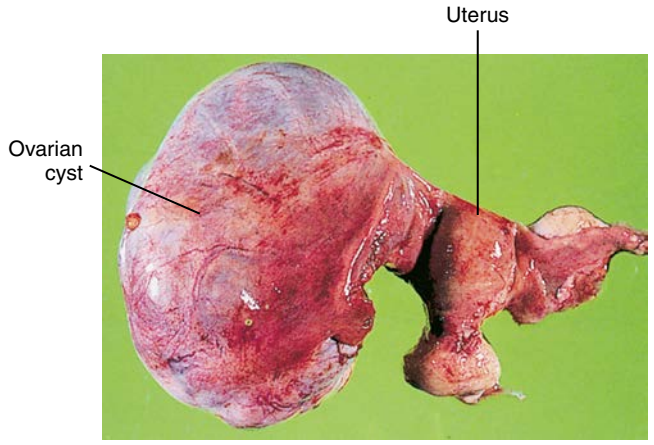

Fig. 58.10 Large ovarian cyst. (From Symonds EM, McPherson MBA: *Colour atlas of obstetrics and gynecology*, London, 1994, Mosby.)

adenomyosis as either diffuse or focal. In *diffuse adenomyosis*, endometrial tissue is found throughout the myometrial layer of the uterus. *Focal adenomyosis* consists of nodular lesions (called adenomyomas) confined to specific areas of the myometrium. The growth of endometrial tissue causes uterine enlargement and can lead to painful and heavy menstruation, pain during intercourse, or chronic pelvic pain. Diagnosis is made through pelvic ultrasound or MRI. Adenomyosis is often treated with hysterectomy. Uterine artery embolization or ablation can improve symptoms in some patients. Hormonal contraceptives and GnRH agonists are options for patients who prefer nonsurgical approaches.

Adnexal Masses

Adnexal masses are those found in the ovary, fallopian tube, or connective tissue. There are many different causes of adnexal masses. HCPs need to consider and assess for serious conditions such as ectopic pregnancy, TOA, or cancer. The most common benign adnexal masses are ovarian cysts and benign tumors.

Follicular or *corpus luteal cysts* are associated with normal, physiologic ovarian function (see Chapter 55). Occasionally, these cysts may become enlarged or painful (Fig. 58.10). Diagnosis is made by ultrasound or MRI. Cysts usually resolve spontaneously. In rare instances, complications such as rupture or torsion (being severely twisted) may cause pain and bleeding requiring surgical treatment.

Adnexal masses can also be caused by benign tumors, such as dermoid cysts or endometriomas. A dermoid cyst (teratoma) is an ovarian germ cell tumor. Patients with teratomas are often asymptomatic. The cysts may be identified incidentally on pelvic examination or imaging. Surgical removal of the cyst (cystectomy) is recommended since they may become cancerous. Endometriomas are a type of benign mass resulting from growth of endometrial tissue in the adnexal region. They are considered a form of endometriosis.

Pelvic Organ Prolapse

Pelvic organ prolapse is a common, benign condition in which the pelvic organs herniate to or beyond the vaginal walls. Types of prolapse include *cystocele* or urethrocele (prolapse of the bladder) (Fig. 58.11), *rectocele* or enterocele (bulging of the rectum in the vagina) (Fig. 58.12), and *uterine prolapse* (descent of the uterus into the vaginal canal). We describe uterine prolapse by degrees (Fig. 58.13). In first-degree prolapse, the cervix rests in the lower part of the vagina. Second-degree prolapse means the cervix is at the vaginal opening. Third-degree prolapse means the uterus protrudes through the introitus.

The cause of pelvic organ prolapse is pelvic floor dysfunction from weak pelvic floor muscles or connective tissue. Patients may have physiologic pelvic organ prolapse as they age. Other

risk factors include having multiple pregnancies, history of vaginal births, obesity, connective tissue disorders, and chronic constipation.[12]

Some patients with pelvic organ prolapse have no symptoms. For others, this condition can be very uncomfortable and limit their quality of life and daily functioning. Pelvic pressure or bulging is a common concern. Other manifestations are difficulty with urination and defecation, decreased sexual function, and backache.

Evaluation starts with the history and physical assessment, including abdominal and pelvic examination. The assessment includes evaluation of pelvic floor function. The Pelvic Organ Prolapse Quantification (POP-Q) tool from the American Urogynecologic Society is used to assess and grade the stage of prolapse.[13]

A patient-centered approach is important to identify the severity and impact of symptoms and goals for treatment. Treatment is often unnecessary in the absence of bothersome symptoms such as pelvic pain/pressure, sexual dysfunction, or bowel or bladder dysfunction. In those cases, patient teaching and reassurance are appropriate. Lifestyle changes such as weight loss, managing constipation, and eliminating heavy lifting can improve minor symptoms. Nonsurgical interventions include pelvic floor physical therapy (see Table 50.18) or vaginal pessaries (a silicone supportive device inserted into the vagina, similar to a diaphragm). When these interventions are ineffective or symptoms are severe, surgery may be needed. Surgical options include hysterectomy, suspension of prolapsed organs, and repair of vaginal walls.

FISTULA

A *fistula* is an abnormal opening between internal organs or between an organ and the exterior of the body. Gynecologic procedures cause most urinary tract fistulas. Other causes include injury during childbirth and disease processes such as cancer. Fistulas may develop between the vagina and bladder, urethra, ureter, or rectum. When *vesicovaginal* fistulas (between the bladder and vagina) develop, some urine leaks into the vagina. With *rectovaginal* fistulas (between the rectum and vagina), flatus and feces escape into the vagina. In both instances, excoriation and irritation of the vaginal and vulvar tissues occur and may lead to severe infections. In addition to wetness, offensive odors may develop, causing embarrassment and limiting socialization.

❖ Interprofessional and Nursing Management

Because small fistulas may heal spontaneously within a matter of months, treatment may not be needed. If the fistula does not heal, surgical repair is needed. The fistulectomy may result in the patient having an ileal conduit or temporary colostomy. Surgical repair is not always effective, even in the best conditions.

After surgery, emphasize ways to avoid stress on the repaired areas and prevent infection. Ensure the indwelling catheter, usually in place for 7 to 10 days, is patent. Encourage the patient to maintain an adequate fluid intake to provide for internal catheter irrigation. Change perineal pads often. Give stool softeners or mild laxatives as ordered. Our encouragement and reassurance help the patient cope.

FEMALE REPRODUCTIVE SYSTEM CANCERS

There are 5 main types of gynecologic cancer: cervical, ovarian, uterine, vaginal, and vulvar.[14] Combined, these cancers affect around 100,000 patients each year in the United States. While they are relatively rare compared to other forms of cancer, it is important to understand screening and diagnosis of gynecologic cancers. Signs and symptoms of gynecologic cancers are shown in Table 58.16. When cancer is present, patients are referred to gynecologic oncologists. Depending on the extent of the cancer, treatment options include surgery, chemotherapy, or radiation (see Chapter 16).

CERVICAL CANCER

Historically, cervical cancer was a common cause of cancer-related death. However, as cervical cancer screening and prevention measures have become widespread, the mortality rate from cervical cancer has significantly declined. One of the key measures in preventing cervical cancer is vaccination for high-risk strains of HPV, the leading cause of cervical cancer (see Chapter 57).

Cervical cancer is the only gynecologic cancer with a reliable screening approach. There is a 2-fold approach to screening for cervical cancer: (1) testing for the virus that causes most cervical cancer (HPV) and (2) screening for cellular changes to the

TABLE 58.17 Cervical Cancer Screening

Age	Recommendation
<21 years	No screening
21–29 years	Cervical cytology (Pap test) every 3 years
25-29 years	Human papillomavirus (HPV) testing alone may be an option, but Pap tests are preferred
30–65 years	3 options for screening: • Pap test every 3 years • HPV testing every 5 years • Co-testing (Pap test and HPV) every 5 years
>65 years	No screening after adequate negative prior screening results

Adapted from PDQ® Screening and Prevention Editorial Board: *PDQ cervical cancer screening*, Bethesda, MD, National Cancer Institute. Available at https://www.cancer.gov/types/cervical/patient/cervical-screening-pdq.

Fig. 58.14 Cervical cancer. (From Drake RL, et al.: *Gray's anatomy for students*, ed 2, Edinburgh, 2010, Churchill Livingstone.)

cervix (Pap test). The *Pap test* (also called Papanicolaou test or Pap smear) is a method of screening for precancerous or cancerous cervical lesions. The specimen is obtained through speculum examination and an endocervical sampler (e.g., spatula, brush). Testing for high-risk HPV infections (that cause these cervical cellular changes) can be done using the same technique. Cervical cancer screening options include either cytology (Pap test alone), primary HPV testing (HPV alone), or co-testing (both cytology and HPV testing).

There are different screening recommendations (Table 58.17). The US Preventive Services Task Force (USPSTF) supports screening all women between the ages of 21 to 29 years who have a cervix with cytology every 3 years. Between the ages 30 and 65, they recommend either screening every 3 years with cytology or every 5 years with either primary HPV testing or cotesting.[15] The American Cancer Society takes a slightly different approach.[16] These guidelines support screening in low-risk women with a cervix starting at 25 years of age. From ages 25 to 65, they recommend primary HPV testing every 5 years. If this option is not available, then cotesting every 5 years or cytology every 3 years are acceptable options. This approach maximizes outcomes and reduces unnecessary procedures in younger patients, in whom HPV often resolves spontaneously. Those at increased risk for cervical cancer due to immunosuppression, HIV infection, or in utero exposure to diethylstilbestrol (DES) may be screened more often.

Early cervical cancer often has no symptoms. An unusual discharge, AUB, or postcoital bleeding eventually occurs. The discharge is usually thin and watery but becomes dark and foul smelling as the disease advances. Vaginal bleeding first presents as spotting. As the tumor enlarges, bleeding becomes heavier and more frequent. Pain is a late symptom. It is followed by weight loss, anemia, and cachexia.

Management of abnormal findings should follow the American Society of Colposcopy and Cervical Pathology (ASCCP) guidelines.[17] The ASCCP has both an online and mobile app to guide HCPs in screening and management recommendations. The primary diagnostic method is colposcopy. *Colposcopy* is an outpatient procedure where the HCP examines the cervix using a magnification device (colposcope) after applying an acetic acid solution (Fig. 58.14). When abnormalities are seen on colposcopy, a biopsy may be done. Cryotherapy, loop electrosurgical excision procedure (LEEP), laser therapy, or cone biopsy can remove abnormal cells and prevent progression to cervical cancer. Treatment depends on the stage of the cancer and if fertility is a concern. The main treatment for early cancer is surgery or radiation therapy (Table 58.7). Care for more advanced cancer can include a combination of surgery, chemotherapy, and radiation.

OVARIAN CANCER

Ovarian cancer is the 5th leading cause of cancer death in women. Each year in the United States, around 21,000 women are diagnosed with ovarian cancer, and about 14,000 die. Ovarian cancer often affects pstmenopausal women. Risk factors include a personal or family history of cancer, genetic predisposition (Box 58.1), family history of Lynch syndrome (hereditary nonpolyposis colorectal cancer [HNPCC]), endometriosis, nulliparity (never having given birth), and infertility. Women who have given birth, breastfed, or used hormonal contraceptive pills for 5 or more years have a reduced risk of ovarian cancer. These factors may have a protective effect because they reduce the number of ovulatory cycles over the lifetime.

There are 3 major types of ovarian cancer. About 90% of ovarian cancers are epithelial cancers that arise from surface epithelial cells. Germ cell tumors account for another 3%, and sex cord stromal, 2%. Histologic grading is important to determine the prognosis. Intraperitoneal dissemination is common in ovarian cancer. It metastasizes to the uterus, bladder, bowel, and omentum. In advanced disease, it can spread to the stomach, colon, liver, and other parts of the body.

Early ovarian cancer usually has no obvious symptoms. There may be nonspecific symptoms such as pelvic or abdominal pain, bloating, urinary urgency or frequency, and difficulty eating or feeling full quickly. In later stages, abdominal enlargement with ascites (fluid in the abdominal cavity), unexplained weight loss or gain, nausea, and abnormal vaginal discharge or bleeding may occur. Adnexal mass or lymphadenopathy may be present on physical exam. A mass may also be identified on pelvic imaging such as ultrasound or MRI. No accurate screening test exists for early detection of ovarian cancer. For those

BOX 58.1 GENETICS IN CLINICAL PRACTICE

Ovarian Cancer and BRCA Genetic Mutations

Genetic Basis

- Normally these genes are tumor suppressor genes involved in DNA repair
- Transmission is autosomal dominant
- Mutations are passed down from either mother or father

Incidence

- About 15% of cases of ovarian cancer are related to *BRCA1* and *BRCA2* mutations.
- Women with *BRCA1* mutations have a 40% lifetime risk for developing ovarian cancer.
- Women with *BRCA2* mutations have a 15% lifetime risk for developing ovarian cancer.
- Family history of both breast and ovarian cancer increases the risk of having a BRCA mutation.

Genetic Testing

- DNA testing is available for *BRCA1/2* genetic mutations.
- All patients with ovarian cancer should be offered testing for *BRCA1/2* mutations.

Clinical Implications

- Genetic counseling and testing for *BRCA* mutations should be offered to those with a personal or family history that puts them at increased risk for ovarian cancer.
- Bilateral salpingectomy-oophorectomy reduces the risk for ovarian cancer in women with *BRCA1/2* mutations.

at increased risk, screening may include serum tumor marker CA-125 and pelvic ultrasound.

The CA-125 test is positive in 80% of women with advanced ovarian cancer. CA-125 is also used to monitor the course of the disease and response to treatment. The problem is that CA-125 levels can be high with other cancers (e.g., pancreatic cancer) or with benign gynecologic problems, including fibroids and endometriosis.

Options for high-risk women based on family and health history include prophylactic removal of the ovaries and fallopian tubes and the use of OCPs. While salpingo-oophorectomy significantly reduces the risk for ovarian cancer, it does not completely eliminate the risk for cancer in the peritoneum.

The initial treatment for all stages of ovarian cancer is a total abdominal hysterectomy and bilateral salpingo-oophorectomy (TAH-BSO) with removal of as much of the tumor as possible (e.g., tumor debulking). Depending on the grade and stage of cancer, treatment options include intraperitoneal and systemic chemotherapy, intraperitoneal instillation of radioisotopes, and external abdominal and pelvic radiation therapy. Combination chemotherapy and radiation therapy should be considered before a single-modality treatment.

The most used chemotherapy agents are taxanes (paclitaxel, docetaxel) and platinums (carboplatin, cisplatin). Among the targeted therapies used to treat advanced ovarian cancer are bevacizumab (Avastin), rucaparib (Rubraca), and olaparib (Lynparza). Rucaparib and olaparib are PARP inhibitors. They block enzymes involved in repairing damaged DNA. They are used for women with cancer associated with defective *BRCA* genes.

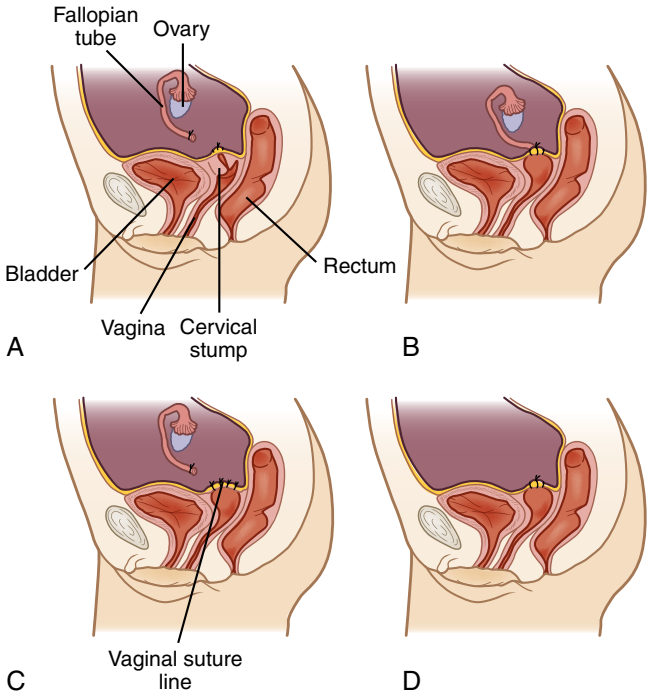

Fig. 58.15 Hysterectomies. (A) Subtotal hysterectomy. Cervical stump, fallopian tubes, and ovaries remain. (B) Total hysterectomy. Fallopian tubes and ovaries remain. (C) Vaginal hysterectomy. Fallopian tubes and ovaries remain. (D) Total hysterectomy, salpingectomy, and oophorectomy. Uterus, fallopian tubes, and ovaries are removed.

UTERINE CANCER

Uterine cancer is the most common gynecologic cancer in high-income countries. It is 2nd globally after cervical cancer. Cancer of the endometrium (lining of the uterus) is the most common site and type of uterine cancer. Other types of uterine cancer are rare, such as gestational trophoblastic tumors (hydatidiform mole) and uterine sarcoma. Endometrial cancer affects 1% to 2% of women in the United States, mainly those over 50.

The major risk factor for endometrial cancer is exposure to estrogen, especially unopposed estrogen therapy (without progesterone). Obesity is a risk factor because of increased estrogen in adipose tissue. Other risk factors include family history of cancer or Lynch syndrome, infertility, and use of tamoxifen. Protective factors include taking OCPs, breastfeeding, increased number of pregnancies, and physical activity.

AUB (especially postmenopause) is the classic sign of endometrial cancer. Other exam findings are often normal. Late symptoms can include dysuria, dyspareunia, unintentional weight loss, and pelvic pain. A thickened endometrium may be seen on ultrasound.

There is no routine screening test for uterine cancer. Diagnosis of endometrial cancer is based on tissue sampling, usually obtained by endometrial biopsy. Alternatively, HCPs may obtain a specimen using curettage or following hysterectomy. Most patients with endometrial cancer have a good prognosis due to early diagnosis. Surgery (total hysterectomy and bilateral salpingo-oophorectomy) is the main treatment for uterine cancer (Table 58.7). It is often curative (Fig. 58.15). For

complex cases, chemotherapy, radiation, or hormone therapy are part of the treatment plan.

VAGINAL AND VULVAR CANCER

Cancers of the vagina and vulva are rare, comprising 6% to 7% of all gynecologic cancers in the United States. Both are associated with HPV infection. Most are squamous cell cancers. Melanoma, sarcoma, basal cell, and adenocarcinoma are less common. Primary vaginal cancer is rare. More often, vaginal cancer results from metastasis from another gynecologic cancer.

These cancers often affect postmenopausal women. Risk factors include smoking, multiple sex partners, immunodeficiency (e.g., HIV), chronic vulvar itching/burning, and having other gynecologic cancers. Having vulvar lichen sclerosus is a risk factor for vulvar cancer.

Manifestations include abnormal vaginal discharge or bleeding, frequent urination, hematuria, feeling constipated, change in bowel habits, and pelvic pain. Assessment includes bimanual, speculum, and rectovaginal examinations. A vaginal mass and enlarged inguinal lymph nodes may be present. Vulvar cancer presents with vulvar skin changes such as redness and lesions. Vulvar itching or burning, dysuria, dyspareunia, and pelvic pain may be present. Diagnostic evaluation often includes cytology, colposcopy, and biopsy. Treatment depends on the location, size, and stage of the cancer. Options include surgery, radiation, and/or chemotherapy.

❖ NURSING MANAGEMENT: FEMALE REPRODUCTIVE SYSTEM CANCERS

The overall goals of nursing care are that the patient will (1) take part in treatment decisions, (2) achieve satisfactory pain and symptom management, (3) recognize and report complications, (4) maintain quality of life, and (5) practice cancer detection. Key concerns for the patient with gynecologic cancer include pain, disturbed body image, and impaired sexual functioning.

Health promotion is an important aspect of nursing care. Teach patients about the importance of HPV vaccination and cervical cancer screening. HPV vaccination can reduce the risk of vaginal and vulvar cancers. Teach about risk factors for cancers of the reproductive system. When high-risk behaviors are identified, help patients change their lifestyles to decrease risk.

◆ Acute Intervention Related to Surgery

Types of surgery of the female reproductive tract are described in Table 58.7. All patients have a degree of anxiety while waiting for cancer surgery. The prospect of major gynecologic surgery increases these concerns. Some women may focus on the effect the surgery will have on their appearance and sexual functions. Discuss the woman's feelings and concerns about her surgery. Be willing to listen since this can provide considerable support.

Standard preoperative care includes perineal or abdominal preparation and urinary catheter insertion (see Chapter 18). After surgery, pain management, bowel and bladder care, and encouraging ambulation and exercise are important. Initiate venous thromboembolism (VTE) prophylaxis. Teach the patient about postoperative care and expectations for recovery. Radiation therapy is discussed in Chapter 16.

CHECK YOUR PRACTICE

You are working in the preoperative surgery holding unit. Your patient is a 60-year-old who is scheduled for a TAH-BSO for endometrial cancer. When you ask her how she is doing, she tells you that she is worried because "life will never be the same."

- How would you approach this situation?
- What information would you provide?

◆ Sexual Dysfunction

Female sexual response is a complex process affected by multiple biologic, psychological, cultural, and environmental factors. **Sexual dysfunction** is a complication of sexual desire, arousal, orgasm, or pain that causes personal distress. Out of every 8 women, 1 reports sexual dysfunction. It can strongly affect quality of life. Common types of sexual dysfunction include sexual interest/arousal disorder, orgasmic disorder, genitopelvic pain/penetration disorder, and medication-induced sexual dysfunction.

There are many potential causes of sexual dysfunction. They include psychological issues (e.g., anxiety, relationship stress), medication or substance use (e.g., SSRIs, hormone agents), medical problems (e.g., diabetes, hypertension), structural problems (e.g., female genital mutilation, gynecologic surgery), gynecologic problems (e.g., endometriosis, uterine fibroids), and physiologic changes (e.g., breastfeeding, menopause).[18] Sexual dysfunction may also be caused by a combination of personal or relationship factors.

Women with sexual dysfunction may present with concerns of low libido or sexual arousal, difficulty in achieving orgasm, genital or pelvic pain, pain with penetration, medication- or substance-induced changes in sexual response, or other distress with sexual activities.

Given the complexity and sensitivity of sexual dysfunction, it may be appropriate to provide a referral to an HCP with experience in female sexual medicine for assessment, diagnosis, and treatment. Assessment begins with the history, including gynecologic, obstetric, sexual, menstrual, and psychiatric histories. Symptom diaries and symptom checklists can help to define the extent and type of dysfunction. Physical assessment may include speculum and pelvic examination. In the absence of underlying medical conditions, laboratory tests are not part of diagnosing sexual dysfunction.

The management is patient-centered and specific to the condition. A team approach may be needed. This may include counseling, sex education and sexual skills training, physical therapy, and gynecologic care. Stress reduction, cognitive–behavioral therapy, and relationship counseling are often important aspects of treatment. Teaching anatomy, sexual response, and methods to achieve sexual health goals can improve sexual functioning. Pelvic floor physical therapy can reduce pain.

Management includes both drugs and nonpharmacologic treatment options. If the patient takes drugs associated with sexual dysfunction, such as certain antidepressants or antipsychotics, they may be discontinued. Hormone therapy or use of

ospemifene (Osphena), a selective estrogen receptor modulator [SERM]), may help with sexual dysfunction due to menopause or estrogen deficiency. Transdermal testosterone, flibanserin (Addyi), a serotonin receptor agonist/antagonist, or bremelanotide (Vyleesi), a melanocortin receptor agonist, may be used to treat sexual interest and arousal disorders. Bupropion, an antidepressant, may be appropriate for dysfunction associated with psychological conditions. Vaginal lubricants and moisturizers, topical anesthesia, and vaginal dilators can improve pain symptoms.

Nursing care starts with an understanding of normal female sexual response. Approach patients with a non-judgmental, sex-positive attitude to support patients in discussing their concerns. Provide teaching about sexual health and functioning. Suggest books or other appropriate resources for additional information. Review safe sex practices and measures to prevent unintended pregnancy. Teach patients about lifestyle changes to support sexual health and well-being. Encourage patients to follow treatment plans. Provide sexual medicine specialists, sex or couples therapists, or pelvic floor physical therapy referrals. Follow up to assess the effectiveness of treatment and next steps to promote sexual health.

SEXUAL ASSAULT

Sexual violence is any sexual activity in which consent was not freely given. It is a serious public health problem that affects millions of people each year. Nearly 1 in 3 women will experience some form of sexual violence in their lifetime. Sexual violence may take many forms, such as unwanted sexual contact, sexual coercion, or rape. Persons of all ages, races, genders, sexual orientations, and socioeconomic statuses experience sexual violence. It has long-lasting consequences on physical and mental health. Nurses play an important role in caring for survivors of sexual violence in both the short and long term. This section focuses on gynecologic nursing care for women who have been recent victims of sexual assault.

Sexual assault is nonconsensual sexual contact, such as penetration of the victim's body. The terms sexual assault and rape are often used interchangeably. Rape is completed or attempted nonconsensual vaginal, anal, or oral penetration, no matter how slight, with any object or part of the body (such as a finger or penis). There are many complex factors associated with an increased risk of sexual assault. Most often, sexual assault is committed by someone known to the victim. The perpetrator is a stranger in only about 20% of cases.

Many victims will not seek medical attention. Others may wait days or even weeks after the assault to seek care. Victims may present with physical trauma or injury on any area of the body, in addition to psychological trauma. A medical forensic exam may be needed to collect evidence. You should be familiar with the legal definition of sexual crimes and rape in your state.[19] A forensic examination is not mandatory. It requires informed consent. HCPs may be asked to testify if sexual assault charges are filed.

Nursing care for a sexual assault victim is complex. Due to the unique needs of caring for sexual assault victims, involve a specially trained provider such as a sexual assault nurse examiner (SANE). Assessment of victims of sexual assault includes (1) treatment of acute traumatic injuries including anogenital injuries, (2) evaluation for STIs, (3) pregnancy screening and prevention, (4) assessment and support for psychological health, and (5) forensic examination (Table 58.18).

First, we must establish consent for care and ensure the patient's physical and psychological safety. Caring for any acute traumatic injuries or urgent medical problems is the priority. Once the patient is stable, contact appropriate services such as a social worker, psychiatric HCP, rape advocate, medical forensic examiner, or SANE. Explain that you are not offering to clean

TABLE 58.18 Assessment of Victims of Sexual Assault

1. Medicolegal
   - Informed consent for assessment and care
   - Informed consent for forensic examination and collection of evidence
   - Appropriate "chain of evidence" documentation
2. History
   - Details of the assault (who, what, when, where)
   - Activities since assault that may affect evidence collection (e.g., changed clothes, showered, douched)
   - Review of symptoms, including any loss of consciousness or memory loss
   - Alcohol or drug intake
   - Health history including menstrual, gynecologic, contraceptive, sexual, and immunization history
3. Physical assessment
   - Vital signs and general appearance
   - Psychological assessment
   - Extragenital and/or anogenital trauma (e.g., bruising, lacerations, abrasions, edema, redness)
   - Pelvic and speculum examination
4. Laboratory tests and diagnostic imaging
   - STI testing (e.g., HIV, hepatitis B, syphilis, chlamydia, gonorrhea, trichomonas)
   - Microscopic analysis of vaginal fluids
   - Pregnancy test
   - Toxicology, as appropriate for victims who may have been drugged
   - Radiology for trauma assessment
5. Forensic samples
   - Clothing
   - Anogenital and/or oral swabs
   - Combed specimens from scalp or pubic hair
   - Fingernail scrapings or clippings
   - Blood, urine, saliva, and hair samples
6. Treatment considerations
   - Care of any traumatic injuries and pain management
   - Empiric treatment for STIs (e.g., gonorrhea, chlamydia)
   - PEP treatment for HIV
   - Tetanus and hepatitis B boosters
   - Emergency contraception
   - HPV vaccination
   - Psychological support and referrals for mental health services
   - Protection of legal rights and compliance with mandatory reporting based on local requirements
   - Recommendation of continued follow-up and services of rape crisis center

the patient until evidence has been collected. Collaborate with the health care team to obtain a history, perform a physical assessment, and collect forensic evidence. Monitor vital signs and emotional status. Provide emotional support. Perform baseline screening for HIV and STIs. Teach patients that it is often not possible to assess for STIs after a recent sexual assault and stress the importance of seeking follow-up care for this screening. Discuss pregnancy prevention measures such as emergency contraception. Provide referrals for counseling services and follow-up care.

Case Study

PCOS

(© Juanmonino/iStock.com.)

Patient Profile

B.C., a 26-year-old female, presents with difficulty getting pregnant. She states she and her male partner have been trying to conceive for almost a year. She has never been pregnant and has no history of STIs. She reports menarche at age 14, irregular menses, and no periods in the past 3 months. She states she hoped she might be pregnant but has had multiple negative urine pregnancy tests. She has been feeling somewhat depressed and has not been sleeping well for the past year. She is not currently taking any drugs and reports no allergies.

Subjective Data

- History of chronic hypertension
- No reports of pelvic or urinary pain, vaginal discharge, or bleeding
- Denies nausea, breast tenderness, fatigue
- Recent weight gain (20 pounds in the past 6 months)

Objective Data

- BP 140/92 mm Hg, pulse 82 beats/min, respirations 14 breaths/min
- Height 5 ft, 6 in; weight 187 lb; BMI 30 kg/m^2
- Acne, facial hair present on upper lip and chin
- Normal pelvic and speculum examination

Diagnostic Studies

- Pregnancy test negative
- Depression screen negative
- Total testosterone and 17-hydroxyprogesterone within normal limits

Plan of Care

- Weight loss, diet, and exercise
- Referral for counseling and infertility treatment

Discussion Questions

1. ***Recognize:*** What criteria are needed to make a diagnosis of PCOS?
2. ***Analyze:*** What is the relationship between PCOS and infertility?
3. ***Plan:*** B.C. asks you about her chances of conceiving without fertility treatments. How would you respond, and what type of teaching would you provide?
4. ***Prioritize:*** Based on the assessment data, what are the priority clinical problems?
5. ***Act:*** B.C. doesn't understand how her weight gain, facial hair, and sleeping problems are related to her irregular periods and difficulty getting pregnant. How would you help her understand her condition and the recommended treatment?
6. ***Safety:*** What measures can B.C. take to avoid long-term health complications associated with PCOS?

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A 33-year-old patient expresses difficulty in achieving pregnancy and asks when a fertility evaluation is appropriate. The nurse advises a formal evaluation is appropriate after
   - **a.** 35 years of age.
   - **b.** 1 or more spontaneous pregnancy losses.
   - **c.** 12 months of regular, unprotected intercourse.
   - **d.** 6 months of lifestyle and behavioral modifications.
2. The nurse reviews the ultrasound report for a woman with a suspected ectopic pregnancy, knowing that it is most often located in the
   - **a.** cervix.
   - **b.** ovaries.
   - **c.** endometrium.
   - **d.** fallopian tube.
3. An appropriate question to ask a patient with painful menstruation to distinguish primary from secondary dysmenorrhea is
   - **a.** "When did you start experiencing painful menstruation?"
   - **b.** "Does your pain become worse with activity or overexertion?"
   - **c.** "Have you had a recent personal crisis or change in your lifestyle?"
   - **d.** "Do non-steroidal antiinflammatory drugs (NSAIDs) like ibuprofen help your pain?"
4. The nurse teaching a woman with an intact uterus about hormone therapy states that it is essential to
   - **a.** start vitamin E and B-complex supplements.
   - **b.** use vaginal lubricants in penetrative sexual activities.
   - **c.** avoid selective serotonin reuptake inhibitor antidepressant agents.
   - **d.** take progesterone with estrogen to reduce the risk of endometrial cancer.
5. The nurse suspects that the patient with vaginal itching and thick, curdy, white discharge most likely has
   - **a.** chlamydia.
   - **b.** bacterial vaginosis.
   - **c.** human papilloma virus.
   - **d.** vulvovaginal candidiasis.
6. In caring for a patient with endometriosis, the nurse teaches that common interventions to treat this condition include *(select all that apply)*
   - **a.** NSAIDs.
   - **b.** antibiotics.
   - **c.** oral contraceptives.
   - **d.** intrauterine device.
   - **e.** surgical removal of tissue.

7. Teaching about cancer prevention includes information that the only gynecologic cancer with reliable routine screening is cancer of the
   a. cervix.
   b. uterus.
   c. vagina.
   d. ovaries.
8. The *first* nursing intervention for a patient who has been sexually assaulted is to
   a. contact a support person.
   b. treat acute traumatic injuries.
   c. examine and document anogenital trauma.
   d. collect specimens for forensic examination.

1. c; 2. d; 3. a; 4. d; 5. d; 6. a, c, e 7. a; 8. b.

Male Reproductive Problems

Anthony Lutz

http://evolve.elsevier.com/Lewis/medsurg/

CONCEPTUAL FOCUS

Cellular Regulation
Infection
Pain
Reproduction
Sexuality

LEARNING OUTCOMES

1. Describe the pathophysiology, clinical manifestations, and interprofessional and nursing management of benign prostatic hyperplasia.
2. Describe the pathophysiology, clinical manifestations, and interprofessional care of prostate cancer.
3. Explain the nursing management of prostate cancer.
4. Specify the pathophysiology, clinical manifestations, and interprofessional and nursing management of prostatitis and problems of the penis and scrotum.
5. Explain the clinical manifestations and interprofessional care of testicular cancer.
6. Describe the pathophysiology, clinical manifestations, and interprofessional and nursing management of problems related to male sexual function.
7. Discuss the psychologic and emotional implications related to male reproductive problems.

KEY TERMS

benign prostatic hyperplasia (BPH)
epididymitis
erectile dysfunction (ED)
orchitis
paraphimosis
phimosis
prostate cancer
prostatitis
radical prostatectomy
testicular cancer
testicular torsion
transurethral resection of the prostate (TURP)
vasectomy

This chapter discusses male reproductive system problems. These involve a variety of structures, including the prostate, penis, urethra, testes, epididymis, and rectum (Fig. 59.1). Many of these problems can profoundly affect sexuality and reproduction. Sexual dysfunction from prostate problems or erectile dysfunction (ED) can cause psychologic and body image problems. The patient may have anxiety because of a perceived loss of his sex role, self-esteem, or quality of sexual interaction with his partner. Patient teaching and counseling are essential for promoting health and optimal sexual well-being.

PROBLEMS OF THE PROSTATE GLAND

BENIGN PROSTATIC HYPERPLASIA

Benign prostatic hyperplasia (BPH) is a condition in which the prostate gland increases in size, disrupting the outflow of urine from the bladder through the urethra. Half of men will have some signs of BPH by the age of 50. That number increases to more than 70% for men 60 to 69 years old.[1]

Etiology and Pathophysiology

There are several factors that may play a role in the development and progression of BPH. We think that hormonal changes associated with aging are a contributing factor. Dihydroxytestosterone (DHT), one of several sex hormones, stimulates prostate cell growth. Excess DHT can cause overgrowth of prostate tissue. As men age, they continue to make and accumulate high levels of DHT, resulting in prostate enlargement.

Another possible cause of BPH is an increased proportion of estrogen as compared with testosterone. Throughout their lives, men make testosterone and small amounts of estrogen. As men age, the amount of testosterone they make decreases, leaving a higher proportion of estrogen. A higher amount of estrogen

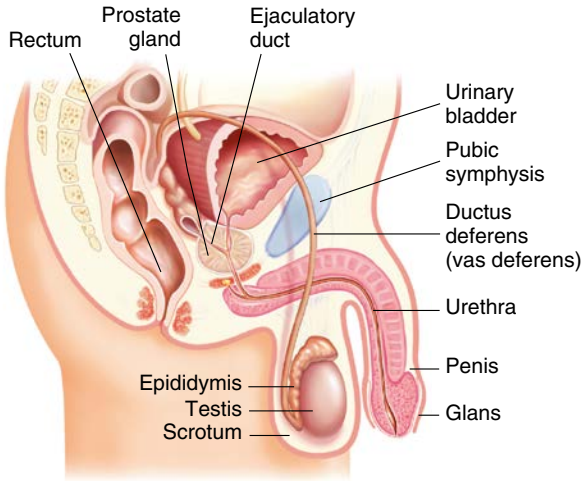

Fig. 59.1 Areas of the male reproductive system in which problems are likely to develop.

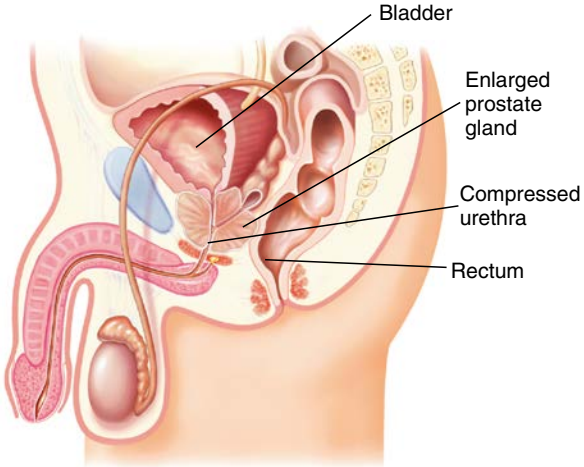

Fig. 59.2 BPH. The enlarged prostate compresses the urethra.

within the prostate gland increases the activity of substances (including DHT) that promote prostate cell growth.

BPH usually develops in the inner part of the prostate, called the transition zone. As the transition zone of the prostate enlarges, it gradually compresses the urethra, leading to partial or complete obstruction (Fig. 59.2). This compression of the urethra leads to the development of clinical manifestations. There is no direct relationship between overall prostate size and the severity of manifestations or degree of obstruction.[2] The location of the enlargement is most significant in the development of obstructive symptoms (Fig. 59.3). For example, it is possible for mild prostate enlargement to cause severe obstructive symptoms or for extreme prostate enlargement to cause few obstructive symptoms.

Risk factors for BPH include aging, obesity (especially increased waist circumference), lack of physical activity, a high intake of red meat and animal fat, alcohol use, ED, smoking, and diabetes.[3] A family history of BPH in a first-degree relative also may be a risk factor.

Clinical Manifestations

Manifestations occur gradually. They may go unnoticed until prostate enlargement has been present for some time. Early

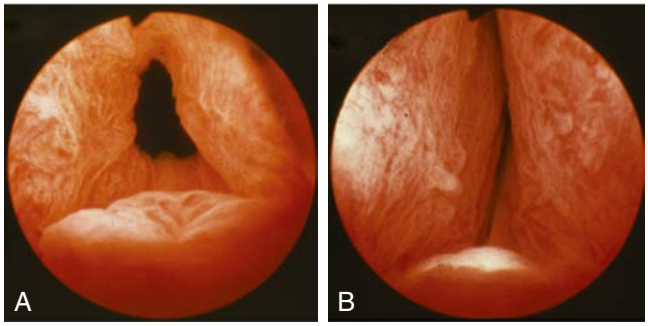

Fig. 59.3 Views of the prostate by cystoscopy. (A) Normal appearance. (B) Moderate BPH with urethral obstruction. (From Townsend CM, Beauchamp RD, Evers BM, et al.: *Sabiston textbook of surgery,* ed 19, Philadelphia, 2012, Saunders.)

symptoms may not cause many problems because the bladder can compensate for a small amount of resistance to urine flow. As the severity of urethral obstruction increases, symptoms gradually worsen.

We place symptoms into 2 groups: irritative and obstructive. *Irritative symptoms* include nocturia, urinary frequency, urgency, dysuria, bladder pain, and incontinence. These symptoms are related to inflammation or infection. Nocturia is often the first symptom that the patient notices. *Obstructive symptoms,* caused by prostate enlargement, include a decrease in the caliber and force of the urinary stream, difficulty in starting a stream, intermittency (stopping and starting stream several times while voiding), and dribbling at the end of urination. These symptoms are due to the increased effort of the bladder as it tries to empty through the decreased diameter of the urethra. As a group, both irritative and obstructive symptoms are considered lower urinary tract symptoms (LUTS).

The American Urological Association (AUA) symptom index (AUA-SI) for BPH (Table 59.1) is a widely used tool to assess voiding symptoms from obstruction.[4] This tool is not diagnostic. It helps determine the extent of symptoms and guide treatment. Higher scores on this tool mean greater symptom severity.

Complications

Some men may have acute urinary retention. They will have the sudden and painful inability to urinate. Treatment involves the inserting a catheter to drain the bladder. Surgery may be needed in severe situations. Bladder damage can occur if treatment is delayed.

Urinary tract infection (UTI) can be a complication of BPH. Since the bladder is unable to empty completely, bacteria can grow in the residual urine that remains in the bladder and cause infection. In more severe cases, infection can progress into the kidney and cause pyelonephritis. In severe cases, infection can spread into the bloodstream and sepsis can develop. Bladder calculi (stones) may develop because of the alkalinization of the residual urine. So, the finding of bladder stones often indicates obstruction related to BPH.

Renal failure can occur due to *hydronephrosis* (distention of the renal pelvis and calyces by urine that cannot flow through the ureter to the bladder).

TABLE 59.1 AUA Symptom Index to Determine Severity of Prostatic Problems

Questions	AUA SYMPTOM SCORE[a] (CIRCLE 1 NUMBER ON EACH LINE)					
	Not At All	Less Than 1 Time in 5	Less Than Half the Time	About Half the Time	More Than Half the Time	Almost Always
Over the Past Month						
1. How often do you have the sensation that your bladder is not completely empty after you finish urinating?	0	1	2	3	4	5
2. How often do you have to urinate again, less than 2 hr after you finish urinating?	0	1	2	3	4	5
3. How often do you stop and start again several times when you urinate?	0	1	2	3	4	5
4. How often do you find it difficult to postpone urination?	0	1	2	3	4	5
5. How often do you have a weak urinary stream?	0	1	2	3	4	5
6. How often do you have to push or strain to begin urination?	0	1	2	3	4	5
7. How many times do you usually get up to urinate from the time you go to bed at night until the time you get up in the morning?	0 (None)	1 (1 time)	2 (2 times)	3 (3 times)	4 (4 times)	5 (5 times or more)
Sum of circled numbers (AUA Symptom Score): _____						

[a]Score is interpreted as follows: 0–7, mild; 8–19, moderate; 20–35, severe.
Source: Barry MJ, Fowler FJ, O'Leary MP, et al.: The AUA symptom index for benign prostatic hyperplasia, *J Urol* 148:1549, 1992. Used with permission.

Diagnostic Studies

A detailed history and physical assessment are important. Diagnostic studies are outlined in Table 59.2. A digital rectal examination (DRE) is done to estimate the prostate size, symmetry, and consistency. In BPH, the prostate is symmetrically enlarged, firm, and smooth.

A urinalysis (UA) and urine culture with sensitivities can detect bacteria, nitrites, leukocyte esterase, white blood cells (WBCs), or microscopic hematuria (RBCs), which could indicate infection or inflammation.

A prostate-specific antigen (PSA) blood test can screen for prostate cancer. Patients with BPH may have slightly increased PSA levels. PSA is released into the bloodstream by both benign and malignant prostate cells. Serum creatinine levels can assess for renal insufficiency. If creatinine levels are high, a renal ultrasound may show hydronephrosis. Because symptoms of BPH and neurogenic bladder are similar, a neurologic examination may be done.

In patients with an abnormal DRE and high PSA, a transrectal ultrasound (TRUS) can be ordered as a stand-alone imaging test. We more often do a TRUS-guided prostate biopsy. An alternative option is a pelvic MRI with attention to the prostate. If abnormal areas are seen on MRI, these areas can be targeted on a TRUS prostate biopsy (MRI-fusion targeted biopsy). Insurance coverage of pelvic MRI is sometimes an issue. Studies have shown that assessment with MRI prior to biopsy and MRI-targeted biopsy are better than standard TRUS biopsy in men at risk for prostate cancer.[5]

Uroflowmetry (measures the volume of urine expelled from the bladder) is helpful to determine the extent of urethral blockage and the treatment needed. Postvoid residual urine volume can determine the degree of urine flow obstruction. Cystoscopy is done if the diagnosis is unclear or to see the degree of prostatic enlargement. If the diagnostic picture is unclear, urodynamic/pressure flow studies can help evaluate bladder function and assess for obstruction.

Interprofessional Care

The goals of care are to (1) restore bladder drainage, (2) relieve symptoms, and (3) prevent or treat the complications of BPH. Treatment is based on the degree to which the symptoms bother the patient or the presence of complications rather than the size of the prostate. Alternatives to surgery include surveillance, drug therapy, and minimally invasive procedures.

The most conservative treatment is called *active surveillance,* or watchful waiting. When the patient has mild symptoms (AUA symptom scores of 0 to 7), we usually take a wait-and-see approach. Teaching patients to make lifestyle changes can help relieve early or mild symptoms. Making diet changes (decreasing intake of bladder irritants, like caffeine, alcohol, carbonated drinks, artificial sweeteners, and spicy or acidic foods), avoiding certain drugs (e.g., decongestants, anticholinergics), and restricting evening fluid intake may improve symptoms. A timed voiding schedule (also called "bladder retraining") may reduce symptoms and eliminate the need for further treatment. If the patient begins to have signs or symptoms that indicate an increase in obstruction, further treatment is needed.

Drug Therapy

The 2 main classes of drugs to treat BPH include 5α-reductase inhibitors and α-adrenergic receptor blockers. Combination therapy using both types of drugs may be more effective in reducing symptoms than using 1 drug alone. An erectogenic drug can also be used to help treat BPH.

5α-reductase inhibitors. 5α-Reductase inhibitors work by reducing the size of the prostate gland. They block the 5α-reductase type 1 and 2 isoenzymes, which are necessary for the conversion of testosterone to DHT (main intraprostatic

TABLE 59.2 Interprofessional Care

BPH

Diagnostic Assessment

- History and physical assessment with DRE
- UA and urine culture and sensitivities
- PSA
- Serum creatinine
- Postvoid residual (by ultrasound)
- Renal ultrasound (if increased serum creatinine, evaluate for hydronephrosis)
- TRUS
- Uroflowmetry
- Cystoscopy
- Urodynamic/pressure flow studies

Management

Active Surveillance

- Annual PSA and DRE
- Repeat AUA symptom score and postvoid residual if any symptoms change

Drug Therapy

- 5α-Reductase inhibitors (e.g., dutasteride, finasteride)
- α-Adrenergic receptor blockers (e.g., alfuzosin, doxazosin, tamsulosin)
- Combination 5α-reductase inhibitor and α-adrenergic receptor blocker (e.g., dutasteride plus tamsulosin [Jalyn])
- Erectogenic drugs (e.g., tadalafil)

Minimally Invasive Therapy (Table 59.3)

- Laser enucleation of the prostate (HoLEP or ThuLEP)
- Photoselective vaporization of the prostate (PVP)
- Prostatic urethral lift (PUL)
- Transurethral microwave thermotherapy (TUMT)
- Transurethral needle ablation (TUNA)
- Water vapor thermal therapy

Surgical Therapy (Table 59.3)

- Transurethral incision of the prostate (TUIP)
- Transurethral resection of the prostate (TURP)
- Simple prostatectomy (open, laparoscopic, robotic assisted)

androgen). Prostate size is directly related to the amount of DHT. By blocking DHT, overly enlarged prostates can decrease in size. These agents are more effective for men with larger prostates who have bothersome symptoms.

Finasteride (Proscar) inhibits only the type 2 isoenzyme. It is an appropriate treatment for men who have a moderate to severe symptom score on the AUA-SI (Table 59.1). Although most men who are treated with the drug have symptom improvement, it can take 6 months to be effective. It must be taken on a regular basis to have an effect. Because it blocks the enzyme needed for conversion of testosterone to DHT, decreased libido is a common side effect.

Serum PSA levels may appear decreased by 50% when taking finasteride. Therefore, to "correct" for the apparent decrease caused by finasteride, the HCP should double the PSA value for a patient who has been on a 5α-reductase inhibitor for at least 6 months. This allows for a more accurate comparison to premedication PSA levels. Dutasteride (Avodart) has the same effect on prostatic tissue as finasteride. It is a dual inhibitor of 5α-reductase types 1 and 2 isoenzymes.

These drugs may lower the risk for some prostate cancers. However, using them to prevent prostate cancer is not recommended, and research is ongoing. Patients who develop a high PSA level while taking these drugs should have further evaluation. Encourage the patient to discuss the need for prostate cancer screening with the HCP.

DRUG ALERT

Finasteride (Proscar)

- Women who may be or are pregnant should not touch tablets due to potential risk to male fetus (anomaly).

α-Adrenergic receptor blockers. α-Adrenergic receptor blockers are another drug treatment option for BPH. These drugs selectively block α_1-adrenergic receptors, which are abundant in the prostate and increased in hyperplastic prostate tissue. They offer symptom relief by relaxing the smooth muscle of the prostate that surrounds the urethra, thus facilitating urinary flow through the urethra. These agents do not decrease the size of the prostate.

α-Adrenergic blockers include alfuzosin (Uroxatral), doxazosin (Cardura), prazosin (Minipress), tamsulosin (Flomax), and silodosin (Rapaflo). Symptom improvement can often be seen within days to weeks of starting therapy. Because they relax the smooth muscle of the prostatic urethra, a common side effect is retrograde ejaculation. The combination of a 5α-reductase inhibitor (dutasteride) and an α-adrenergic receptor blocker (tamsulosin) is available in a single oral medication (Jalyn).

Erectogenic drugs. Tadalafil (Cialis) can be used in men who have symptoms of BPH alone or in combination with ED. It can be effective in reducing symptoms for both conditions.

Herbal therapy. Some patients take plant extracts, such as saw palmetto *(Serenoa repens)*. However, research shows that saw palmetto has no benefit over a placebo.[6] Advise patients to discuss herbal therapies with their HCP.

Minimally Invasive Therapy

Minimally invasive therapies are becoming more common as an alternative to watchful waiting and surgery (Table 59.3). A benefit of these procedures is a decreased length of stay in the hospital. They are associated with fewer adverse events. Many minimally invasive therapies have outcomes comparable to surgery.

Photoselective vaporization of the prostate. *Photoselective vaporization of the prostate* (PVP) uses a high-power green laser light to vaporize prostate tissue. Laser therapy through visual or ultrasound guidance is an effective alternative to transurethral resection of the prostate (TURP). The laser beam is delivered through a fiber instrument inserted into the meatus and through the urethra. It can cut, coagulate, and vaporize prostatic tissue. Improvements in urine flow and symptoms are almost immediate. PVP works well for larger prostate glands. Irritative voiding symptoms may persist for several weeks.

Laser enucleation of the prostate. Laser enucleation also involves delivering a laser beam transurethrally through a fiber instrument. It is used for rapid coagulation and vaporization of prostatic tissue, with better coagulative properties in the tissue

TABLE 59.3 Treatment for BPH

Description	Advantages	Disadvantages
Minimally Invasive		
Laser Enucleation of the Prostate		
Laser beams used to rapidly vaporize and coagulate prostate tissue. Laser does not penetrate deep tissue. 2 types of lasers in this class: holmium laser enucleation of the prostate (HoLEP), thulium laser enucleation of the prostate (ThuLEP).	• Outpatient procedure • Better coagulative properties in tissue compared with TURP • Comparable results to TURP and PVP • Minimal bleeding • Fast recovery time	• Catheter needed after for 24–48 hr • Irritative voiding symptoms, urinary incontinence • Hematuria • Retrograde ejaculation • May be more difficult to perform compared with PVP
Photoselective Vaporization of the Prostate (PVP)		
Uses a laser beam to cut or destroy part of the prostate. May be more effective for small to moderate-sized prostates.	• Short procedure • Comparable results to TURP • Minimal bleeding • Fast recovery time • Rapid symptom improvement • Very effective	• Catheter needed up to 7 days after due to edema and urinary retention • Delayed sloughing of tissue • Takes several weeks to reach optimal effect • Retrograde ejaculation
Prostatic Urethral Lift (PUL)		
Permanent transprostatic implants/tension sutures placed transurethrally via cystoscope. Mechanically open the prostatic urethra by compressing the prostate tissue/parenchyma.	• Outpatient procedure • ED, urinary incontinence, and retrograde ejaculation are minimal • No change in PSA since no prostate tissue ablated	• Lack of long-term durability/results • Treatment response rates slightly lower when compared with TURP • If unsuccessful, may need repeat PUL or TURP in the future
Transurethral Microwave Thermotherapy (TUMT)		
Use of microwave radiating heat to produce coagulative necrosis of the prostate.	• Outpatient procedure • ED, urinary incontinence, and retrograde ejaculation are rare • Mild effects: bladder spasm, hematuria, dysuria	• Potential for damage to surrounding tissue • Urinary catheter needed after for 2–7 days • Not appropriate for men with rectal problems
Transurethral Needle Ablation (TUNA)		
Low-wave radiofrequency used to heat the prostate, causing necrosis.	• Outpatient procedure • ED, urinary incontinence, and retrograde ejaculation are rare • Precise delivery of heat to desired area • Very little pain • Early return to activities	• Urinary retention common • Irritative voiding symptoms • Hematuria for up to a week • May need a catheter for a short time after
Transurethral Vaporization of Prostate (TUVP)		
Electrosurgical modification of the standard TURP. Vaporization and desiccation used together to destroy prostatic tissue. Can use a variety of energy delivery mediums (e.g., button, rollerball, vaportrode).	• Minimal risks • Minimal bleeding and sloughing	• Retrograde ejaculation • Intermittent hematuria
Water Vapor Thermal Therapy		
Heated water vapor/steam used to destroy obstructive prostate tissue. Delivered transurethrally via hand-held device with a retractable needle that releases the water vapor in 9-second doses.	• Outpatient procedure • Can be done in an outpatient office setting • ED, urinary incontinence, and retrograde ejaculation are rare • Precise delivery of steam to desired area • Very little pain	• Relatively new, so lack of long-term results • Irritative voiding symptoms and UTI • Hematuria
Surgical Therapy		
Transurethral Incision of Prostate (TUIP)		
Involves transurethral incisions into prostatic tissue to relieve obstruction. Effective for small to moderate prostates.	• Outpatient procedure • Minimal complications • Low occurrence of ED or retrograde ejaculation • Outcomes similar to TURP	• Urinary catheter needed after

TABLE 59.3 Treatment for BPH—cont'd

Description	Advantages	Disadvantages
Transurethral Resection of Prostate (TURP)		
Use of excision and cauterization to remove prostate tissue via cystoscope. Standard for treatment of BPH.	• ED unlikely	• Bleeding, clot retention • Retrograde ejaculation • Catheter needed after
Simple Prostatectomy (Open, Laparoscopic, or Robotic Assisted)		
Surgery of choice for men with large prostates (often >100 g), bladder damage, or other complicating factors. If open, involves an external incision with retropubic or perineal approach (Fig. 59.6). If laparoscopic and/or robotic assisted, involves several small abdominal incisions and 1 slightly larger incision near the umbilicus.	• Complete visualization of the prostate and surrounding tissue	• ED • Bleeding • Pain • Risk for infection

compared with TURP. There are 2 types of lasers in this class: holmium laser enucleation of the prostate (HoLEP) and thulium laser enucleation of the prostate (ThuLEP). Neither penetrate deep tissue, which decreases side effects.

Prostatic urethral lift. *Prostatic urethral lift* (PUL) is a relatively new minimally invasive treatment. PUL involves permanent transprostatic implants or tension sutures delivered transurethrally via cystoscope. They mechanically open the prostatic urethra by compressing the prostate tissue. This alters prostate anatomy without ablating any tissue. So far, PUL has been done only in prostates less than 80 g in size and without an obstructive median lobe.[2] There is a lack of long-term data on the durability of PUL over time and the rates of needing either repeat treatment or progression to TURP.

Transurethral microwave thermotherapy. *Transurethral microwave thermotherapy* (TUMT) involves the delivery of microwaves directly to the prostate through a transurethral probe. The microwaves increase the temperature of the prostate tissue to about 113°F (45°C). The heat causes death of tissue, relieving the obstruction. A rectal temperature probe is used during the procedure to ensure that the temperature in the rectum stays less than 110°F (43.5°C) to prevent rectal tissue damage. The procedure takes about 90 minutes. It is an outpatient procedure.

Urinary retention is a common complication. Patients often go home with an indwelling catheter for 2 to 7 days to maintain urinary flow and facilitate the passing of small clots or necrotic tissue. Antibiotics, pain medication, and bladder antispasmodics are used to treat and prevent postprocedure problems. Anticoagulant therapy should be stopped 10 days before treatment.

Transurethral needle ablation. *Transurethral needle ablation* (TUNA) is another procedure that increases the temperature of prostate tissue, thus causing localized necrosis. TUNA differs from TUMT in that low-wave radiofrequency is used to heat the prostate. Only prostate tissue in direct contact with the needle is affected. This allows for more precise removal of the target tissue. Most patients have an improvement in symptoms. It is done in an outpatient unit or HCP's office using local anesthesia and IV or oral sedation. TUNA takes about 30 minutes.

CHECK YOUR PRACTICE

You are caring for a patient who is scheduled for a transurethral needle ablation for BPH. He appears anxious. He tells you he is worried about not being able to urinate normally after the procedure.

- What type of information and teaching would you provide?

Transurethral vaporization of the prostate. *Transurethral vaporization of the prostate* (TUVP) is an electrosurgical modification of the standard TURP. Vaporization and desiccation are used together to destroy obstructive prostatic tissue. There are a variety of energy delivery mediums that can be used to deliver the energy (e.g., button, rollerball, vaportrode). This is why many call it a "button TURP." The results, side effects, and long-term outcomes are equal to TURP. Because TUVP uses a bipolar energy delivery surface, an energy current is not passed through the patient's body to a grounding pad. This allows the HCP to use saline irrigation during the procedure, which decreases the risk for TUR syndrome.

Water vapor thermal therapy. *Water vapor thermal therapy* uses heated water vapor/steam to destroy obstructive prostate tissue. The steam is delivered transurethrally directly into the prostate by a hand-held device with a retractable needle. It releases the heated water vapor in 9-second doses. It is potentially a good option for a patient who is looking to minimize the risk for postprocedure ED. This treatment has been done only on prostates less than 80 g in size. It lacks long-term durability data.

Surgical Therapy

Invasive treatment of symptomatic BPH involves surgery. The approach used depends on the size and location of the prostatic enlargement and patient factors, such as age and surgical risk. Table 59.3 describes common surgeries.

Surgery is indicated when a decrease in urine flow causes pain, persistent residual urine, acute urinary retention because

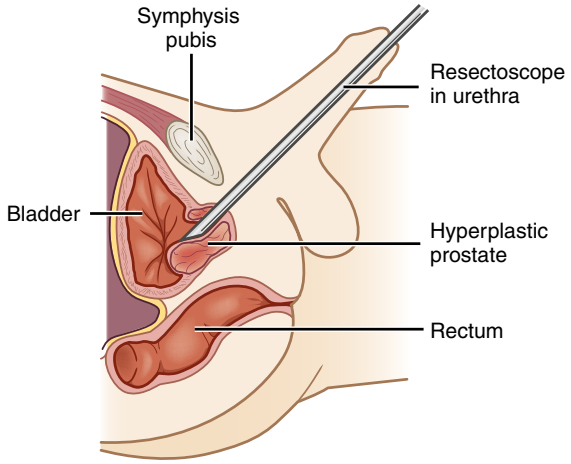

Fig. 59.4 Transurethral resection of the prostate.

of obstruction with no reversible precipitating cause, or hydronephrosis. Intermittent catheterization or insertion of an indwelling catheter can temporarily reduce symptoms and bypass the obstruction. However, avoid long-term catheter use because of the increased risk for infection.

Transurethral incision of the prostate. Transurethral incision of the prostate (TUIP) is a surgical procedure done under local anesthesia for men with moderate to severe symptoms. Several small incisions are made into the prostate gland to expand the urethra, which relieves pressure on the urethra and improves urine flow. TUIP is an option for patients with a small or moderately enlarged prostate gland.

Transurethral resection of the prostate. **Transurethral resection of the prostate (TURP)** involves the removal of prostate tissue using a resectoscope inserted through the urethra. TURP is the gold standard for surgical treatment of obstructing BPH. Most patients have marked improvements in symptoms and urinary flow rates.

In TURP there is no external incision. A resectoscope is inserted through the urethra to excise and cauterize obstructing prostatic tissue (Fig. 59.4). A large 3-way indwelling catheter with a 30-mL balloon is inserted into the bladder after the procedure to provide hemostasis and to facilitate urinary drainage. If there is a large amount of hematuria with clots after surgery, then the bladder can be irrigated, either continuously or intermittently, for the first 24 hours to prevent obstruction from blood clots.

TURP has a relatively low risk. We do have to assess for transurethral resection syndrome (TUR or TURP syndrome). Signs and symptoms include nausea, vomiting, confusion, bradycardia, and hypertension. TUR syndrome is due to hyponatremia from long operative times and prolonged intraoperative bladder irrigation with iso-osmolar fluid. If the HCP uses saline irrigation during the procedure, the risk for TUR syndrome dramatically decreases.

Other complications include bleeding and clot retention. Because bleeding is a common complication, patients taking aspirin, warfarin, or other anticoagulants must stop taking these several days before surgery. BPH medications are stopped after the procedure.

TABLE 59.4 NURSING ASSESSMENT

BPH

Subjective Data

Important Health Information

Medications: Testosterone supplementation

Surgery or other treatments: Previous BPH treatment

Functional Health Patterns

Health perception–health management: Knowledge of the condition

Nutritional-metabolic: Voluntary fluid restriction

Elimination: Urinary urgency, diminution in caliber and force of urinary stream. Hesitancy in starting voiding. Postvoid dribbling, urinary retention, urinary incontinence

Sleep-rest: Nocturia

Cognitive-perceptual: Dysuria, sensation of incomplete voiding, bladder discomfort

Sexuality-reproductive: Anxiety about sexual dysfunction

Objective Data

General

Older adult male

Urinary

Distended bladder on palpation. Smooth, firm, elastic enlargement of prostate on rectal examination

Possible Diagnostic Findings

Enlarged prostate on ultrasonography, bladder neck obstruction on cystoscopy, residual urine with postvoiding ultrasound or catheterization. WBCs, bacteria, or microscopic hematuria with bladder infection. ↑ Serum creatinine levels with renal involvement

❖ NURSING MANAGEMENT: BENIGN PROSTATIC HYPERPLASIA

Because you will be most directly involved in care of patients with BPH having surgery, the focus of nursing management in this section is on preoperative and postoperative care.

◆ Assessment

Subjective and objective data that you should obtain from a patient with BPH are outlined in Table 59.4.

◆ Clinical Problems

Clinical problems for the patient with BPH before surgery may include:

- Pain
- Risk for infection
- Impaired urinary elimination

Clinical problems and interventions for the patient with BPH who has surgery are presented in eNursing Care Plan 59.1 (available on the website for this chapter).

◆ Planning

The overall preoperative goals for the patient having surgery are to (1) restore urinary drainage; (2) resolve any UTI; and (3) understand the upcoming procedure, implications for sexual function, and urinary control. The overall postoperative goals

are to have (1) no complications, (2) restoration of urinary control, (3) complete bladder emptying, and (4) satisfying sexual expression.

Implementation

Health Promotion

Health promotion focuses on early detection and treatment of BPH. When symptoms of BPH are present, further diagnostic screening may be needed (Table 59.2).

Some men find that consuming alcohol, caffeine, or other bladder irritants tends to increase prostatic voiding symptoms because the diuretic effect increases bladder distention and overactivity. Compounds found in common cough and cold remedies, such as pseudoephedrine (e.g., Sudafed) and phenylephrine, often worsen the symptoms of BPH. These drugs are α-adrenergic agonists that cause smooth muscle contraction. If this occurs, the patient should avoid these drugs.

Teach patients with obstructive symptoms to urinate every 2 to 3 hours and when they first feel the urge. This will minimize urinary stasis and acute urinary retention. Teach patients to maintain a normal level of fluid so that they do not become dehydrated. The patient may think that if he restricts fluid intake, symptoms will be less severe. This actually increases the risk of infection while concentrating his urine.

Acute Care

The following discussion focuses on perioperative care for the patient undergoing a TURP.

Preoperative care. Antibiotics are usually given before any invasive genitourinary (GU) procedure. UTI must be treated before surgery. Restoring urinary drainage and encouraging a high fluid intake (2 to 3 L/day unless contraindicated) are helpful in managing infection. Prostatic obstruction may result in acute retention or inability to void. Urinary drainage must be restored before surgery.

A urethral foley catheter may be needed to restore bladder drainage. In many health care settings, 2% lidocaine gel is inserted into the urethra before catheter placement. The lidocaine gel acts as a lubricant, provides local anesthesia, and helps open the urethral lumen. If a sizable obstruction of the urethra exists, the HCP may need to use a special catheter or dilation tools to pass through the obstruction. Aseptic technique is important to avoid introducing bacteria into the bladder.

Patients may be concerned about the impact of the impending surgery on sexual function. Provide an opportunity for the patient and partner to express their concerns. Tell the patient that ejaculate volume may be decreased or absent after the procedure. Most types of prostatic surgery result in some degree of *retrograde ejaculation*. This is a condition in which some semen travels back into the bladder during orgasm instead of traveling out of the penis. This may decrease orgasmic sensations felt during ejaculation. Retrograde ejaculation is not harmful. The semen is voided with the next urination.

Postoperative care. The main complications after surgery are bleeding, bladder spasms, urinary incontinence, and infection. Adjust the plan of care to the type of surgery, reasons for surgery, and patient's response to surgery.

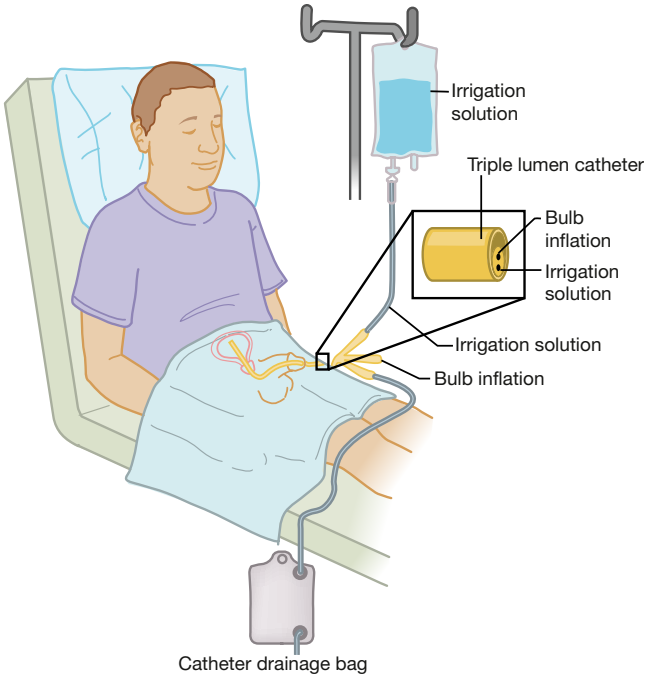

Fig. 59.5 Bladder irrigation with a triple lumen urinary catheter.

After surgery, the patient will have a standard 2-way foley catheter or a 3-way urethral catheter. Bladder irrigation is typically done to remove clotted blood from the bladder and ensure drainage of urine (Fig. 59.5). The bladder is irrigated either manually on an intermittent basis or more often, as continuous bladder irrigation (CBI) with sterile normal saline solution or another prescribed solution. If the bladder is manually irrigated, instill 50 mL of irrigating solution. Then withdraw with a syringe to remove clots that may be in the bladder and catheter. Painful bladder spasms often occur with manual irrigation.

With CBI, irrigating solution is continuously infused and drained from the bladder. The rate of infusion is based on the color of drainage. The urine drainage should be light pink without clots. Continuously monitor the inflow and outflow of the irrigant (Table 59.5). If outflow is less than inflow, assess the catheter patency for kinks or clots. If the outflow is blocked and patency cannot be reestablished by manual irrigation, stop the CBI and notify the HCP.

Blood clots are expected after prostate surgery for the first 24 to 36 hours. However, large amounts of bright red blood in the urine can indicate bleeding. Bleeding may occur from catheter displacement, dislodgment of a large clot, or increased abdominal pressure.

Release or displacement of the catheter dislodges the balloon that provides counterpressure on the operative site. Traction on the catheter may be applied to provide counterpressure (tamponade) on the bleeding site in the prostate, thereby decreasing bleeding. Such traction can result in local necrosis if pressure is applied for too long. Pressure should be relieved on a scheduled basis by qualified personnel.

The patient should avoid activities that increase abdominal pressure in the recovery period. These include sitting or walking for prolonged periods and straining to have a bowel movement (Valsalva maneuver).

TABLE 59.5 NURSING MANAGEMENT

Patient Receiving Bladder Irrigation

- Continuously monitor the inflow and outflow of the irrigant.
- Assess for bleeding and the presence of bladder spasms.
- Assess catheter patency for kinks or clots.
- Manually irrigate catheter if bladder spasms or decreased outflow occurs.
- Use careful aseptic technique because you can easily introduce bacteria into the urinary tract.
- Maintain a closed drainage system.
- Give antispasmodics and analgesics as needed.
- Monitor catheter drainage for increased blood or clots.
- Do not disconnect the system unless it is being removed, changed, or irrigated.
- Discontinue CBI and notify HCP if obstruction occurs.
- Secure the catheter to the leg with tape or a catheter strap to prevent urethral irritation and minimize the risk for infection.
- Teach patient Kegel exercises after catheter removal.
- Provide care instructions for patient discharged with indwelling catheter.

Bladder spasms are a distressing complication. They occur because of irritation of the bladder mucosa from the insertion of the resectoscope, presence of a catheter, or clots leading to catheter obstruction. If bladder spasms develop, check the catheter for clots. If present, remove the clots by irrigation so that urine can flow freely. Tell the patient not to urinate around the catheter because this increases the chance of spasm. Belladonna and opium suppositories or other antispasmodics (e.g., oxybutynin), along with relaxation techniques, can relieve pain and decrease spasm.

We often remove the catheter 2 to 4 days after surgery. The patient should have a voiding trial after catheter removal. If he cannot urinate, he will have a catheter reinserted for a day or so or perform clean intermittent self-catheterization (see Chapter 50).

Sphincter tone may be poor right after catheter removal, resulting in urinary incontinence or dribbling. This is a common but distressing situation for the patient. Performing Kegel exercises (pelvic floor muscle technique) 10 to 20 times per hour while awake (see Table 50.18) can strengthen sphincter tone. Encourage the patient to practice starting and stopping the stream several times during urination. This helps the patient to target the correct pelvic floor muscles when doing Kegel exercises.

It can take several weeks to achieve urinary continence. In some instances, control of urine may never be fully regained. Continence can improve for up to 12 months. If continence has not been achieved by that time, the patient may be referred to a continence clinic. A variety of methods, including biofeedback, have been used to achieve positive results.

Teach the patient how to use a penile clamp, a condom catheter, or incontinence pads or briefs to avoid embarrassment from dribbling. In severe cases, an occlusive cuff that serves as an artificial sphincter can be surgically implanted to restore continence. Help the patient find ways to manage the problem that allow him to continue socializing and interacting with others. Urinary incontinence is discussed in Chapter 50.

Observe the patient for signs of infection. If an external wound is present (e.g., from an open, laparoscopic, or robotic-assisted prostatectomy), assess the area for redness, heat, swelling, and purulent drainage. Take special care if a perineal incision is present because of the proximity of the anus. Avoid rectal procedures, such as rectal temperatures and enemas. The insertion of well-lubricated belladonna and opium suppositories is acceptable.

Diet intervention and stool softeners are important to prevent the patient from straining while having bowel movements. Straining increases the intraabdominal pressure, which can lead to bleeding at the operative site. A diet high in fiber promotes the passage of stool.

Ambulatory Care

Discharge planning and home care issues are important after prostate surgery. Teaching, especially about the procedure and the possible complications, directly impacts quality of life. Teaching includes (1) caring for an indwelling catheter (if present), (2) managing urinary incontinence, (3) maintaining fluid intake, (4) observing for signs and symptoms of urinary tract and wound infection, (5) preventing constipation, (6) avoiding heavy lifting (more than 10 lb [4.5 kg]), and (7) refraining from driving or intercourse after surgery as directed by the HCP.

The patient may have a change in sexual function after surgery (Box 59.1). Recovery depends on the type of surgery done and the interval of time between when symptoms first appeared and the date of surgery. For example, it may 2 years for complete sexual function to return after nerve-sparing prostatectomy. Many men have retrograde ejaculation because of trauma to the internal urethral sphincter. ED may occur if the nerves are cut or damaged during surgery. The patient may have anxiety over the change because of a perceived loss of his sex role, self-esteem, or quality of sexual interaction with his partner. Discuss these changes with the patient and his partner and allow them to ask questions and express their concerns. Sexual counseling and treatment options may be needed if ED becomes a chronic issue.

The bladder may take 2 months to return to its normal capacity. Teach the patient to drink at least 2 to 3 L of fluid per day and urinate every 2 to 3 hours to flush the urinary tract. Teach the patient to avoid or limit the amounts of bladder irritants, such as caffeine products, citrus juices, and alcohol. Because the patient may have incontinence or dribbling, he may incorrectly believe that decreasing fluid intake will relieve this problem.

Urethral strictures may result from instrumentation or catheterization. Treatment may include teaching the patient intermittent clean self-catheterization or having a urethral dilation.

Tell the patient to discuss the need for a yearly DRE with his HCP if he has had any procedure other than complete removal of the prostate. Hyperplasia or cancer can occur in the remaining prostatic tissue.

Evaluation

The expected outcomes are that the patient with BPH who has surgery will report:

- Acceptable pain control
- Improved urinary function with no pain or incontinence

BOX 59.1 EVIDENCE-BASED PRACTICE

Effect of a Sexual Health Discharge Program

You are caring for D.P., a 62-year-old patient who had a TURP. D.P. has been on your surgical unit for 2 days and is ready for discharge. As you are reviewing postoperative self-care, you discuss D.P.'s understanding of the possible effects of surgery on sexual function.

Making Clinical Decisions

Synthesis of Best Available Evidence

A TURP often is associated with stress incontinence, stricture, and erectile and ejaculatory dysfunction. Patients may have distress about their sexual function and sexuality. Managing sexual problems is an important part of holistic care for a patient recovering after TURP.

Clinician Expertise

Standardized discharge instructions after TURP include information about the hospital's nurse-led sexual health program available to patients who had a TURP. You explain to D.P. that the program is based on a thorough review of the literature and consults with urology experts. The program involves 3 weekly 1-hr group sessions with the urology nurse practitioner.

Patient Preferences and Values

D.P. responds, "I wasn't excited about having this surgery. However, I was up to the bathroom many times during the night…I can't remember the last time I had a full night's sleep…and I know that was disruptive for my wife. Now that the surgery is behind me, I need to find my way to a complete recovery."

Implications for Nursing Practice

1. What topics on sexual function after TURP should we address before discharge?
2. Should we include patients' partners in the discharge program?

Reference for Evidence

BOX 59.2 PROMOTING HEALTH EQUITY

Cancers of the Male Reproductive System

Prostate Cancer

- Black men have the highest rate of prostate cancer.
- Black men are diagnosed with prostate cancer at an earlier age, have more advanced disease at the time of diagnosis, and have a higher mortality rate than do White men.
- Although the mortality rate for prostate cancer among Black men is high, the mortality rate is declining.
- Asian American men have a lower incidence and lower mortality rates from prostate cancer than White men.

Testicular Cancer

- Testicular cancer occurs most often among White men.

PROSTATE CANCER

Prostate cancer is a tumor of the prostate gland. Prostate cancer is the most common cancer among men, excluding skin cancer. It is the second leading cause of cancer death in men, exceeded only by lung cancer. The American Cancer Society (ACS) estimates that in 2021 there will be 248,530 men diagnosed with prostate cancer, and 34,130 men will die from prostate cancer. A man has a 1 in 8 risk for developing prostate cancer in his lifetime. More than 3.1 million men in the United States are prostate cancer survivors.[7]

Etiology and Pathophysiology

Prostate cancer is a slow-growing, androgen-dependent cancer. It is most likely to develop in the outer part of the prostate, called the peripheral zone. It can spread by 3 routes: by direct extension, through the lymph system, or through the bloodstream. Spread by direct extension involves the seminal vesicles, urethral mucosa, bladder wall, and external sphincter. The cancer later spreads through the lymphatic system to the regional lymph nodes. The bloodstream is the mode of spread to the axial skeleton (e.g., pelvic bones, head of the femur, lower lumbar spine), liver, and lungs.

Age, ethnicity, and family history are known risk factors for prostate cancer (Box 59.2). The incidence of prostate cancer rises markedly after age 50. The median age at diagnosis is 66 years old. However, many cases occur in younger men. They sometimes have a more aggressive type of cancer.

Diet factors and obesity may be related to prostate cancer. A diet high in red and processed meat and high-fat dairy products along with a low intake of vegetables and fruits may increase the risk for prostate cancer. Environment may play a role. There is an increased prevalence of prostate cancer in farmers and commercial pesticide applicators. This might be due to chemicals found in pesticides. It is not clear if smoking is a risk factor.

Genetic Link

Currently no known single gene causes prostate cancer. Some genes or gene mutations are more common in men with prostate cancer. From a genetics viewpoint, we classify prostate cancer into 3 categories.

Most prostate cancers (about 75%) are *sporadic,* which means that damage to the genes occurs by chance after a person is born. Prostate cancer that runs in a family, called *familial prostate cancer,* is less common (about 20%). It occurs because of a combination of genes and environment or lifestyle factors. Familial prostate cancer is when 2 or more first-degree relatives (father, brother, son) have prostate cancer.

Hereditary (inherited) prostate cancer is rare (5% to 10%). It occurs when gene mutations are passed down in a family from 1 generation to the next. In hereditary prostate cancer, a family has any of the following characteristics: (1) 3 or more first-degree relatives with prostate cancer, (2) prostate cancer in 3 generations on the same side of the family, and (3) 2 or more close relatives (father, brother, son, grandfather, uncle, nephew) on the same side of the family diagnosed with prostate cancer before age 55.

Having a family history does not mean that a man will develop prostate cancer. It means that he has an increased risk. Men with a family history of prostate cancer should talk with their HCP about their concerns. It is important for the HCP to obtain a detailed family history. Depending on the findings, a referral to a genetic counselor may be appropriate.

Hereditary breast and ovarian cancer (HBOC) syndrome is associated with mutations in the *BRCA1* and/or *BRCA2* genes (BRCA stands for *BR*east *CA*ncer). Women with HBOC have an increased risk for breast and ovarian cancer. Men with HBOC have an increased risk for breast cancer and prostate cancer. Mutations in *BRCA1* and *BRCA2* cause only a small number of familial prostate cancers. Genetic testing may be appropriate for families with prostate cancer that have HBOC.

Clinical Manifestations and Complications

Prostate cancer typically has no symptoms in the early stages. Eventually, the patient may have LUTS similar to those of BPH. Pain in the lumbosacral area that radiates down to the hips or the legs, when combined with urinary symptoms, may indicate metastasis.

The tumor can spread to pelvic lymph nodes, bones, bladder, lungs, and liver. Once the tumor has spread to distant sites, the major problem becomes pain. As the cancer spreads to the bones (common site of metastasis), pain can become severe, especially in the back and legs because of spinal cord compression and bone destruction.

Diagnostic Studies

Most men in the United States with prostate cancer are diagnosed by PSA screening. As prostate cancer screening has become more widespread, smaller cancers are being found in older men. In most cases, slow-growing cancers probably do not need to be treated. Many men live and die *with* prostate cancer, but most will not die *from* it.

Men can make an informed decision with their HCP about whether to be screened for prostate cancer. Men should be told about the potential risks (e.g., subsequent evaluation and treatment that may not be needed) and benefits (early detection of prostate cancer) of PSA screening before being tested. After this discussion, men who want to be screened may have an annual PSA test and DRE. On DRE, an abnormal prostate may feel hard, nodular, and asymmetric.

The AUA states that men ages 55 to 69 have the greatest potential benefit from PSA screening. They recommend shared decision making and potential screening every 2 years. Men at higher risk (Black men, men with a first-degree relative with prostate cancer) should have a more personalized screening schedule.

The ACS recommends men decide about screening after they discuss information about the risks and benefits with their HCP.[8] This discussion should take place at:

- Age 50 for men who are at average risk for prostate cancer and expected to live at least 10 more years.
- Age 45 for men at high risk for developing prostate cancer. This includes Blacks and men who have a first-degree relative (father, brother, son) diagnosed with prostate cancer at an early age (younger than age 65).
- Age 40 for men at even higher risk (those with more than 1 first-degree relative who had prostate cancer at an early age).

High PSA levels do not always indicate prostate cancer. Mild PSA increases may occur with aging, BPH, recent ejaculation, constipation, prostatitis, or after long bike rides. Cystoscopy, indwelling urethral catheters, and prostate biopsies may cause transient increases in PSA levels.

Neither PSA nor DRE is a definitive diagnostic test for prostate cancer. If PSA levels are continually high or if the DRE is abnormal, a biopsy of the prostate tissue is usually done. Biopsy can confirm the diagnosis of prostate cancer. The biopsy is typically done using a transrectal approach. In a TRUS procedure, an ultrasound probe allows the HCP to see abnormalities in the prostate. When a suspicious area is found, biopsy needles are inserted through the wall of the rectum into the prostate to obtain tissue samples. A pathologic examination of the specimen is done to assess for cancer. For patients at a high risk for infection with a transrectal biopsy, or with a history of prior post-biopsy sepsis, a transperineal approach is another option if it is available. There can be a lower risk for infection with the transperineal approach as the biopsy needles do not pierce the rectal wall. It is typically done in the operating room.

Another approach for biopsies is to use an MRI/ultrasound fusion biopsy. In this approach, pelvic MRI 3-dimensional images are fused with real-time, TRUS images. This technique is more accurate than the traditional approach. Typically, men who undergo this procedure have a history of a previous negative ultrasound-guided biopsy and increasing PSA. This approach may also be used for men who are on active surveillance. Recent studies show risk assessment with MRI before biopsy and MRI-targeted biopsy are better than standard TRUS biopsy in men at risk for prostate cancer who have not had a prostate biopsy before.[5]

PSA is used to monitor the success of treatment. When treatment has been successful, with either prostatectomy or hormone therapy, PSA levels should decrease to undetectable levels. With successful radiation therapy, the PSA level should decrease to a very low number (the nadir) and remain stable near that number. The regular measurement of PSA levels after treatment is important to evaluate the effectiveness of treatment and possible recurrence of prostate cancer.[8]

With advanced prostate cancer, serum alkaline phosphatase can be increased because of bone metastases. Other tests used to determine the location and extent of the spread of the cancer may include a nuclear medicine whole body bone scan, a CT scan of the abdomen and pelvis, and an MRI of the pelvis with special attention to the prostate.

Interprofessional Care

Chemoprevention of prostate cancer is an active area of research. Finasteride and dutasteride, used to treat BPH, may reduce the chance for getting prostate cancer. Men who are concerned about prostate cancer should discuss with their HCP the risks and benefits of taking finasteride or dutasteride.

Early recognition and treatment are important to control tumor growth, prevent metastasis, and preserve quality of life. Most patients with prostate cancer are diagnosed when the cancer is at a local or regional stage.[8] The 5-year survival rate with a diagnosis at this stage is almost 100%.

The most common classification system for determining the extent of prostate cancer is the tumor, node, and metastasis (TNM) system (Table 59.6). The tumor is graded based on tumor histology using 2 different grading systems: the Gleason

TABLE 59.6 Staging of Prostate Cancer

Stage	Tumor Size	Lymph Node Involvement	Metastasis	PSA Level	Gleason Score
I	Not felt on DRE. Not seen by visual imaging.	No	No	<10	≤6
II	Felt on DRE. Seen by imaging. Tumor confined to prostate.	No	No	10–20	6–7
III	Cancer outside prostate. Possible spread to seminal vesicles.	No	No	Any level	Any score
IV	Any size.	Any nodal involvement.	Yes	Any level	Any score

Adapted from ACS: How is prostate cancer staged? Retrieved from https://www.cancer.org/Cancer/ProstateCancer/DetailedGuide/prostate-cancer-staging.

score and the Grade Group. The Gleason score grades the tumor from 3 to 5 based on the degree of glandular differentiation. Grade 3 represents the most well-differentiated or lowest grade (most like the original cells), and grade 5 represents the most poorly differentiated (unlike the original cells) or highest grade. The 2 most commonly occurring patterns of cells are graded, and the 2 scores are added together to create a Gleason score. Gleason score ranges from 6 to 10. Currently the lowest risk Gleason score is Gleason 6 (3+3).

The Grade Group system grades the cells based on their differentiation. The Grade Group assigns the tumor a number on a scale from 1 to 5. Grade Group 1 is the lowest risk, and Grade Group 5 the highest risk. Currently, the Gleason score and the Grade Group system are used together. A low-risk, well-differentiated prostate cancer specimen may be graded a Grade Group 1, Gleason 6 (3+3) prostate cancer. The trend is moving toward Grade Group scoring only.

The PSA level at diagnosis and the Gleason score and Grade Group are used with the TNM system to determine the stage of the tumor, which is vital to determine treatment options.

The care of the patient with prostate cancer depends on the stage of the cancer and the patient's overall health (Table 59.7). None of the diagnostic options can predict the progression of prostate cancer. At all stages, there is more than one treatment option depending on the stage, Gleason score, and PSA. The decision of which treatment to pursue should be made jointly by patients, their partners, and the health care team.[8]

TABLE 59.7 Interprofessional Care

Prostate Cancer

Diagnostic Assessment
- History and physical assessment with DRE
- PSA
- TRUS or pelvic MRI
- Prostate biopsy
- Whole body bone scan (to assess for bone metastases)
- CT abdomen and pelvis with contrast (to assess for metastatic disease)

Management

Active Surveillance
- Closely monitor PSA and DRE (annually, at minimum)
- Repeat/surveillance prostate biopsies
- Repeat imaging
- Consider genomic testing on biopsy tissue, if appropriate

Surgery
- Radical prostatectomy
- Cryotherapy
- Orchiectomy (for metastatic disease)

Radiation Therapy
- External beam for primary, adjuvant, and recurrent disease
- Brachytherapy

Drug Therapy
- Androgen deprivation therapy (Table 59.7)
- Chemotherapy for metastatic disease

Active Surveillance

Low-grade prostate cancer is slow growing. Therefore a conservative approach is active surveillance, or "watchful waiting." This strategy is appropriate when the patient has (1) a life expectancy of less than 10 years (low risk for dying of the disease); (2) a low-grade, low-stage tumor; and (3) serious coexisting medical conditions. With active surveillance, patients are typically followed with frequent PSA measurements and DRE to monitor the progress of the disease. Significant changes in PSA level, DRE, or the development of symptoms warrant a reevaluation of treatment options.

Surgical Therapy

Radical prostatectomy. With **radical prostatectomy**, the entire prostate gland, seminal vesicles, and part of the bladder neck (ampulla) are removed. The entire prostate is removed because the cancer tends to be in many different places within the gland. A pelvic lymph node dissection is typically done at the same time as prostatectomy to assess for nodal metastases in the local pelvic area. Typically, a higher number of lymph nodes are removed if the prostate cancer is higher grade/higher risk on biopsy. Surgery is usually not an option for advanced-stage disease except to relieve symptoms from obstruction.

Traditional surgical approaches for an open radical prostatectomy include retropubic and perineal approaches (Fig. 59.6). With the *retropubic* approach, a low midline abdominal incision is made to access the prostate gland and the pelvic lymph nodes can be dissected. With the *perineal* resection, an incision is made between the scrotum and anus.

With a robotic assisted (e.g., da Vinci system) prostatectomy, the HCP sits at a computer console while controlling

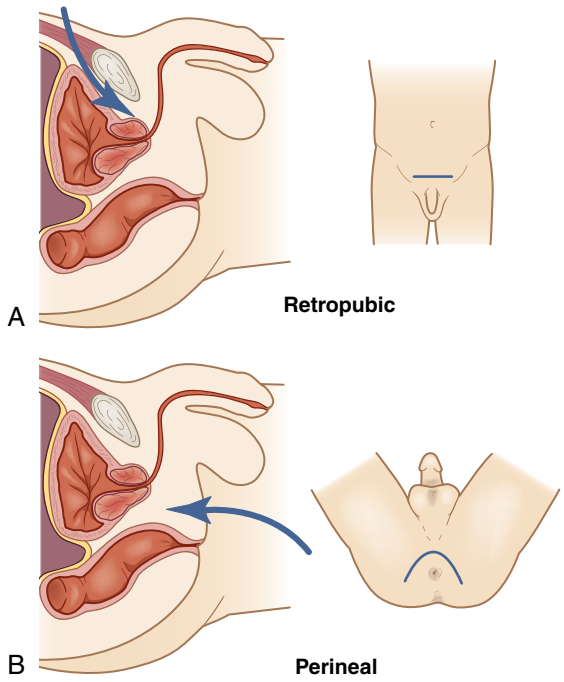

Fig. 59.6 Common approaches used to perform a prostatectomy. (A) Retropubic approach involves a midline abdominal incision. (B) Perineal approach involves an incision between the scrotum and the anus.

high-resolution cameras and microsurgical instruments. Robotics is being used more often since it allows for increased precision, visualization, and dexterity by the HCP when removing the prostate gland. It results in less bleeding, less pain, and a faster recovery compared with other approaches.[9]

After surgery, the patient has a large indwelling catheter with a 10- or 30-mL balloon placed in the bladder via the urethra. A drain is left in the surgical site to aid in removing drainage from the area. This drain is typically removed after a few days. Because the perineal approach has a higher risk for infection (location of the incision related to the anus), careful dressing changes and perineal care after each bowel movement are important for comfort and to prevent infection. Depending on the type of surgery, the length of hospital stay ranges from 1 to 3 days.

Two major adverse outcomes after a radical prostatectomy are ED and urinary incontinence. The incidence of ED depends on the patient's age, preoperative sexual function, whether nerve-sparing surgery was done, and the HCP's expertise. Sexual function tends to return gradually over at least 24 months or more. Phosphodiesterase type 5 (PDE5) inhibitor drugs may help improve sexual function.

Problems with urinary control may occur for the first few months after surgery because the bladder must be reattached to the urethra after the prostate is removed. Over time, the bladder adjusts, and most men regain urinary continence. Kegel exercises strengthen the pelvic floor muscles and the urinary sphincter. They may help improve continence (see Table 50.18). Other complications of surgery include bleeding, lymphocele, urinary retention, infection, wound dehiscence, and VTE.

Nerve-sparing procedure. Near the prostate gland are neurovascular bundles that maintain erectile function. The preservation of these bundles during a prostatectomy is possible while still removing all the cancer. Nerve-sparing prostatectomy is not indicated for patients with cancer outside of the prostate gland. Although the risk for ED is reduced with this procedure, there is no guarantee that potency will be maintained.

Cryotherapy. *Cryotherapy* (cryoablation) is a surgical technique that destroys cancer cells by freezing the tissue. It has been used both as an initial treatment and as a second-line treatment after radiation therapy has failed. A TRUS probe is inserted to see the prostate gland. Probes containing liquid nitrogen are then inserted into the prostate. Liquid nitrogen delivers freezing temperatures, thus destroying the tissue. The treatment takes about 2 hours under general or spinal anesthesia. It does not involve an abdominal incision.

Complications include damage to the urethra and, in rare cases, an urethrorectal fistula (an opening between the urethra and rectum) or a urethrocutaneous fistula (an opening between the urethra and skin). Tissue sloughing, ED, urinary incontinence, prostatitis, and bleeding can occur.

Radiation Therapy

Radiation therapy is another common treatment option. Radiation therapy may be the only treatment, or it may be used in combination with surgery or with hormone therapy. Salvage radiation therapy given for prostate cancer recurrence after a radical prostatectomy may improve survival in some men.

External beam radiation. External beam radiation is the most widely used method of delivering radiation treatments for prostate cancer. This therapy can be used to treat cancer confined to the prostate and/or surrounding tissue. Patients are usually treated on an outpatient basis 5 days a week for 4 to 8 weeks. Each treatment lasts less than 1 hour.

Side effects from radiation can be acute (occurring during treatment or within 90 days that follow) or delayed (occurring months or years after treatment). The most common side effects involve changes to the skin (dryness, redness, irritation, pain), gastrointestinal tract (diarrhea, abdominal cramping, bleeding, radiation proctitis), urinary tract (dysuria, hematuria, frequency, hesitancy, urgency, nocturia, radiation cystitis), and sexual function.[10] Fatigue may occur. There is a rare risk for secondary cancers after radiation to the pelvic area (e.g., bladder cancer, rectal cancer). In patients with localized prostate cancer, cure rates with external beam radiation are comparable with those with radical prostatectomy.

Brachytherapy. *Brachytherapy* involves placing radioactive seed implants into the prostate gland. This delivers high doses of radiation directly to the tissue while sparing the surrounding tissue (rectum and bladder). The radioactive seeds are placed in the prostate gland with a needle through a grid template guided by TRUS (Fig. 59.7) to ensure correct placement of the seeds.

Because brachytherapy is a 1-time outpatient procedure, many patients find this more convenient than external beam radiation treatment. Brachytherapy is best suited for patients with early-stage disease. The most common side effect is the development of urinary irritative or obstructive problems.

Some men may have ED. The AUA-SI (Table 59.1) can measure urinary function for patients undergoing brachytherapy and can be part of nursing management. For those with more advanced tumors, brachytherapy may be used in combination with external beam radiation treatment. Brachytherapy is discussed in Chapter 16.

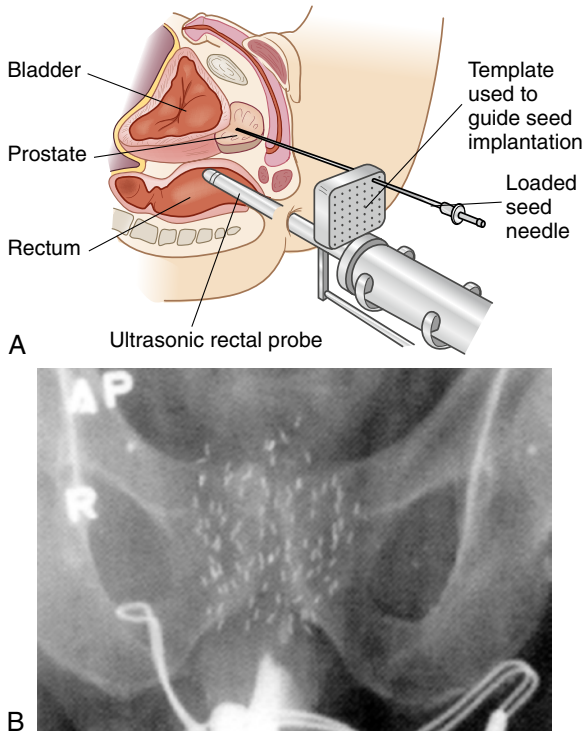

Fig. 59.7 (A) Prostate brachytherapy. Implantation of radioactive seeds with a needle guided by ultrasound and a template grid. (B) Radioactive seeds. (B, From Abeloff MD, Armitage JO, Niederhuber JE, et al., editors: *Abeloff's clinical oncology,* ed 4, Philadelphia, 2008, Churchill Livingstone.)

Drug Therapy

Drug therapy for the treatment of advanced or metastatic prostate cancer includes androgen deprivation (hormone) therapy, chemotherapy, or a combination of both.

Androgen deprivation therapy. Prostate cancer growth is largely dependent on the presence of androgens. *Androgen deprivation therapy* (ADT) reduces the levels of circulating androgens to reduce the tumor growth. Androgen deprivation can be produced by inhibiting androgen production or blocking androgen receptors (Table 59.8).

One of the biggest challenges with ADT is that almost all tumors treated become resistant to this therapy *(hormone refractory)* within a few years. A high PSA level is often the first sign that this therapy is no longer effective. Patients taking ADT have an increased risk for cardiovascular side effects, including high serum cholesterol and triglyceride levels and coronary artery disease.[11]

Osteoporosis and fractures may occur in those receiving ADT. Drugs recommended to reduce bone mineral loss include zoledronic acid (Reclast) and raloxifene (Evista). Zoledronic acid is a bisphosphonate therapy given IV. A rare complication of therapy is osteonecrosis of the jaw. Denosumab (Prolia, Xgeva), a drug that slows the breakdown of bone, may be used to increase bone mass in men with nonmetastatic prostate cancer.

Androgen synthesis inhibitors. The hypothalamus produces luteinizing hormone–releasing hormone (LHRH), which stimulates the anterior pituitary to produce luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH

TABLE 59.8 Drug Therapy

Androgen Deprivation Therapy for Prostate Cancer

Therapy	Mechanism of Action	Side Effects
Androgen Receptor Blockers		
apalutamide (Erleada) bicalutamide (Casodex) darolutamide (Nubeqa) enzalutamide (Xtandi) nilutamide (Nilandron)	• Block action of testosterone by competing with receptor sites	• Loss of libido, ED • Hot flashes • Breast pain, gynecomastia
Androgen Synthesis Inhibitors		
CYP17 Enzyme Inhibitor		
abiraterone (Zytiga)	• Inhibits CYP17, an enzyme needed to produce testosterone • Inhibits testosterone synthesis from testes, adrenal glands, and prostate cancer cells	• Joint swelling, fluid retention • Muscle aches • Hot flashes • Diarrhea
LHRH Agonists		
goserelin (Zoladex) leuprolide (Eligard, Lupron Depot) triptorelin (Trelstar)	• ↓ Secretion of LH and FSH • ↓ Testosterone production	• Hot flashes, gynecomastia, ↓ libido, ED • Depression, mood changes
LHRH Antagonist		
degarelix (Firmagon)	• Blocks LH receptors • Immediate testosterone suppression	• Pain, redness, swelling at injection site • ↑ Liver enzymes

stimulates the testicular Leydig cells to make testosterone. *LHRH agonists* super stimulate the pituitary, downregulating the LHRH receptors and leading to a refractory condition in which the anterior pituitary is unresponsive to LHRH. These drugs cause an initial transient increase in LH and FSH; testosterone abruptly rises resulting in a *flare*. Symptoms may worsen during this time. However, with continued administration, LH and testosterone levels decrease.

LHRH agonists include goserelin (Zoladex), leuprolide (Lupron Depot, Eligard), and triptorelin (Trelstar) (Table 59.8). These drugs produce a chemical castration similar to the effects of an orchiectomy. They are given by subcutaneous or IM injections on a regular basis.

Degarelix (Firmagon) is an LHRH antagonist. It lowers testosterone levels to castration levels. Unlike the LHRH agonists, degarelix does not cause a testosterone flare because it acts directly to block LH and FSH receptors. It is given as a subcutaneous injection. Results are seen in 3 days.

Abiraterone (Zytiga) works by inhibiting an enzyme, CYP17, which is needed to produce testosterone. This drug is given orally to men with castration-resistant prostate cancer, usually in combination with prednisone. It improves overall survival by 4 to 5 months.

Androgen receptor blockers. Androgen receptor blockers are another classification of antiandrogen drugs that compete with circulating androgens at the receptor sites. These drugs include bicalutamide (Casodex), enzalutamide (Xtandi), apalutamide (Erleada), darolutamide (Nubeqa), and nilutamide (Nilandron). They are taken orally each day. They be used in combination with an LHRH agonist (e.g., goserelin). Combining an androgen receptor blocker with an LHRH agonist results in combined androgen blockade.

Chemotherapy. Chemotherapy is limited to treatment for those with hormone-refractory prostate cancer (HRPC) in late-stage disease. In HRPC the cancer is progressing despite treatment. This occurs in patients who have taken an antiandrogen for a certain period. The goal of chemotherapy is mainly palliative. Common chemotherapy drugs include cabazitaxel (Jevtana), cyclophosphamide, docetaxel (Taxotere), estramustine (Emcyt), mitoxantrone, paclitaxel (Abraxane), and vinblastine.

Men with advanced prostate cancer who have HRPC may receive a vaccine (sipuleucel-T [Provenge]). We do not know exactly how, but the vaccine stimulates the patient's immune system against the cancer. Use prolongs survival by about 4 months. It is individually prepared for each man by a process that combines his own WBCs with granulocyte-macrophage colony-stimulating factor (GM-CSF), which then attacks the prostate tumor cells.

Radiotherapy. Radium-223 dichloride (Xofigo) can be used in the treatment of patients with castration-resistant prostate cancer, symptomatic bone metastases, and no known visceral metastatic disease. It is an alpha particle–emitting radiotherapy drug that mimics calcium and forms complexes with hydroxyapatite at areas of increased bone turnover, such as bone metastases.

Orchiectomy. A bilateral orchiectomy is the surgical removal of the testes. It may be done alone or after prostatectomy. It is the gold standard for androgen deprivation. For advanced stages of prostate cancer, an orchiectomy is an option for cancer control, with rapid relief of bone pain associated with advanced tumors. Orchiectomy may shrink the prostate, thus relieving urinary obstruction in the later stages of disease when surgery is not an option. After an orchiectomy, weight gain and loss of muscle mass can change a man's physical appearance. These physical changes can affect self-esteem, leading to grief and depression. Because this procedure is permanent, many men prefer drug therapy over an orchiectomy.

Culturally Competent Care: Prostate Cancer

Nurses need to be aware of ethnic and cultural considerations when providing information about the risk for prostate cancer and screening recommendations. Consider not only the ethnic differences in the incidence of prostate cancer but also differences in health promotion practices.

Black men have the highest mortality rates from prostate cancer, in part because their prostate cancer often is more advanced at the time of diagnosis (Box 59.2). Despite the availability of screening measures, Black men and those in lower socioeconomic groups may not access these services. This is only partially related to knowledge levels about prostate cancer. In comparison with White men, Black men with prostate cancer report more problems with financial access to transportation and health care costs. They describe using more religious coping strategies.[12]

Although exposure to electronic and print media is successful in informing some men about prostate cancer, the effectiveness differs significantly based on demographic variables, such as ethnicity, age, education level, and socioeconomic level. Ideally, all men should be aware of the risks of prostate cancer and the screening methods available. Consider the best method to communicate this information to men of all cultures and ethnicities to promote understanding and participation in prostate cancer screening for men in at-risk groups.

NURSING MANAGEMENT: PROSTATE CANCER

Assessment

Subjective and objective data that you should obtain from a patient with prostate cancer are outlined in Table 59.9.

Clinical Problems

Clinical problems for the patient with prostate cancer depend on the stage of the cancer. These may include:

- Deficient knowledge
- Pain
- Impaired urinary elimination
- Impaired sexual function
- Difficulty coping

Planning

The overall goals are that the patient with prostate cancer will (1) be an active participant in the treatment plan, (2) have acceptable pain control, (3) follow the treatment plan, (4) understand

TABLE 59.9 NURSING ASSESSMENT

Prostate Cancer

Subjective Data

Important Health Information

Medications: Testosterone supplements. Use of any drugs affecting urinary tract such as morphine, anticholinergics, monoamine oxidase inhibitors, tricyclic antidepressants

Functional Health Patterns

Health perception–health management: Positive family history. ↑ Fatigue and malaise

Nutritional-metabolic: High-fat diet. Anorexia, weight loss (may indicate metastasis)

Elimination: Hesitancy or straining to start stream, urinary urgency, frequency, retention with dribbling, weak stream, hematuria

Sleep-rest: Nocturia

Cognitive-perceptual: Dysuria. Low back pain radiating to legs or pelvis, bone pain (may indicate metastasis). Pain level

Self-perception–self-concept: Anxiety about self-concept

Objective Data

General

Older adult male. Pelvic lymphadenopathy (late sign)

Urinary

Distended bladder on palpation. Unilaterally hard, enlarged, fixed prostate on rectal examination

Possible Diagnostic Findings

Serum PSA. Serum alkaline phosphatase. Nodular and irregular prostate on ultrasonography, positive biopsy results. Anemia

the effect of the treatment plan on sexual function, and (5) find an acceptable way to manage bladder and bowel function.

Implementation

Health Promotion

One of the most important roles in relation to prostate cancer is to encourage patients, in consultation with their HCPs, to have annual prostate screening (PSA and DRE). Because of their increased risk for prostate cancer, Black men and other men at high risk, such as those with a family history of prostate cancer, should discuss the need for annual PSA and DRE beginning at age 45.[7]

Acute Care

Care of the patient having a radical prostatectomy is similar to surgical procedures for BPH. Care of the patient receiving radiation therapy and chemotherapy are discussed in Chapter 16. Another consideration is the patient's psychologic response to the cancer diagnosis. Provide sensitive, caring support for the patient and his family to help them cope with the diagnosis. Prostate cancer support groups are available for men and their families to encourage them to be active, informed participants in their own care.

Ambulatory Care

Teach catheter care if the patient is discharged with an indwelling catheter in place. Teach the patient to clean the urethral meatus with soap and water once a day; always keep the collection bag lower than the bladder; and keep the catheter securely anchored to the inner thigh or abdomen. Tell them to report any signs of bladder infection, such as bladder spasms, fever, or hematuria. They should maintain a high fluid intake.

If urinary incontinence is a problem, encourage the patient to practice pelvic floor muscle exercises (Kegel exercises) at every urination and throughout the day. Continuous practice during the 4- to 6-week healing process improves the success rate. Products used for incontinence specifically designed for men are available through home care product catalogs and retail stores. Urinary incontinence is discussed in Chapter 50.

Palliative and end-of-life care are often appropriate and beneficial to the patient with advanced disease and his family (see Chapter 10). Common problems with advanced prostate cancer include fatigue, bladder outlet obstruction and ureteral obstruction (caused by compression of the urethra and/or ureters from tumor mass or lymph node metastasis), severe bone pain and fractures (from bone metastasis), spinal cord compression (from spinal metastasis), and leg edema (from lymphedema, VTE). Nursing care must focus on managing these problems.

Pain management is important. Pain control involves ongoing pain assessment, giving prescribed medications (both opioid and nonopioid agents), and nonpharmacologic methods of pain relief (e.g., relaxation breathing). Pain management is discussed in Chapter 9.

Evaluation

The outcomes are that the patient with prostate cancer will:

- Be an active participant in the treatment plan
- Have acceptable pain control
- Follow the treatment plan
- Understand the effect of the treatment on sexual function
- Find an acceptable way to manage bladder or bowel function

PROSTATITIS

Etiology and Pathophysiology

Prostatitis is a broad term that describes a group of inflammatory and noninflammatory conditions affecting the prostate gland. Prostatitis is one of the most common urologic disorders. We believe that 10% of all men in the United States will have prostatitis in their lifetime.[13] Almost 2 million men are treated for prostatitis every year.

The 4 categories of prostatitis syndromes are (1) acute bacterial prostatitis, (2) chronic bacterial prostatitis, (3) chronic prostatitis/chronic pelvic pain syndrome, and (4) asymptomatic inflammatory prostatitis. The most common type is nonbacterial.

Both acute and chronic bacterial prostatitis generally result from organisms reaching the prostate gland by ascending from the urethra, descending from the bladder, or invading via the bloodstream or the lymphatic channels. Common causative organisms are *Escherichia coli* (most common), *Klebsiella, Pseudomonas, Enterobacter, Proteus*, *Chlamydia trachomatis, Neisseria gonorrhoeae,* and group D streptococci.

Chronic bacterial prostatitis differs from acute prostatitis in that it involves recurrent episodes of infection. It is the most common reason for recurrent UTIs in adult men.

Chronic prostatitis/chronic pelvic pain syndrome describes a syndrome of prostate and urinary pain in the absence of an obvious infectious process. The cause of this syndrome is not known. It may occur after a viral illness, or with a sexually transmitted infection (STI), especially in younger adults. A culture reveals no causative organisms. WBCs may be found in prostatic secretions.

Asymptomatic inflammatory prostatitis is usually diagnosed in those who have no symptoms but are found to have an inflammatory process in the prostate. These patients are usually diagnosed during the evaluation of other GU tract problems. WBCs are present in the seminal fluid from the prostate. We do not know the cause.

Clinical Manifestations and Complications

Common manifestations of acute prostatitis include fever, chills, back pain, and perineal pain. Acute urinary symptoms such as dysuria, urinary frequency, urgency, and cloudy urine may occur. The patient may progress to acute urinary retention caused by prostatic swelling if he remains untreated. With DRE, the prostate is extremely swollen, extremely tender, and boggy. The clinical features of prostatitis can mimic those of a UTI. However, remember that acute cystitis is not common in men.

Manifestations of chronic prostatitis are similar but generally milder than those of acute bacterial prostatitis. They include irritative voiding symptoms (frequency, urgency, dysuria), backache, perineal and pelvic pain, and ejaculatory pain. Obstructive symptoms are rare unless there is coexisting BPH. With DRE, the prostate feels enlarged and soft or boggy. It may be slightly tender with palpation. Chronic prostatitis can predispose the patient to recurrent UTIs.

Complications include epididymitis and cystitis. Sexual function may be affected. Manifestations include postejaculation pain, libido problems, and ED. Prostatic abscess is a potential but rare complication.

Diagnostic Studies

Because patients with prostatitis have urinary symptoms, a UA and urine culture and sensitivities are needed. Often WBCs and bacteria are present. The patient with a fever needs blood cultures and a complete blood count (CBC) to check the WBC count. The PSA test may be done to rule out prostate cancer. However, PSA levels are often increased with prostatic inflammation or infection. Thus, when inflammation or infection is present, the PSA may not be diagnostic.

Microscopic evaluation and culture of expressed prostate secretion can potentially be useful in the diagnosis of prostatitis. Expressed prostate secretion is obtained using a premassage and postmassage test. The patient is asked to void into a specimen cup just before and just after a vigorous prostate massage. Prostatic massage (for expressed prostate secretion) is becoming less common unless all other diagnostic options are exhausted. It should not be done if acute bacterial prostatitis is suspected. Compression is extremely painful and can increase the risk for bacterial spread. TRUS is not useful in the diagnosis of prostatitis. However, TRUS or MRI can rule out an abscess in the prostate.

Interprofessional and Nursing Care

Common antibiotics used for acute and chronic bacterial prostatitis include fluoroquinolones (e.g., ciprofloxacin, levofloxacin, ofloxacin), clindamycin, cephalexin, doxycycline, trimethoprim/sulfamethoxazole (Bactrim), or tetracycline. Antibiotics are usually given orally for up to 4 weeks for acute bacterial prostatitis. However, if the patient has high fever or other signs of impending sepsis, they need hospitalized and IV antibiotics.

Chronic bacterial prostatitis may be treated with oral antibiotic therapy for 8 to 12 weeks. Antibiotics may be given for a lifetime if the patient is immunocompromised. A short course of oral antibiotics is usually prescribed for those with chronic prostatitis in case of bacterial infection. However, antibiotic therapy is often ineffective for patients whose prostatitis is not due to bacteria.

Patients with bacterial prostatitis tend to have a great amount of pain. The pain resolves as the infection resolves. However, they may have residual pain for several weeks after a course of antibiotics because it takes time for the prostate to return to normal. Managing pain for patients with chronic prostatitis is more difficult because the pain persists for weeks to months. No single approach provides relief for everyone. Antiinflammatory agents (e.g., ibuprofen, naproxen) may be used for pain control, but these drugs provide only some pain relief.

Warm sitz baths may help to relieve pain. α-Adrenergic blockers (e.g., tamsulosin, alfuzosin) relax muscle tissue in the prostate. They are effective in reducing pain for some men.

Acute urinary retention can develop in acute prostatitis, requiring insertion of a urinary catheter. However, passage of a catheter through an inflamed urethra is contraindicated in acute prostatitis. The patient may need a suprapubic catheter. Repetitive prostatic massage may be recommended as an adjunct therapy. It can relieve congestion within the prostate by squeezing out excess prostatic secretions, providing pain relief. Like massage, measures to stimulate ejaculation (masturbation, intercourse) may help to drain the prostate and provide some relief.

Encourage the patient to drink plenty of fluids. Men with acute bacterial prostatitis have increased fluid needs from fever and infection. Managing fever is important (see Table 12.5).

PROBLEMS OF THE PENIS

We describe problems of the penis as congenital, problems of the prepuce, problems with the erectile mechanism, and cancer. Penis problems are rare once we exclude STIs (see Chapter 57).

CONGENITAL PROBLEMS

Hypospadias is a urologic problem in which the urethral meatus is on the ventral surface of the penis. This can be anywhere from the corona to the perineum. Causes include hormonal influences in utero, environmental factors, and genetic factors.

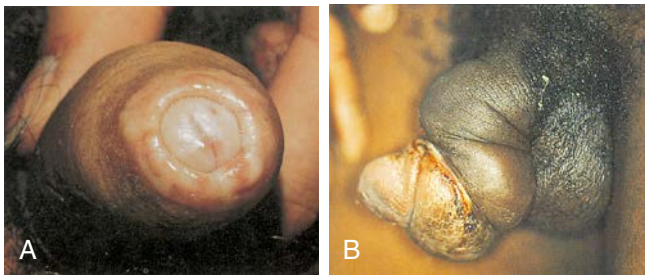

Fig. 59.8 (A) Phimosis: inability to retract the foreskin due to secondary lesions on the prepuce (foreskin). (B) Paraphimosis: ulcer with edema from foreskin remaining contracted over the prepuce (foreskin).

Surgical repair of hypospadias, especially those that are close to the scrotum or perineum, is usually done while the boy is young. Surgery may be done if it is associated with *chordee* (a painful downward curvature of the penis during erection) or if it prevents intercourse or normal urination. Surgery may be considered for cosmetic reasons or emotional well-being in older boys and adult men.

PROBLEMS OF PREPUCE

Problems of the prepuce (foreskin) are not as common in the United States as in most other countries because circumcision (surgical removal of the foreskin of the penis) is a routine procedure for many male infants. When these conditions do occur, they can be very painful and potentially an emergency. It is important to be familiar with these problems so proper treatment and pain relief can be promptly provided.

Phimosis is a tightness or constriction of the foreskin around the head of the penis, making retraction difficult (Fig. 59.8A). It is caused by chronic inflammation of the foreskin. It is usually related to poor hygiene techniques that allow bacterial and yeast organisms to become trapped under the foreskin. Topical corticosteroid cream, with or without an antifungal, applied 2 or 3 times daily to the exterior and interior of the tip of the foreskin may be effective in the initial treatment of inflammation. Definitive treatment is either circumcision or a dorsal slit surgery.

Paraphimosis is tightness of the foreskin resulting in the inability to pull it forward from a retracted position, thus preventing normal return over the glans. It is a urologic emergency. A tightly retracted phimotic ring can compromise arterial flow to the glans. An ulcer can develop if the foreskin stays contracted (Fig. 59.8B). Paraphimosis can occur when the foreskin is pulled back during bathing, use of urinary catheters, or intercourse and is not placed back in the forward position. Replacement of the foreskin after careful cleaning helps prevent this condition. The goal of treatment is to return the foreskin to its natural position over the glans penis through manual reduction. One strategy involves pushing the glans back through the prepuce by applying constant thumb pressure while the index fingers pull the prepuce over the glans. Ice and/or hand compression on the foreskin, glans, and penis may be applied before to reduce edema. Treatment may include antibiotics or warm soaks. Definitive treatment is either circumcision or a dorsal slit.

PROBLEMS OF ERECTILE MECHANISM

Priapism is a painful erection lasting longer than 4 hours. It is caused by complex vascular and neurologic factors that result in an obstruction of venous outflow in the penis. Conditions that may be associated with priapism include sickle cell disease, diabetes, trauma to the spinal cord, degenerative lesions of the spine, and drugs (e.g., cocaine, trazodone). Vasoactive drugs (e.g., alprostadil) injected into the corpora cavernosa for ED can cause priapism. Complications include penile tissue necrosis caused by lack of blood flow or hydronephrosis from bladder distention. Without immediate medical treatment, the risk for permanent ED is high.

Treatment varies depending on the cause. Patients with sickle cell disease may need a blood exchange transfusion. Other patients may be treated with sedatives, an injection of a smooth muscle relaxant directly into the penis, or aspiration and irrigation of the corpora cavernosa with a large-bore needle.

Peyronie disease is caused by plaque formation in the corpora cavernosa of the penis that results in inelasticity during erection. The palpable, nontender, hard plaque formation may occur spontaneously or result from trauma to the penile shaft. The plaque prevents adequate blood flow into the spongy tissue, which results in a curvature during erection. The condition is not dangerous but can result in painful erections, ED, or embarrassment. Patients may improve slightly over time, stabilize, or need surgery. Collagenase clostridium histolyticum (Xiaflex) and intralesional verapamil (ILV) are other options. Each is given as a series of injections into the plaque. The goal of therapy is to reduce the curvature and avoid surgery.

CANCER OF PENIS

Cancer of the penis is rare in the United States. More than 95% are squamous cell carcinoma. It occurs more often in men who have human papillomavirus (HPV) infection and phimosis or uncircumcised men.[14] The tumor may appear as a superficial ulceration or a pimple-like nodule. Pain is rare. This contributes to a delay in seeking treatment. The nontender warty lesion may be mistaken for a genital wart. Treatment in the early stages is laser removal of the growth. A radical resection of the penis may be done if the cancer has spread. Surgery, radiation, or chemotherapy are options, depending on the extent of the disease, lymph node involvement, or metastasis.

PROBLEMS OF SCROTUM AND TESTES

It is important for the patient to see the HCP if he feels any scrotal lumps or painful areas in the scrotum or testes. He would not be able to tell normal variations from cancer when performing self-examination. An incidental finding of a "scrotal lump" may result in high anxiety.

INFLAMMATORY AND INFECTIOUS PROBLEMS

Skin Problems

The skin of the scrotum is susceptible to several common skin problems. The most common are fungal infections, dermatitis

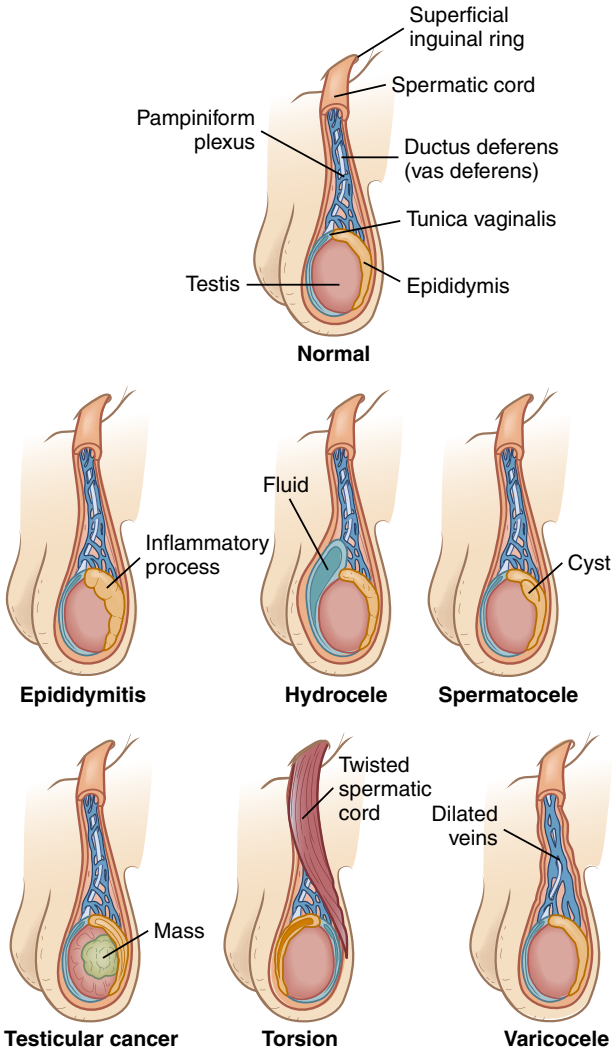

Fig. 59.9 Scrotal masses.

(neurodermatitis, contact dermatitis, seborrheic dermatitis), and parasitic infections (scabies, lice). These conditions involve discomfort but cause few severe complications (see Chapter 25).

Epididymitis

Epididymitis is an acute, painful inflammatory process of the epididymis (Fig. 59.9). It is often due to an infectious process, trauma, or urinary reflux down the ductus (vas) deferens. It is usually unilateral. Swelling may progress to the point that the epididymis and testis are indistinguishable. In men younger than 35 years of age, the most common cause is gonorrhea or chlamydial infection. In men older than 35, the most common cause is *E. coli* infection. BPH and prostatitis are common contributors in older men.

The use of antibiotics is important. We treat both partners if the transmission is through sexual contact. Encourage patients to refrain from sexual intercourse until treatment is complete. They should use a condom if they do engage in intercourse. Conservative treatment consists of elevating the scrotum, ice packs, and analgesics. Ambulation places the scrotum in a dependent position and increases pain. Acute tenderness subsides within 1 week, although some pain and swelling may last for weeks or months.

Fig. 59.10 Hydrocele. (From Swartz MH: *Textbook of physical diagnosis,* ed 6, Philadelphia, 2010, Saunders.)

Orchitis

Orchitis is an acute inflammation of the testis. In orchitis, the testis is painful, tender, and swollen. It generally occurs after an episode of bacterial or viral infection, such as mumps, pneumonia, tuberculosis, or syphilis. It can be a side effect of epididymitis, trauma, infectious mononucleosis, influenza, catheterization, or complicated UTI. Mumps orchitis contributes to infertility. It can be avoided by childhood vaccination against mumps. Treatment is similar to that for epididymitis.

CONGENITAL PROBLEMS

Cryptorchidism (undescended testes) is failure of the testes to descend into the scrotal sac before birth. It is the most common congenital testicular condition. The condition may occur bilaterally or unilaterally. It is more common on the right. We believe it is a contributing factor to male infertility if corrective surgery is not done by age 2. The incidence of testicular cancer is higher if the condition is not corrected before puberty. Surgery is done to locate and suture the testis or testes to the scrotum.

ACQUIRED PROBLEMS

Hydrocele

A *hydrocele* is a nontender, fluid-filled mass that results from interference with lymphatic drainage of the scrotum and swelling of the tunica vaginalis that surrounds the testis (Figs. 59.9 and 59.10). Diagnosis is aided by shining a flashlight through the scrotum (transillumination). No treatment is needed unless the swelling becomes large and uncomfortable, then surgical repair is needed. Hydrocele repair is avoided in men who have not started their family or seek to add to their family as repair can contribute to subfertility or infertility.

Spermatocele

A *spermatocele* is a firm, sperm-containing cyst of the epididymis. It may be visible with transillumination (Fig. 59.9). The cause is unknown. They can become large, tense, and painful. Their size can wax and wane with time. Spermatocele repair is avoided in men who have not started their family or seek to

add to their family as repair can contribute to subfertility or infertility.

Varicocele

A *varicocele* is a dilation of the veins that drain the testes (Fig. 59.9). The scrotum can feel worm-like when palpated if the venous dilation is significant. We do not know the cause of the problem. A varicocele is usually on the left side of the scrotum because of retrograde blood flow from the left renal vein.

Varicoceles are associated with 40% to 50% of cases of infertility. We think that the varicocele damages the sperm. Surgery is considered if fertility is a concern. Repair options include injecting a sclerosing agent or surgical ligation of the spermatic vein.

Testicular Torsion

Testicular torsion involves a twisting of the spermatic cord that supplies blood to the testes and epididymis (Fig. 59.9). It is considered a surgical emergency. It most often occurs in males younger than age 20. It can occur spontaneously or because of trauma or an anatomic abnormality.

The patient has severe, sudden onset of scrotal pain, tenderness, swelling, nausea, and vomiting. The pain does not usually subside with rest or elevating the scrotum. The cremasteric reflex is absent on the side of the swelling. Normal anatomic landmarks are lost due to tissue edema.

A Doppler ultrasound is done to assess blood flow within the testicle. Decreased or absent blood flow confirms the diagnosis. Torsion is an emergency! If the blood supply to the affected testicle is not restored within 4 to 6 hours, ischemia to the testis will occur, leading to necrosis. Unless the torsion resolves spontaneously, surgery to untwist the cord and restore the blood supply must be done emergently.

TESTICULAR CANCER

Etiology and Pathophysiology

Testicular cancer is relatively rare. It accounts for less than 1% of all cancers found in males. However, it is the most common cancer in young men between 15 and 34 years of age. In the United States, about 9560 new cases occur annually.[15]

Testicular tumors are more common in males who have had undescended testes (cryptorchidism) or a family history of testicular cancer or anomalies. Other predisposing factors include orchitis, human immunodeficiency virus (HIV) infection, maternal exposure to exogenous estrogen, and testicular cancer in the other testis.

Most testicular cancers develop from 2 types of embryonic germ cells: seminomas and nonseminomas. Seminoma germ cell cancers are the most common but are the least aggressive. Nonseminoma testicular germ cell tumors are rare but very aggressive. Non–germ cell tumors arise from other testicular tissue. These include Leydig cell and Sertoli cell tumors. They cause less than 10% of testicular cancers.

Clinical Manifestations

Testicular cancer may have a slow or rapid onset depending on the type of tumor (Fig. 59.9). There may be a painless, firm lump in the scrotum and scrotal swelling. Some patients report a dull ache or heavy sensation in the lower abdomen, perianal area, or scrotum. Acute pain is the first symptom in about 10% of patients. Manifestations of advanced disease vary. They include lower back or chest pain, cough, and dyspnea.

Diagnostic Studies

Palpation of the scrotal contents is the first step in diagnosing testicular cancer. A cancerous mass is firm and does not transilluminate. Ultrasound is done if testicular cancer is suspected (e.g., palpable mass) or when persistent or painful testicular swelling is present. Serum tumor markers are done to assess α-fetoprotein (AFP), lactate dehydrogenase (LDH), and human chorionic gonadotropin (hCG) levels.

A chest x-ray, CBC, basic metabolic panel, and liver function tests may be done. Anemia may be present. Liver function levels may be increased in metastatic disease. If cancer is confirmed by pathology, then a CT scan of the abdomen and pelvis (and possibly the chest) is done to further stage and assess for metastases.

Interprofessional and Nursing Care

Testicular cancer is one of the most curable types of cancer. Treatment generally involves a radical inguinal orchiectomy (removal of the affected testis, spermatic cord, and regional lymph nodes). Some patients with early-stage disease do not need further treatment after an orchiectomy. Retroperitoneal lymph node dissection and removal also may be done in early-stage disease. These nodes are the primary route for metastasis.

Postorchiectomy treatment may involve radiation therapy or chemotherapy depending on the stage of the cancer. Radiation therapy is mainly used for patients with a seminoma, which is very sensitive to radiation. Radiation does not work well for nonseminomas.

Testicular germ cell tumors are more sensitive to systemic chemotherapy than any other adult solid tumor. Chemotherapy protocols use a combination of agents, including bleomycin, cisplatin, etoposide, and ifosfamide (Ifex). Retroperitoneal lymph node dissection may be done after chemotherapy as adjunct therapy in patients with advanced testicular cancer.

CHECK YOUR PRACTICE

You are working on the urologic oncology unit caring for a 24-year-old man who recently had an orchiectomy for testicular cancer. He appears quiet and nonengaged when you assess him. He says, "I'm never going to have a normal sex life."

- How would you respond? What kind of support and information would you provide?

The prognosis for men with testicular cancer has greatly improved; 95% obtain complete remission if the disease is found in the early stages. Because of treatment successes, many men with testicular cancer are long-term survivors.

However, some drugs used to treat testicular cancer can cause serious long-term side effects. These include lung problems,

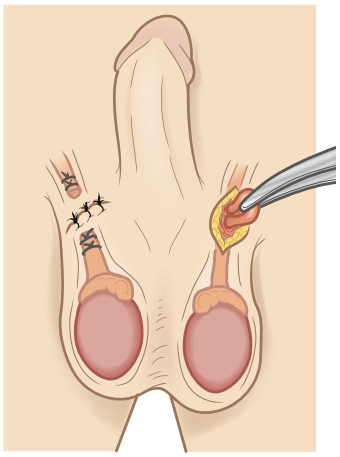

Fig. 59.11 Vasectomy procedure. The ductus deferens is ligated or resected for sterilization.

kidney damage, nerve damage (which can cause numbness and tingling), and hearing loss (from nerve damage). Secondary cancers can occur after chemotherapy (see Chapter 16).

All patients with testicular cancer need surveillance and regular physical assessments, chest x-rays, CT scans, and serum tumor markers (hCG, AFP, LDH). The goal is to detect relapse when the tumor burden is minimal.

Pretreatment subfertility or impaired fertility is identified at diagnosis. Chemotherapy with cisplatin and/or pelvic radiation often damages the testicular germ cells. However, spermatogenesis can return in some patients. Because of the high risk for infertility, the cryopreservation of sperm in a sperm bank before treatment begins should be discussed and recommended. Ejaculatory dysfunction may result from retroperitoneal lymph node dissection. These issues may be hard to discuss with the newly diagnosed patient. Men may feel the disease is a threat to their masculinity and self-worth.

SEXUAL FUNCTION

VASECTOMY

Vasectomy is the bilateral surgical ligation or resection of the ductus deferens done for the purpose of sterilization (Fig. 59.11). The procedure takes only 15 to 30 minutes. It is usually done with the patient under local anesthesia on an outpatient basis. Although vasectomy is considered a permanent form of sterilization, successful vasectomy reversals *(vasovasostomy, vasoepididymostomy)* are common.

After vasectomy, the patient should not notice any difference in the look or feel of the ejaculate because its major components are seminal and prostatic fluid. The patient must use a different form of contraception until semen examination reveals no sperm. Sperm cells continue to be made by the testes but are stored in the epididymis and reabsorbed by the body rather than being passed through the ductus deferens. Vasectomy does not affect the hormone production, ability to ejaculate, or physiologic mechanisms related to erection or orgasm. Psychologic adjustment may be a problem after surgery. It may be hard for the patient to separate vasectomy from castration at a subconscious level. Some men develop psychogenic ED or feel the need to be more sexually active than they were to prove their masculinity.

TABLE 59.10 Common Risk Factors for ED

Drug Induced
- Alcohol
- Antiandrogens
- Antihypertensives
- Antilipidemic agents
- Major tranquilizers (diazepam [Valium], alprazolam [Xanax])
- Marijuana, cocaine
- Nicotine
- Tricyclic antidepressants (e.g., amitriptyline [Elavil])

Endocrine
- Diabetes
- Hypogonadism
- Obesity

Genitourinary
- Radical prostatectomy
- Renal failure

Neurologic
- Cerebrovascular disease
- Parkinson disease
- Trauma to the spinal cord
- Tumors or transection of spinal cord

Psychologic
- Anxiety
- Depression
- Stress

Vascular
- Atherosclerosis
- Hypertension
- Peripheral vascular disease

Other
- Aging

ERECTILE DYSFUNCTION

Erectile dysfunction (ED) is the inability to attain or maintain an erection that allows satisfactory sexual activity. Although sexual function is a topic that many persons are uncomfortable discussing, health care professionals must be able and willing to address ED.

ED is a condition that is significant because of its prevalence. More than 10 million men in the United States have ED. It can occur at any age, although the incidence increases with age. We estimate that 50% of men between ages 40 and 70 have at least some degree of ED. ED is increasing in all sexually active males. In younger men, the increase is attributed to substance use (e.g., recreational drugs, alcohol), stress, and anxiety. Middle-aged men are more likely to have ED due to chronic medical conditions (e.g., diabetes, hypertension) or treatment for these conditions (e.g., antihypertensive drugs) that may cause ED.

Etiology and Pathophysiology

ED can be due to many factors (Table 59.10). Common causes include diabetes, vascular disease, drug side effects, result of surgery (e.g., prostatectomy), trauma, chronic illness, stress, difficulty in a relationship, or depression. Since ED results from reduced blood flow to the penis, there is a potential association with cardiovascular disease because the risk factors for both disorders are the same.

Normal physiologic age-related changes are associated with changes in erectile function. They may be an underlying cause of ED for some men. Table 55.3 lists age-related changes in sexual function. Review age-related changes (if necessary) to reassure an anxious older man about normal changes in his sexual abilities.

Clinical Manifestations and Complications

The typical symptom is a patient's self-report of problems with erectile activity, describing an inability to attain or maintain an erection. The symptoms may occur only occasionally, may be continual with a gradual onset, or may have a sudden onset. A gradual onset of symptoms is usually due to physiologic factors. A sudden or rapid onset of symptoms may be related to psychologic issues. It is common for younger men who seek care for ED to be diagnosed with diabetes, hypertension, depression, or cholesterol abnormalities during their evaluation for ED.

A man's inability to perform sexually can cause great distress in his interpersonal relationships and interfere with his concept of himself as a man. It can affect the relationship between the man and his partner. ED can lead to personal issues, including anger, anxiety, and depression.

Diagnostic Studies

The first step in the diagnosis of ED is a thorough sexual, health, and psychosocial history. Self-administered assessment and treatment-related questionnaires may be used as primary screening tools. For example, the International Index of Erectile Function (IIEF) assesses a man's response to 5 key areas of male sexual function: erectile function, orgasmic function, sexual desire, intercourse satisfaction, and overall satisfaction.

The physical assessment should focus on secondary sexual characteristics. Note if secondary sexual characteristics reflect the person's chronologic age (Tanner stage). A DRE is done to assess prostate size, consistency, and presence of nodules. Assess BP and peripheral pulses. Auscultate the femoral arteries.

Further testing is typically based on findings from the history and physical assessment. A serum glucose, hemoglobin A1C (Hb A1C), and lipid profile are recommended to rule out diabetes. Hormonal levels for testosterone, prolactin, LH, and thyroid hormones may identify endocrine-related problems. PSA level and a CBC may help to identify other diseases.

Other diagnostic tests may be done to diagnose ED. Nocturnal penile tumescence and rigidity testing is a noninvasive method that involves the continuous measurement of penile circumference and axial rigidity during sleep. These tests distinguish between physiologic or psychogenic causes of ED. Vascular studies, including penile arteriography, penile blood flow study, and duplex Doppler ultrasound studies, can assess penile blood inflow and outflow. These tests help to identify vascular problems interfering with erection.

Interprofessional and Nursing Care

The goal of ED therapy is for the patient and his partner to achieve a satisfactory sexual relationship. The treatment for ED can be based on the underlying cause. In general, men are moved directly into treatment without a costly workup. A variety of treatment options are available (Table 59.11). Advise patients that no option will restore ejaculation or tactile sensations if they were absent before treatment.

It is important to determine if ED is reversible before treatment is started. For example, if ED is a side effect of prescribed drugs, other treatments can be explored. With an established diagnosis of testicular failure (hypogonadism), androgen replacement therapy may be part of the prescribed treatment.

For men with ED that is psychologic in nature, counseling (with or without his partner) is recommended. This counseling should be carried out by a qualified sex therapist.

The man with ED needs a great deal of emotional support for both himself and his partner. Men often do not feel comfortable discussing their problems because of their perceptions of society's expectations of a man's sexual abilities. Many men delay seeking medical care or expect immediate solutions to ED. The health care team should provide a support system and accurate information.

Erectogenic Drugs

PDE5 inhibitors cause smooth muscle relaxation and increased blood flow into the corpus cavernosum, promoting penile erection. These drugs include avanafil (Stendra), sildenafil (Viagra), tadalafil (Cialis), and vardenafil (Levitra, Staxyn). Most are taken orally before sexual activity. These drugs are generally safe and effective for the treatment of most types of ED. They are ineffective in the absence of arousal.

Side effects include headaches, leg/back pain, dyspepsia, flushing, and nasal congestion. Rare side effects are blurred or blue-green vision problems, sudden hearing loss, and an erection lasting more than 4 hours (priapism). Teach the patient to seek immediate medical attention if any of these reactions occur. Because these drugs may potentiate the hypotensive effect of nitrates, they are contraindicated for those taking nitrates (e.g., nitroglycerin).

Some men seek other ways to obtain ED medications. This includes compounding pharmacies and online pharmacies. This may be due to both the cost of ED medications and the lack of insurance coverage for them.

TABLE 59.11 Interprofessional Care

ED

Diagnostic Assessment
- History and physical assessment
- Sexual history
- Serum glucose and lipid profile
- Testosterone, prolactin, and thyroid hormone levels
- Nocturnal penile tumescence and rigidity testing
- Vascular studies

Management
- Modify reversible causes
- Sexual counseling

Drug Therapy
- avanafil (Stendra)
- sildenafil (Viagra)
- tadalafil (Cialis)
- vardenafil (Levitra, Staxyn)

Devices and Implants
- Intraurethral medication pellet
- Intracavernosal self-injection
- Penile implants
- Vacuum erection device (VED)

DRUG ALERT

Phosphodiesterase Type 5 (PDE5) Inhibitors

- Should not be used with nitrates (nitroglycerin) in any form.
- Can potentiate hypotensive effects of nitrates.

Vacuum Erection Devices

Vacuum erection devices (VEDs) are suction devices that are applied to a flaccid penis then produce an erection by pulling blood up into the corporeal bodies. A penile ring or constrictive band is placed around the base of the penis to retain venous blood, preventing the erection from subsiding.

Intraurethral Devices and Intracavernosal Injections

Intraurethral devices include the use of vasoactive drugs applied as a topical gel or a medication pellet inserted into the urethra using a medicated urethral system for erection (MUSE) device. Intracavernosal self-injections may be combined with medication injected directly into the corpus cavernosum.

Alprostadil (Caverject, Edex) is a vasoactive drug that enhances blood flow into the penile arteries. It can be given either by injection or as a transurethral pellet (suppository). When given as a suppository, the drug is placed into the opening at the tip of the penis. When injected, a needle and syringe is used to inject the drug directly into the corpus cavernosum. Trimix (a combination product) includes alprostadil, papaverine, and phentolamine.

Penile Implants

Penile implants are placed into the corporeal bodies to provide an erection firm enough for penetration. The inflatable implant consists of cylinders in the penis, a small pump in the scrotum, and a reservoir in the lower abdomen. The main complications of penile prostheses are infection, erosions, and, rarely, mechanical failure. Implantation requires surgery. It can sometimes be done in an outpatient setting.

Sexual Counseling

Sexual counseling can be recommended at any point during treatment for ED. It may be most valuable in cases with a component of psychogenic ED. Counseling should address psychologic or interpersonal factors that may enhance sexual expression, as well as other factors that are of concern. Counseling can be effective for the patient. It can include his partner, especially if he is involved in a long-term relationship.

HYPOGONADISM

Hypogonadism is a gradual decline in androgen secretion that occurs in most men as they age. Thus we also call it *late onset-hypogonadism* or *hypogonadism of old age*. It can begin as early as age 40. The primary male androgen that is reduced is testosterone (Fig. 59.12). It is unclear what causes the decline in testosterone. Obesity is a contributing factor.

Manifestations of low testosterone include decreased libido, fatigue, ED, depression and mood swings, and sleep problems. Since many of these manifestations can be associated with aging, some patients may not mention this to their HCP, or the HCP may not recognize these manifestations as signs of low testosterone. Long-term effects of low testosterone include loss of muscle mass and strength, which may contribute to an increased risk for falls and fractures.

Hypogonadism is diagnosed with a blood test and physical assessment. Replacement testosterone therapy is considered if

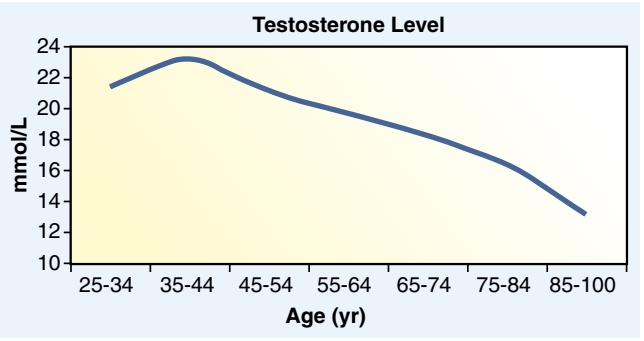

Fig. 59.12 Changes in testosterone plasma level in men as they age.

total serum testosterone levels are less than 300 ng/dL on 2 separate early morning measurements/occasions and the patient has manifestations of low testosterone.[16] Therapy may be started earlier depending on severity of symptoms. Testosterone replacement therapy (TRT) should not be started until the patient, in consultation with his HCP, considers the risks and benefits of therapy. Potential risks of TRT include lowered levels of high-density lipoprotein (HDL) cholesterol, increased hematocrit, and worsening sleep apnea, although these are rare. Since TRT may cause increased growth of prostate tissue, TRT is contraindicated in patients with unmanaged BPH or prostate cancer. Before treatment is started, a DRE and PSA test should be done. Once TRT begins, the HCP should closely monitor the patient.

Replacement therapy is available in different forms, including injection, transdermal, topical, buccal, or intranasal preparations. IM injections, such as testosterone cypionate (Depo-Testosterone) and testosterone enanthate, are available in varying doses. These drugs create a cyclic rise and fall in serum testosterone levels. The highest levels occur 2 to 3 days after the injection. Testosterone levels slowly decrease until the next injection. One side effect of IM TRT is that men may report mood swings with the hormone fluctuations.

Transdermal preparations, including patches and gels (e.g., Androderm, Testim), are often prescribed. They are applied to the skin at product-specific sites, including the back, arm, and abdomen. Skin irritation is a common side effect.

Emphasize to the patient the importance of hand washing with soap and water after applying testosterone preparations to the skin. Have the patient cover the area with clothing until the preparation has dried. Women of childbearing age and children should not touch testosterone products. Testosterone may cause early signs of puberty in young children and changes (virilization) in the external genitalia of a female fetus.

INFERTILITY

Infertility in a couple is the inability to conceive after 1 year of frequent unprotected intercourse. Infertility is a problem with the couple, not of a person. For this reason, both partners must be involved in evaluating infertility. Some estimate up to 40% of infertility cases are related to male factors.[17]

Problems of the hypothalamic-pituitary system, testicular disorders, and problems of the ejaculatory system can cause

male infertility. We consider the physical causes of infertility in 3 categories: pretesticular, testicular, and posttesticular. The *pretesticular* or endocrine causes occur in only about 3% of the cases. They can generally be treated with medication or surgery.

Testicular problems make up 50% of the cases. The most common cause of male infertility is a varicocele. Other factors that influence the testes include infection (e.g., mumps virus, STIs, bacterial infections), congenital anomalies, drugs, radiation, substance use (alcohol, nicotine, drugs), and environmental hazards.

Posttesticular causes account for 5% to 7% of the cases. Obstruction, infection, and the result of a surgical procedure are the primary causes. The remaining 40% are *idiopathic,* or of unknown causes.

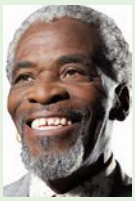
A careful health history and assessment may reveal the cause of infertility. The history is a starting point for determining cause and treatment. The history should include age; occupation; past injury, surgery, or infections of the genital tract; lifestyle issues (e.g., hot tubs, weight training, wearing tight undergarments); sexual practices; frequency of intercourse; and emotional factors, such as stress level. Have they fathered a child? Record the use of drugs, such as chemotherapeutic agents, anabolic steroids or testosterone, sulfasalazine, cimetidine, and recreational drugs. These drugs can reduce the sperm count. The assessment may identify a varicocele, Peyronie disease, or other physical findings.

The first test in the male infertility evaluation is a semen analysis to evaluate sperm concentration, motility, and morphology. Hormone studies, including plasma testosterone and serum LH and FSH measurements, are helpful. Be tactful in dealing with the male patient undergoing infertility studies. Many cultures equate fertility and masculinity. Both male and female partners should undergo evaluation simultaneously to avoid potential treatment delays.

Treatment options for the man include drugs, conservative lifestyle changes (e.g., avoiding scrotal heat, substance use, high stress), in vitro fertilization techniques, and corrective surgery. Infertility can seriously strain a relationship. The couple may need counseling and discussion of alternatives if they do not achieve conception. Female infertility is discussed in Chapter 58.

Case Study

Benign Prostatic Hyperplasia With Acute Urinary Retention



(© IPGGutenbergUKLtd/iStock/Thinkstock.)

Patient Profile

B.G., a 60-year-old Black man with hypertension, COPD, and coronary artery disease, presents to the emergency department because of an inability to void for the past 13 h.

Subjective Data

- Reports the urge to void, and pain in the lower abdomen
- Reports gradually worsening dysuria for 2 days prior to presentation
- Appears restless, anxious, and agitated

Objective Data

- Has prostate enlargement on digital rectal examination
- Has a tender and palpable bladder above the umbilicus
- Urinalysis (from catheter): >100 WBC, 30 RBC, positive bacteria and nitrites
- PSA test: 8 ng/mL

Interprofessional Care

- Indwelling urinary catheter inserted by emergency department nurse, with 900-mL cloudy urine drained from the bladder with relief of symptoms
- Admitted for observation

Discussion Questions

1. ***Recognize:*** What risk factors do you identify for prostate problems?
2. ***Analyze:*** Interpret the high PSA level.
3. ***Analyze:*** Based on the assessment, what problem does B.G. have?
4. ***Plan:*** What treatment options are possible?
5. ***Prioritize*** What is the most important problem to manage right now?
6. ***Act***. What teaching will you provide so B.G. can successfully self-manage care?
7. ***Evaluate:*** What do you need to continually monitor?
8. ***Safety:*** What risk factors does B.G. have for DVT? Infection?

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Postoperatively, a patient who had a green light laser photoselective vaporization of the prostate (PVP) has continuous bladder irrigation (CBI) with a 3-way urinary catheter with a 30-mL balloon. On assessment, CBI outflow is light pink. The patient reports bladder spasms with the catheter in place. The nurse would
   - **a.** inflate the balloon to 35 mL to decrease bulk in the bladder.
   - **b.** stop the irrigation and notify the HCP of possible obstruction.
   - **c.** deflate the balloon and then reinflate to ensure that the catheter is patent.
   - **d.** tell him spasms are expected and he should not try to urinate around the catheter.
2. Which factors would place a patient at a higher risk for prostate cancer? *(select all that apply)*
   - **a.** Older than 65 years
   - **b.** Asian or Native American
   - **c.** Long-term use of an indwelling urethral catheter
   - **d.** Father diagnosed with early-stage prostate cancer
   - **e.** History of undescended testicle and testicular cancer
3. A patient who is recovering from a radical prostatectomy for prostate cancer expresses concern that he will have erectile dysfunction. In responding to this patient, the nurse would keep in mind that
   - **a.** testosterone therapy will improve his libido.
   - **b.** PDE5 inhibitors are contraindicated in prostatectomy patients.

c. erectile dysfunction can occur even with a nerve-sparing procedure.
d. he will not be able to ejaculate which will decrease his desire for sex.

4. The nurse explains to the patient with chronic bacterial prostatitis who is undergoing antibiotic therapy that *(select all that apply)*
a. all patients require hospitalization.
b. treatment is generally 8 to 12 weeks.
c. α-adrenergic blockers can help with pain.
d. long-term therapy may be needed in immunocompromised patient.
e. if the condition is not treated appropriately, he is at risk for prostate cancer.

5. Assessment findings that may be present in a patient with testicular cancer include
a. painful ejaculation.
b. urinary incontinence.
c. painless mass in the scrotal area.
d. rapid onset of dysuria with scrotal swelling and fever.

6. Which points would the nurse include in a teaching plan for a patient with erectile dysfunction? (*select all that apply*)
a. The most common cause is benign prostatic hypertrophy.
b. Only men who are 65 years or older benefit from PDE5 inhibitors.
c. There are medications and devices that can be used to help with erections.
d. This condition can be caused by psychologic problems like anxiety or depression.
e. If they take a PDE5 inhibitor, they may experience a headache and nasal congestion.

7. When discussing a male patient's reproductive organs, the nurse should
a. arrange to have male nurses care for the patient.
b. look away and avoid eye contact with the patient.
c. maintain a nonjudgmental attitude toward his sexual practices.
d. use medical terms and anatomic names for his genitalia and sexual organs.

1. d; 2. a; 3. c; 4. b, d; 5. c; 6. c, d, e; 7. c.

Case Study

Applying Clinical Judgment With Multiple Patients

You are working on the medical-surgical unit. The following are 4 of the 6 patients you have been assigned to care for this shift. An LPN and AP assist another RN and you.

(© iStockphoto/ Thinkstock.)	L.M. is a 35-year-old woman admitted for hypertension caused by newly diagnosed Cushing syndrome. She has been depressed and crying because of her appearance. Vital signs: 164/94, 84, RR 18.
(© iStockphoto/ Thinkstock.)	N.B. is a 48-year-old man admitted to the ICU 2 days ago in diabetic ketoacidosis (DKA). He was transferred to the clinical unit yesterday evening. Laboratory results: glucose 296 mg/dL.
(© XiXinXing/ iStock/Thinkstock.)	A.K. is a 68-year-old woman with cancer of her right breast. She had a partial mastectomy and axillary node dissection yesterday. She has a Jackson-Pratt drain in her right chest. Her last pain medication was given 1 hour ago, at which time she rated her pain as a 7 (0–10 scale).
(© Jupiterimages/ Photos.com/ Thinkstock.)	R.D., a 52-year-old woman with Graves disease, had a subtotal thyroidectomy yesterday. Is to start a soft diet and ambulate in the hall this morning. In report it was noted that her voice has become slightly "hoarse" in the last hour.

1. Highlight all the findings above that require your follow-up.
2. After receiving report, which patient should you see first? Second?
3. Which tasks could you delegate to AP? (*Select all that apply*)
   a. Assist N.B. to ambulate in the hallway.
   b. Obtain daily weights for L.M. and N.B.
   c. Take R.D.'s vital signs and report the results to you.
   d. Assess A.K.'s mastectomy incision for signs of infection.
   e. Listen to L.M. talk about her feelings while helping her with AM care.
4. While you are assessing R.D., the LPN tells you that A.K.'s chest dressing is totally saturated with bloody drainage. Which *initial* action would be most appropriate?
   a. Ask the LPN to call the laboratory for a stat hemoglobin (Hgb) and hematocrit (Hct) on A.K.
   b. Tell the LPN to reinforce the dressing with sterile 4 × 4 gauze pads.
   c. Have the LPN stay with R.D. while you assess A.K.'s Jackson-Pratt drain.
   d. Ask the LPN to stay with A.K., have the AP monitor R.D. while you call A.K.'s HCP.

Case Study Progression

A.K.'s Jackson-Pratt drain was not functioning properly. You get it working and change the chest dressing. The incision is well approximated without signs of infection. When you leave the room, the Jackson-Pratt has a small amount of serosanguineous drainage in it. As you enter R.D.'s room, you notice she is having a carpal spasm on the same arm on which the LPN is taking her BP. You obtain a focused assessment and notify the health care provider.

4. Which assessment findings would be *most* important to include in a discussion with the health care provider about R.D.? *(select all that apply)*
   a. Patient is anxious
   b. Hoarseness of voice
   c. Most recent Hgb and Hct
   d. Carpal spasm upon inflation of BP cuff
   e. BP of 138/76 and heart rate of 78
5. Based on R.D.'s assessment findings, the priority need will be prevention of _____**1**_____. To reduce this risk, the most important intervention is to _____**2**_____.

Options for 1	Options for 2
bleeding	administer IV calcium gluconate
respiratory distress	increase IV fluids and apply a pressure dressing
thyrotoxicosis	start O_2 therapy

6. Which intervention would be of *highest* priority in caring for L.M.?
   a. Assess her for fall risk.
   b. Assess her for signs and symptoms of hypoglycemia.
   c. Teach her the need for a high-carbohydrate, low-protein diet.
   d. Reassure her that her physical appearance will improve with treatment.
7. You are concerned N.B. may redevelop DKA. For each of assessment finding, use an X to indicate whether it is Expected (no follow-up is required) or Requires Follow-up (could be harmful to the patient) at this time.

Assessment Finding	Expected	Requires Follow-up
Potassium 2.7 mEq/L		
Lungs sounds clear bilaterally		
Restlessness		
Slightly labored respirations		
Reports of dizziness when ambulating		
Skin pink, warm, and dry		

8. You see that you need to review N.B.'s medication record for new HCP orders. Choose the most likely options for the information missing from the table by selecting from the lists of options provided.

Continued

Case Study—cont'd

Medication	Dose, Route, Frequency	Drug Class	Indication
Insulin glargine	1	Long-acting insulin	Decrease glucose levels
2	20 mEq IV in 250 mL 0.9% over 2 hr	Electrolyte replacement	Reverse low potassium levels
enoxaparin sodium	40 units subcut daily	Anticoagulant	3
Ondansetron	4 mg IV q8hr as needed	4	Reduce feelings of nausea and vomiting

Options for 1	Options for 2	Options for 3	Options for 4
20 units IV daily 22 units subcut daily 100 units subcut daily	Magnesium, potassium, sodium sulfates Penicillin G potassium Potassium chloride	Decrease insulin resistance Reduce risk of atrial fibrillation VTE prophylaxis	Antiemetic Antihypergly-cemic Hormone analog

9. The LPN is assigned to give medications to N.B., including his sliding scale Novolog insulin with lunch. The AP, who is also a senior nursing student, tells you that the LPN gave N.B.'s insulin at least 30 minutes after the patient ate his lunch. What is your *best* initial action?
   a. Report the incident to the charge nurse for follow up.
   b. Talk to the LPN about the importance of timely medication administration.
   c. Ask the LPN what time the insulin was given and when the patient ate breakfast.
   d. Ask the AP to first discuss the concern with the LPN to follow lines of communication.

Assessment: Nervous System

Kristen J. Costello

http://evolve.elsevier.com/Lewis/medsurg/

CONCEPTUAL FOCUS

Cognition
Functional Ability
Intracranial Regulation
Sensory Perception

LEARNING OUTCOMES

1. Compare the functions of neurons and glial cells.
2. Explain the anatomic location and functions of the cerebrum, brainstem, cerebellum, spinal cord, peripheral nerves, and cerebrospinal fluid.
3. Identify the major arteries supplying the brain.
4. Describe the functions of the 12 cranial nerves.
5. Compare the functions of the 2 divisions of the autonomic nervous system.
6. Link the age-related changes in the neurologic system to the differences in assessment findings.
7. Obtain significant subjective and objective data related to the nervous system from a patient.
8. Perform a physical assessment of the nervous system using the appropriate techniques.
9. Discern normal from abnormal findings of a physical assessment of the nervous system.
10. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the nervous system.

KEY TERMS

autonomic nervous system (ANS)
blood-brain barrier
central nervous system (CNS)
cerebrospinal fluid (CSF)
cranial nerves (CNs)
dermatome
glial cells
lower motor neurons (LMNs)
meninges
neurons
neurotransmitters
peripheral nervous system (PNS)
reflex
synapse
upper motor neurons (UMNs)

The nervous system is one of the most complex systems. It controls all the body's activities. Having a good understanding of the nervous system is critical to be able to analyze and interpret clinical findings. This chapter reviews the structures and functions, assessment, and diagnostic studies of the nervous system.

STRUCTURES AND FUNCTIONS OF NERVOUS SYSTEM

The nervous system is responsible for the control and integration of the body's many activities. It is divided into the central nervous system and peripheral nervous system. The **central**

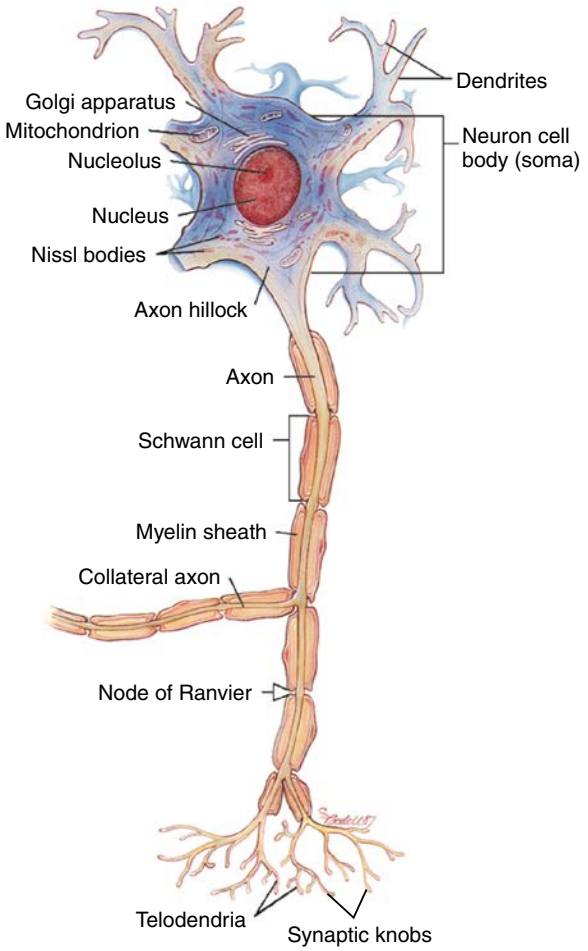

Fig. 60.1 Structural features of neurons: dendrites, cell body, and axons. (Modified from Thibodeau GA, Patton KT: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.)

nervous system (CNS) consists of the brain, spinal cord, and cranial nerves I and II. The **peripheral nervous system (PNS)** consists of cranial nerves III to XII, spinal nerves, and peripheral components of the autonomic nervous system (ANS).

Cells of Nervous System

The nervous system is made up of 2 types of cells: neurons and supportive glial cells.

Neurons

Neurons are the main functional unit of the nervous system. Neurons come in many shapes and sizes. They share 3 characteristics: (1) *excitability,* or the ability to generate a nerve impulse; (2) *conductivity,* or the ability to transmit an impulse; and (3) the ability to influence other neurons, muscle cells, or glandular cells.

A typical neuron consists of a cell body, multiple dendrites, and an axon (Fig. 60.1). The *cell body* contains the nucleus and cytoplasm. It is the metabolic center of the neuron. *Dendrites* are short processes extending from the cell body. They receive impulses or signals from other neurons and conduct them toward the cell body. The *axon* projects varying distances from the cell body. The axon carries nerve impulses to other neurons or to end organs, such as smooth and striated muscles and glands.

Many axons in the CNS and PNS are covered by a *myelin sheath*. It is a white, lipid protein substance that acts as an insulator for impulse conduction. Axons may be myelinated or unmyelinated, as in the case of smaller nerve fibers.

Glial Cells

Glial cells (glia, neuroglia) provide support, nourishment, and protection to neurons. Glial cells make up about half of the brain and spinal cord mass. Glial cells are divided into microglia and macroglia. *Microglia* are specialized macrophages capable of phagocytosis. They protect the neurons. These cells are mobile within the brain. They multiply when the brain is damaged.

Macroglial cells include astrocytes, oligodendrocytes, and ependymal cells. *Astrocytes* are found mainly in gray matter. They provide structural support to neurons. Their delicate processes form the *blood-brain barrier* with the endothelium of the blood vessels. They play a role in *synaptic transmission* (impulse conduction between neurons). When the brain is injured, astrocytes act as phagocytes for cleaning up neuronal debris. They help restore the neurochemical milieu and provide support for repair. Proliferation of astrocytes contributes to the formation of scar tissue *(gliosis)* in the CNS.

Oligodendrocytes produce the myelin sheath of nerve fibers in the CNS. They are found mainly in the white matter of the CNS. *Ependymal cells* line the brain ventricles. They aid in cerebrospinal fluid (CSF) secretion.

Nerve Regeneration

If the axon of the nerve cell is damaged, the cell tries to repair itself. Damaged nerve cells try to grow back to their original destinations by sprouting many branches from the damaged ends of their axons. Axons in the CNS are generally less successful than peripheral axons in regeneration.[1]

Schwann cells myelinate the nerve fibers in the PNS. Injured nerve fibers in the PNS can regenerate by growing within the protective myelin sheath of the Schwann cells if the cell body is intact and the environment is optimal.[2] The final result of nerve regeneration depends on the number of axon sprouts that join with the appropriate Schwann cell columns and reinnervate appropriate end organs.

Neurons have long been thought to be nonmitotic. That is, after being damaged, neurons could not be replaced. Recent research shows a subset of astrocytes proliferate after some CNS injuries, and neurogenesis may occur from stem cells.[3] These findings support the fact that the patient will have a certain amount of recovery after injury involving the neurons.

Nerve Impulse

The purpose of a neuron is to initiate, receive, and process messages about events both within and outside the body. The initiation of a neuronal message *(nerve impulse)* involves the generation of an action potential. A series of action potentials travel along the axon. When the impulse reaches the end of the nerve fiber, a chemical interaction involving neurotransmitters transfers the impulse across the junction *(synapse)* between

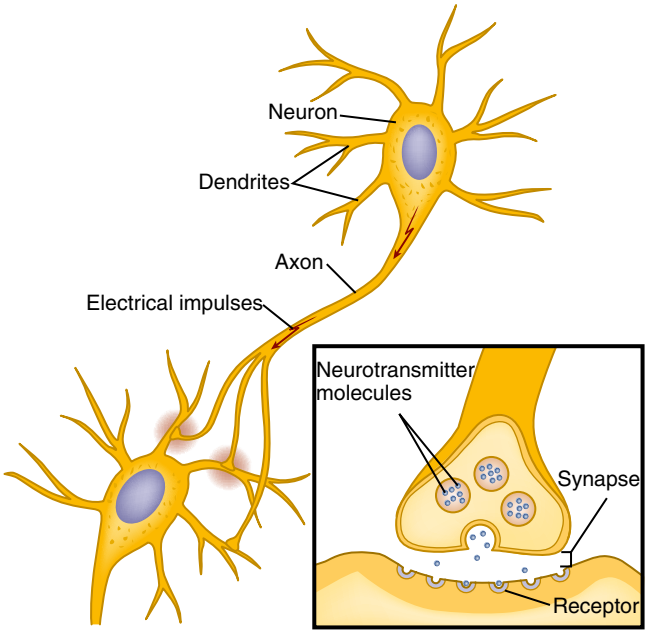

Fig. 60.2 Impulse generation between neurons. Synapse shown with neurotransmitters and receptors.

nerve cells. This chemical interaction generates another set of action potentials in the next neuron. These events are repeated until the nerve impulse reaches its destination.

Because of its insulating capacity, myelination of axons speeds the conduction of an action potential. Many peripheral nerve axons have *nodes of Ranvier* (gaps in the myelin sheath) that allow an action potential to travel much faster by jumping from node to node. We call this *saltatory* (hopping) *conduction*. In an unmyelinated fiber, conduction is slower. The wave of depolarization travels the entire length of the axon, with each part of the membrane becoming depolarized in turn.

Synapse

A **synapse** is the structural and functional junction between 2 neurons. It is where the nerve impulse is transmitted from one neuron to another. The nerve impulse also can be transmitted from neurons to glands or muscles. The essential structures of synaptic transmission are a presynaptic terminal, synaptic cleft, and receptor site on the postsynaptic cell (Fig. 60.2).

Neurotransmitters

Neurotransmitters are chemicals that affect the transmission of impulses across the synaptic cleft. *Excitatory neurotransmitters* (e.g., epinephrine, norepinephrine, glutamate) activate postsynaptic receptors that increase the chance that an action potential will be generated. *Inhibitory neurotransmitters* (e.g., serotonin, γ-aminobutyric acid [GABA], dopamine) activate postsynaptic receptors to decrease the chance that an action potential will be generated. For example, endorphins block pain transmission while substance P makes nerves more sensitive to pain.

In general, the net effect (excitatory or inhibitory) depends on the number of presynaptic neurons releasing neurotransmitters on the postsynaptic cell. A presynaptic cell that releases an excitatory neurotransmitter does not always cause the postsynaptic cell to depolarize enough to generate an action potential.

When many presynaptic cells release excitatory neurotransmitters on a single neuron, the sum of their input is enough to generate an action potential. Neurotransmitters continue to combine with the receptor sites at the postsynaptic membrane until they are inactivated by enzymes, taken up by the presynaptic endings, or diffuse away from the synaptic region. Drugs and toxins can affect neurotransmitters by changing their function or blocking their attachment to receptor sites on the postsynaptic membrane. Cerebral microdialysis can be used to measure neurotransmitter levels in the cerebral cortex (see Chapter 61).

Central Nervous System

The components of the CNS include the cerebrum (cerebral hemispheres), brainstem, cerebellum, and spinal cord.

Spinal Cord

The *spinal cord* is continuous with the brainstem and exits from the cranial cavity through the foramen magnum. A cross section of the spinal cord reveals gray matter that is centrally located in an H shape and surrounded by white matter. The gray matter contains the cell bodies of voluntary motor neurons, preganglionic autonomic motor neurons, and association neurons (interneurons). The white matter contains the axons of the ascending sensory and descending motor fibers. The myelin surrounding these fibers gives them their white appearance. The spinal pathways or tracts are named for the point of origin and the point of destination (e.g., spinocerebellar tract [ascending], corticospinal tract [descending]).

Ascending tracts. In general, the ascending tracts carry specific sensory information to higher levels of the CNS. This information comes from special sensory receptors in the skin, muscles and joints, viscera, and blood vessels. It enters the spinal cord by way of the dorsal roots of the spinal nerves. The ascending tracts are organized by sensory modality and anatomy. The fasciculus gracilis and the fasciculus cuneatus (*dorsal* or *posterior columns*) carry information about touch, deep pressure, vibration, position sense, and kinesthesia (appreciation of movement, weight, and body parts). The *spinocerebellar tracts* carry information about muscle tension and body position to the cerebellum for coordination of movement. The *spinothalamic tracts* carry pain and temperature sensations.

Other ascending tracts may also carry sensory information. The signs and symptoms of various neurologic problems suggest there are other pathways for touch, position sense, and vibration.

Descending tracts. Descending tracts carry impulses that are responsible for muscle movement. Important descending tracts are the corticobulbar and corticospinal tracts, collectively termed the *pyramidal tract.* These tracts carry voluntary impulses from the cerebral cortex to the cranial and peripheral nerves. Another group of descending motor tracts carries impulses from the extrapyramidal system (all motor systems except the pyramidal) concerned with voluntary movement. It includes pathways originating in the brainstem, basal ganglia,

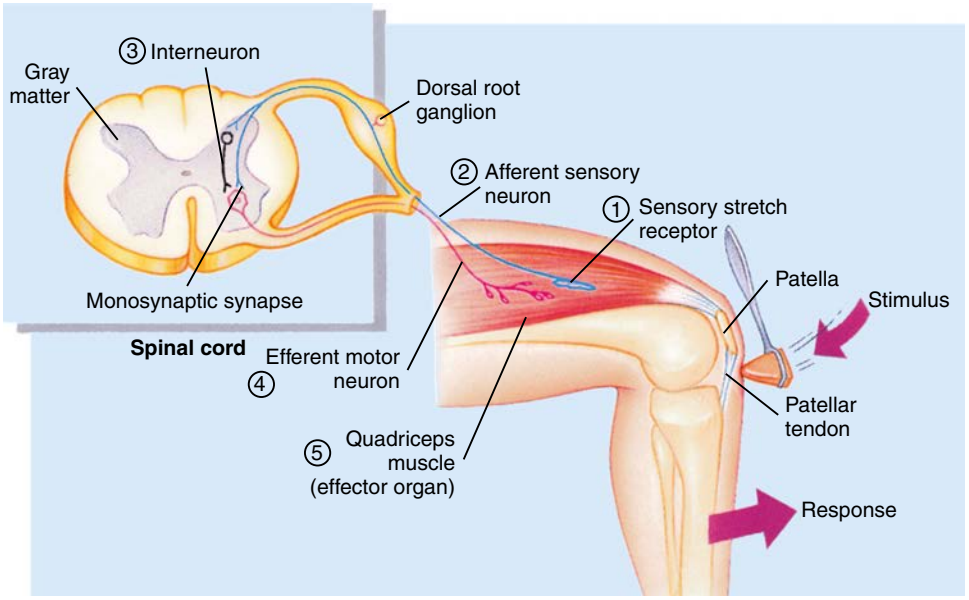

Fig. 60.3 Basic diagram of the patellar "knee jerk" reflex arc, including the *(1)* sensory stretch receptor, *(2)* afferent sensory neuron, *(3)* interneuron, *(4)* efferent motor neuron, and *(5)* quadriceps muscle (effector organ). (Modified from Thibodeau GA, Patton KT: *Anatomy and physiology,* ed 6, St Louis, 2007, Mosby.)

and cerebellum. The motor output exits the spinal cord through the ventral roots of the spinal nerves.

Reflex arc. A **reflex** is an involuntary response to stimuli. In the spinal cord, reflex arcs play an important role in maintaining muscle tone, which is essential for body posture. The components of a monosynaptic reflex arc (Fig. 60.3) are a receptor organ, afferent neuron, effector neuron, and effector organ (e.g., skeletal muscle). The afferent neuron synapses with the efferent neurons in the gray matter of the spinal cord, producing an involuntary response. More complex reflex arcs involve interneurons in addition to the afferent neuron influencing the effector neuron.

Lower and upper motor neurons. **Upper motor neurons (UMNs)** originate in the cerebral cortex and project downward. The corticobulbar tract ends in the brainstem, and the corticospinal tract descends into the spinal cord. These neurons influence skeletal muscle movement. UMN lesions generally cause weakness or paralysis, disuse atrophy, hyperreflexia, and increased muscle tone (spasticity).

Lower motor neurons (LMNs) are the final common pathway through which descending motor tracts influence skeletal muscle. The cell bodies of LMNs, which send axons to innervate the skeletal muscles of the arms, trunk, and legs, are found in the anterior horn of the corresponding segments of the spinal cord (e.g., cervical segments contain LMNs for the arms). LMNs for skeletal muscles of the eyes, face, mouth, and throat are found in the corresponding segments of the brainstem. These cell bodies and their axons make up the somatic motor components of the **cranial nerves (CNs)**. LMN lesions generally cause weakness or paralysis, denervation atrophy, hyporeflexia or areflexia, and decreased muscle tone (flaccidity).

Brain

The brain has 3 major intracranial components: cerebrum, brainstem, and cerebellum.

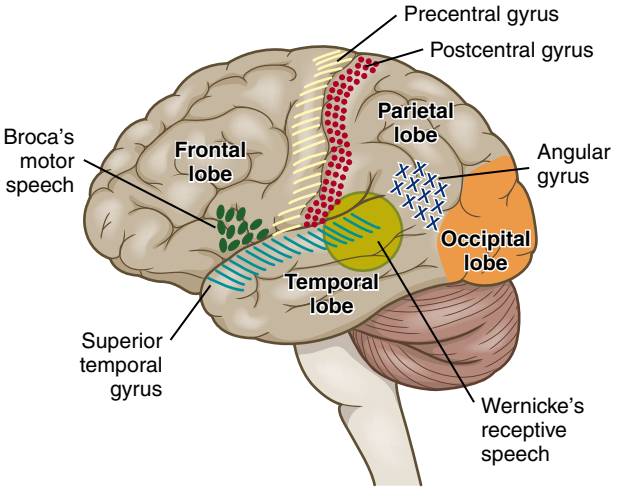

Fig. 60.4 Left hemisphere of cerebrum, lateral surface, showing major lobes and areas of the brain.

Cerebrum. The *cerebrum* is composed of the right and left cerebral hemispheres. It is divided into 4 lobes: frontal, temporal, parietal, and occipital (Fig. 60.4). The functions of the cerebrum are multiple and complex (Table 60.1). The *frontal lobe* controls higher cognitive function, memory retention, voluntary eye movements, voluntary motor movement, and motor functions involved in speech production *(Broca area)*. The *temporal lobe* integrates somatic, visual, and auditory data. It contains *Wernicke receptive speech area*. The *parietal lobe* interprets spatial information. It contains the sensory cortex. Processing of sight takes place in the *occipital lobe*.

The division of the cerebrum into lobes is useful to delineate portions of the neocortex (gray matter), which makes up the outer layer of the cerebral hemispheres. Neurons in specific parts of the neocortex are essential for various complex and

TABLE 60.1 Function of Cerebrum

Part	Location	Function
Cortical Areas		
Motor		
Primary	Precentral gyrus	Motor control and movement on opposite side of body
Supplemental	Anterior to precentral gyrus	Facilitates proximal muscle activity, including activity for stance and gait, and spontaneous movement and coordination
Sensory		
Association areas	Parietal lobe	Integrates somatic and sensory input
	Posterior temporal lobe	Integrates visual and auditory input for language comprehension
	Anterior temporal lobe	Integrates past experiences
	Anterior frontal lobe	Controls higher order processes (e.g., judgment, reasoning)
Auditory	Superior temporal gyrus	Registers auditory input
Somatic	Postcentral gyrus	Sensory response from opposite side of body
Visual	Occipital lobe	Registers visual images
Language		
Comprehension	Wernicke area in dominant posterior temporal lobe	Integrates auditory language (understanding of spoken words)
Expression	Broca area in dominant frontal lobe	Regulates motor speech
Basal Ganglia	Near lateral ventricles of both cerebral hemispheres	Controls and refines learned and automatic movements
Thalamus	Below and slightly posterior to basal ganglia	Relays sensory and motor input to and from cerebrum
Hypothalamus	Below and anterior to thalamus	Regulates endocrine and autonomic functions
Limbic System	Lateral to hypothalamus	Influences emotional behavior and basic drives, such as feeding and sexual behavior

sophisticated functions. These include language, memory, and interpreting visual-spatial relationships.

The basal ganglia, thalamus, hypothalamus, and limbic system are specific groups of neuron clusters in the cerebrum. The *basal ganglia* are found centrally in the cerebrum and midbrain. Most of them are on both sides of the thalamus. The function of the basal ganglia includes the initiation, execution, and completion of voluntary movements, learning, emotional response, and automatic movements associated with skeletal muscle activity (e.g., swallowing saliva, blinking, swinging the arms while walking).

The *thalamus* lies directly above the brainstem (Fig. 60.5). It is the major relay center for sensory input from the body, face, retina, and cochlear and taste receptors. Motor relay nuclei in

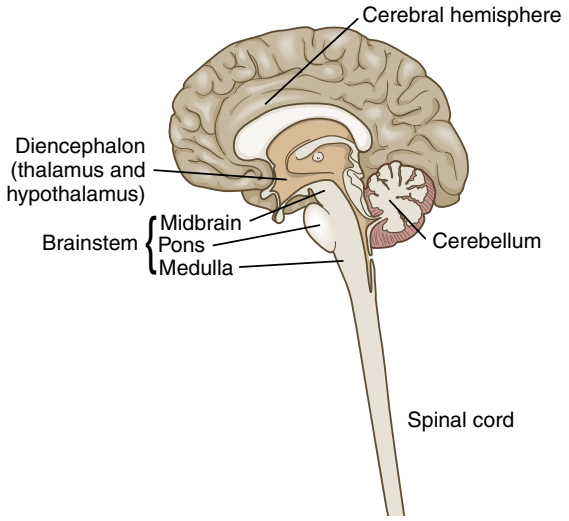

Fig. 60.5 Major divisions of the CNS.

the thalamus connect the cerebellum and basal ganglia to the frontal cortex.

The *hypothalamus* is just below the thalamus and slightly in front of the midbrain. It exerts a direct influence on release of hormones from the anterior pituitary gland. It has a rich capillary connection to the pituitary gland to aid in the transport of hormones. These hormones include thyroid-stimulating hormone, growth hormone, luteinizing hormone, and prolactin-releasing hormone (see Chapter 52). In contrast, the supraoptic and paraventricular neurons travel directly through the pituitary stalk to the posterior pituitary. There, they release vasopressin and oxytocin. The hypothalamus contains the satiety center that regulates appetite. With input from the limbic system, it regulates body temperature, water balance (through influence on vasopressin secretion), circadian rhythm, and expression of emotion. The *limbic system* is found near the inner surfaces of the cerebral hemispheres. It is concerned with emotion, aggression, feeding behavior, and sexual response.

Brainstem. The *brainstem* includes the midbrain, pons, and medulla (Fig. 60.5). Ascending and descending fibers to and from the cerebrum and cerebellum pass through the brainstem. The nuclei of CNs III through XII are in the brainstem. The vital centers concerned with respiratory, vasomotor, and heart function are in the medulla. The brainstem contains the centers for sneezing, coughing, hiccupping, vomiting, sucking, and swallowing.

We find the *reticular formation* in the brainstem. It is a diffusely arranged group of neurons and their axons that extends from the medulla to the thalamus and hypothalamus. The reticular formation relays sensory information, influences excitatory and inhibitory control of spinal motor neurons, and controls vasomotor and respiratory activity. The *reticular activating system* (RAS) is a complex system that requires communication among the brainstem, reticular formation, and cerebral cortex. The RAS regulates arousal and sleep-wake transitions.

Cerebellum. The *cerebellum* is in the posterior cranial fossa below the occipital lobe. It coordinates voluntary movement and maintains trunk stability and equilibrium. The cerebellum receives information from the cerebral cortex, muscles, joints,

and inner ear. It influences motor activity through axonal connections to the thalamus, motor cortex, and brainstem nuclei and their descending pathways.

Ventricles and cerebrospinal fluid. The ventricles are 4 interconnected fluid-filled cavities. The lower part of the 4th ventricle becomes the central canal in the lower part of the brainstem. The spinal canal extends centrally through the full length of the spinal cord.

Cerebrospinal fluid (CSF) is made largely in the choroid plexuses of the brain within the ventricles. It circulates within the subarachnoid space that surrounds the brain, brainstem, and spinal cord and flows from the cranial cavity to the spinal cavity. CSF cushions the brain and spinal cord and carries nutrients through passive diffusion and active transport. We make CSF at an average rate of about 500 mL/day. The ventricles and central canal are filled with an average of 150 mL at any given time. Changes in the rate of CSF production or absorption can occur. This leads to a change in the volume within the ventricles and central canal. Too much CSF results in *hydrocephalus*.

CSF circulates throughout the ventricles and seeps into the subarachnoid space surrounding the brain and spinal cord. It is absorbed mainly through the *arachnoid villi* (tiny projections into the subarachnoid space) into the intradural venous sinuses and eventually into the venous system.

Analyzing CSF composition provides useful diagnostic information related to certain nervous system diseases. We often measure CSF pressure in patients with actual or suspected intracranial injury. Increased intracranial pressure, indicated by increased CSF pressure, can force downward (central) herniation of the brain and brainstem. The signs marking this event are part of the herniation syndrome (see Chapter 61).

Peripheral Nervous System

The PNS includes all the neuronal structures that lie outside the CNS. It consists of the spinal and CNs, their associated ganglia (groupings of cell bodies), and parts of the ANS.

Spinal Nerves

The spinal cord can be seen as a series of spinal segments, each on top of another with no visible boundaries. In addition to the cell bodies, each segment has a pair of dorsal (afferent) sensory nerve fibers or roots and ventral (efferent) motor fibers or roots. They innervate a specific region of the body. This combined motor-sensory nerve is called a *spinal nerve* (Fig. 60.6). The cell bodies of the voluntary motor system are in the anterior horn of the spinal cord gray matter. The cell bodies of the autonomic (involuntary) motor system are in the anterolateral part of the spinal cord gray matter. The cell bodies of sensory fibers are in the dorsal root ganglia just outside the spinal cord. On exiting the spinal column, each spinal nerve divides into ventral and dorsal rami, a collection of motor and sensory fibers that eventually goes to peripheral structures (e.g., skin, muscles, viscera).

A **dermatome** is the area of skin innervated by the sensory fibers of a single dorsal root of a spinal nerve (Fig. 60.7). The dermatomes give a general picture of somatic sensory innervation by spinal segments. A *myotome* is a muscle group innervated by the primary motor neurons of a single ventral root. The

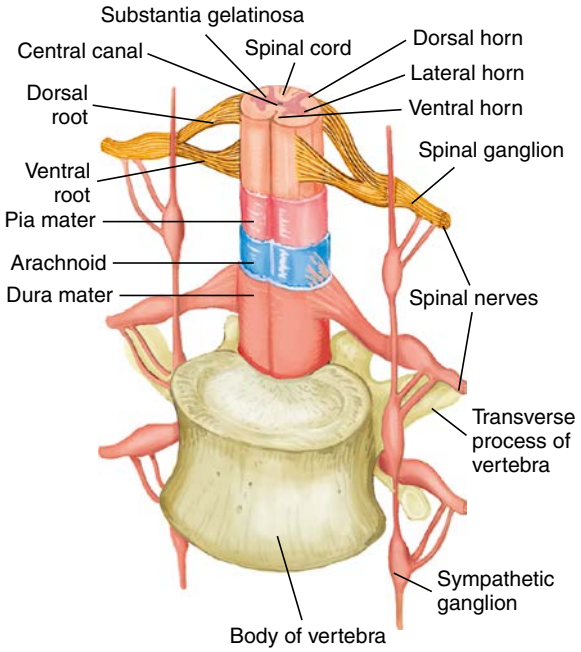

Fig. 60.6 Cross section of spinal cord showing attachments of spinal nerves and coverings of the spinal cord.

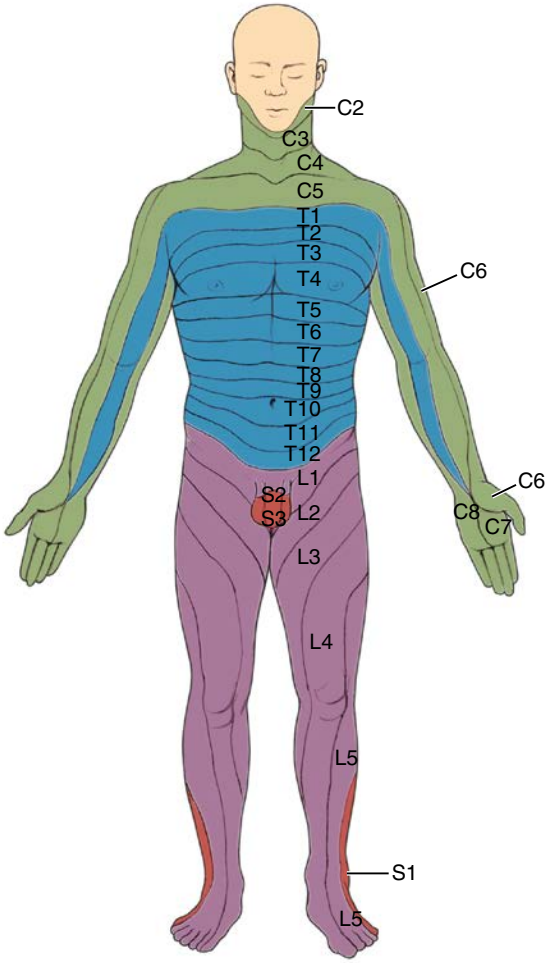

Fig. 60.7 Dermatomes of the body. (From Herlihy B: *The human body in health and illness,* ed 4, St Louis, 2011, Saunders.)

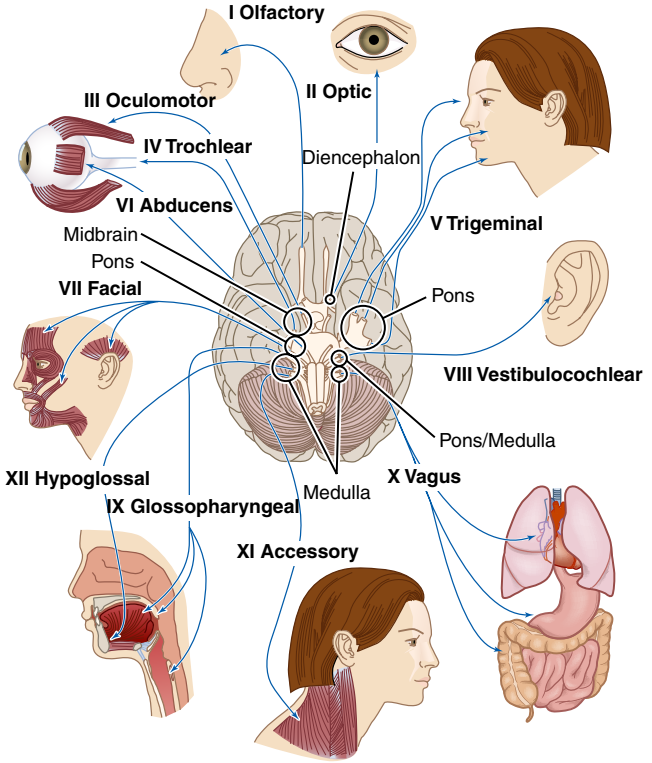

Fig. 60.8 The cranial nerves are numbered by the order in which they leave the brain. (Redrawn from McCance KL, Huether SE: *Pathophysiology: the biologic basis for disease in adults and children*, ed 6, St Louis, 2010, Mosby.)

dermatomes and myotomes of a given spinal segment overlap with those of adjacent segments because of the development of ascending and descending collateral branches of nerve fibers.

Cranial Nerves

The **cranial nerves (CNs)** are the 12 paired nerves composed of cell bodies with fibers that exit from the cranial cavity. Unlike the spinal nerves, which always have both afferent sensory and efferent motor fibers, some CNs are only sensory, some only motor, and some both.

Table 60.4 (later in this chapter) outlines the motor and sensory components of the CNs. Fig. 60.8 shows the position of the CNs in relation to the brain and spinal cord. Just as the cell bodies of the spinal nerves are in specific segments of the spinal cord, cell bodies (nuclei) of the CNs are in specific segments of the brainstem. Exceptions are the nuclei of the olfactory and optic nerves. The primary cell bodies of the olfactory nerve are in the nasal epithelium. The cell bodies of the optic nerve are in the retina.

Autonomic Nervous System

The **autonomic nervous system (ANS)** is divided into the sympathetic and parasympathetic systems. The ANS governs involuntary functions of heart muscle, smooth muscle, and glands through both efferent and afferent pathways. The 2 systems function together to maintain a relatively balanced internal environment. The preganglionic cell bodies of the *sympathetic nervous system* (SNS) are found in spinal segments T1 through L2. The major neurotransmitter released by the postganglionic fibers of the SNS is norepinephrine. The neurotransmitter released by the preganglionic fibers is acetylcholine.

The preganglionic cell bodies of the *parasympathetic nervous system* (PSNS) are found in the brainstem and sacral spinal segments (S2 through S4). Acetylcholine is the neurotransmitter released at both preganglionic and postganglionic nerve endings.

SNS stimulation activates the mechanisms required for the "fight-or-flight" response that occurs throughout the body (Fig. 60.9). In contrast, the PSNS is geared to act in localized and discrete regions. It conserves and restores the body's energy stores. The ANS provides dual and often reciprocal innervation to many structures. For example, the SNS increases the rate and force of heart contraction and the PSNS decreases the rate and force.

Cerebral Circulation

Knowing the distribution of the brain's major arteries is essential for evaluating the signs and symptoms of cerebrovascular disease and trauma. The brain's blood supply arises from the internal carotid arteries (anterior circulation) and the vertebral arteries (posterior circulation) (Fig. 60.10).

The internal carotid arteries provide blood flow to the anterior and middle portions of the cerebrum. The vertebral arteries join to form the basilar artery. It branches to supply the middle and lower parts of the temporal lobes, occipital lobes, cerebellum, brainstem, and part of the diencephalon. The main branch of the basilar artery is the posterior cerebral artery. The *circle of Willis* is formed by communicating arteries that join the basilar and internal carotid arteries (Fig. 60.11). It plays a key role in cerebral blood flow. Interestingly, research shows the formation of the circle of Willis varies greatly. Imaging shows that many people have an incomplete formation.[4]

Superior to the circle of Willis, 3 pairs of arteries supply blood to the left and right hemispheres. The anterior cerebral artery feeds the medial and anterior portions of the frontal lobes. The middle cerebral artery feeds the outer portions of the frontal, parietal, and superior temporal lobes. The posterior cerebral artery feeds the medial portions of the occipital and inferior temporal lobes. Venous blood drains from the brain through the dural sinuses, which form channels that drain into the 2 jugular veins.

Blood-Brain Barrier

The **blood-brain barrier** is a physiologic barrier between blood capillaries and brain tissue. This barrier protects the brain from harmful agents, while allowing nutrients and gases to enter. The structure of brain capillaries differs from that of other capillaries. Substances that normally pass into most tissues are prevented from entering brain tissue. Lipid-soluble compounds enter the brain easily. Water-soluble and ionized drugs enter the brain and the spinal cord slowly. Thus, the blood-brain barrier affects drug penetration. Only some drugs can enter the CNS from the bloodstream.

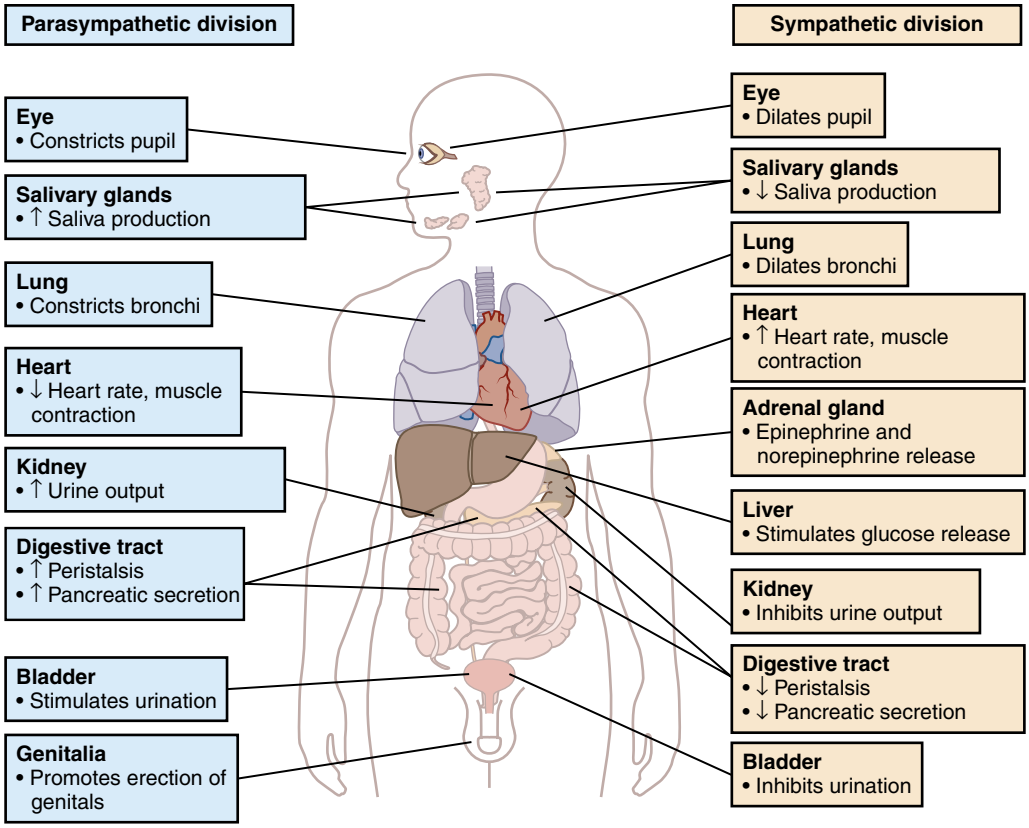

Fig. 60.9 Effects of the sympathetic and parasympathetic systems.

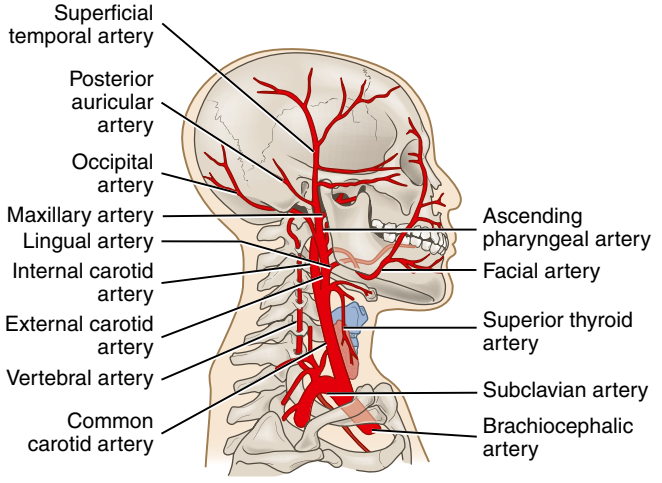

Fig. 60.10 Arteries of the head and neck. Brachiocephalic artery, right common carotid artery, right subclavian artery, and their branches. The major arteries to the head are the common carotid and vertebral arteries. (Modified from Thibodeau GA, Patton KT: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.)

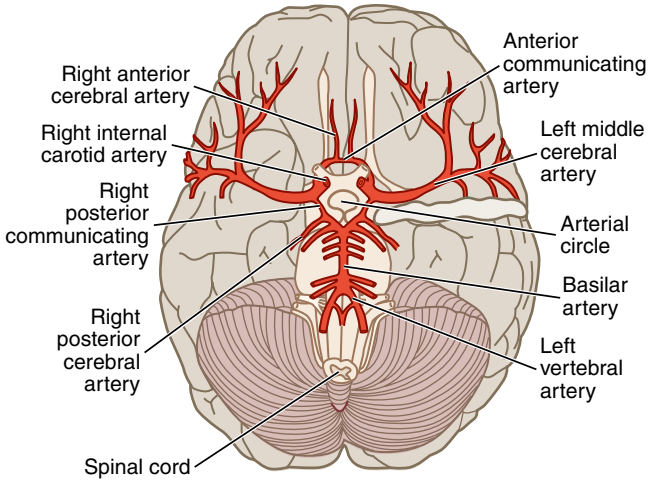

Fig. 60.11 Arteries at the base of the brain. The arteries that compose the circle of Willis are the 2 anterior cerebral arteries joined to each other by the anterior communicating cerebral artery and to the posterior cerebral arteries by the posterior communicating arteries. (Modified from Thibodeau GA, Patton KT: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.)

Protective Structures

Meninges

The **meninges** consist of 3 protective membranes that surround the brain and spinal cord: the dura mater, arachnoid, and pia mater (Fig. 60.12). The thick *dura mater* forms the outermost layer. The *falx cerebri* is a fold of the dura that separates the 2 cerebral hemispheres. It slows expansion of brain tissue in conditions such as a rapidly growing tumor or acute hemorrhage.

The *tentorium cerebelli* is a fold of dura that separates the cerebral hemispheres from the posterior fossa (which contains the brainstem and cerebellum).

The *arachnoid* layer is a fragile, web-like membrane that lies between the dura mater and *pia mater* (the vascular innermost layer of the meninges). The area between the arachnoid layer and pia mater *(subarachnoid space)* is filled with CSF. Structures such as arteries, veins, and CNs passing to and from the brain and skull

must pass through the subarachnoid space. A larger subarachnoid space in the region of the 3rd and 4th lumbar vertebrae is the area used to obtain CSF during a lumbar puncture (LP).

Skull

The *skull* protects the brain from external trauma. It is composed of 8 cranial bones and 14 facial bones. Although the top and sides of the inside of the skull are fairly smooth, the bottom surface is uneven. It has many ridges, prominences, and foramina (holes through which blood vessels and nerves enter the intracranial vault). The largest hole is the *foramen magnum,* through which the brainstem extends to the spinal cord. The foramen magnum is the only major space for the expansion of brain contents when increased intracranial pressure occurs.

Vertebral Column

The *vertebral column* protects the spinal cord, supports the head, and provides flexibility. The vertebral column is made up of 33 individual vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 sacral (fused into 1), and 4 coccygeal (fused into 1). Each vertebra has a central opening through which the spinal cord passes. A series of ligaments holds the vertebrae together. Intervertebral discs occupy the spaces between vertebrae, allowing cushion and movement of the column. Fig. 60.13 shows the natural curvature of the spinal column and its relation to the trunk.

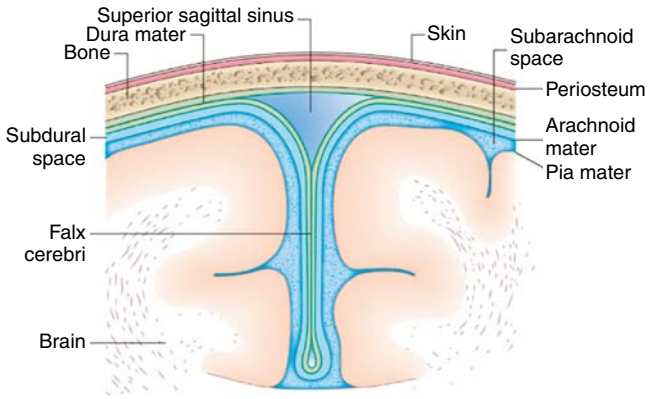

Fig. 60.12 Meninges.

Gerontologic Considerations: Effects of Aging on Nervous System

Aging affects several parts of the nervous system. In the CNS, the gradual loss of neurons in certain areas of the brainstem, cerebellum, and cerebral cortex begins in early adulthood. With loss of neurons, the ventricles widen or enlarge, brain weight decreases, and cerebral blood flow decreases. CSF production declines.

In the PNS, degenerative changes in myelin cause a decrease in nerve conduction. Coordinated neuromuscular activity, such as maintaining BP in response to changing from a lying to a standing position, is altered with aging. As a result, older adults are more likely to have orthostatic hypotension. Similarly, coordination of neuromuscular activity to maintain body temperature becomes less efficient with aging. Older adults are less able to adapt to extremes in environmental temperature. They are more vulnerable to hypothermia and hyperthermia.

Other changes include decreases in memory, vision, hearing, taste, smell, vibration, position sense, muscle strength, and reaction time. Decreases in taste and smell may result in decreased intake in the older adult. Reduced hearing and vision can result in perceptual confusion.[5] Problems with balance and coordination can put the older adult at risk for falls.[6] Changes in assessment findings result from age-related changes in the nervous system (Table 60.2). Consider other underlying causes before attributing changes to aging.

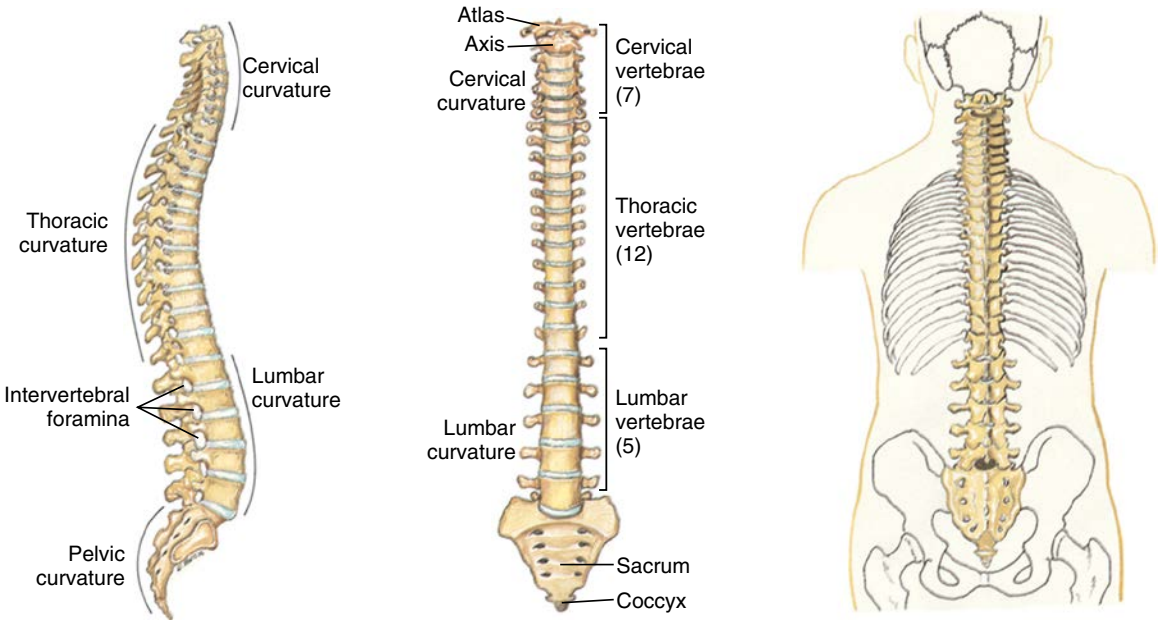

Fig. 60.13 The vertebral column (3 views). (Modified from Thibodeau GA, Patton KT: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.)

TABLE 60.2 GERONTOLOGIC ASSESSMENT DIFFERENCES

Nervous System

Component	Changes	Differences in Assessment Findings
Central Nervous System		
Brain	↓ Cerebral blood flow and metabolism Cerebral tissue atrophy and ↑ size of ventricles ↓ Efficiency of temperature-regulating mechanism ↓ Neurotransmitters, loss of neurons ↓ O_2 supply	• Altered balance, vertigo, syncope, ↑ postural hypotension • Changes in gait and ambulation • Changes in mental functioning • ↓ Kinesthetic sense • ↓ Ability to adapt to environmental temperature • ↓ Proprioception, ↓ sensory input • Slowed conduction of nerve impulses, with slowed response time
Peripheral Nervous System		
Cranial and Spinal Nerves	Cell degeneration, death of neurons Loss of myelin and ↓ conduction time	• ↓ Reaction time in specific nerves • ↓ Speed and intensity of neuronal reflexes
Functional Divisions		
Motor	↓ Muscle bulk	• ↓ Strength, tone, agility
Sensory[a]	Atrophy of taste buds Degeneration and loss of fibers in olfactory bulb Degenerative changes in nerve cells in inner ear, cerebellum, and proprioceptive pathways ↓ Electrical activity ↓ Sensory receptors	• ↓ Sense of touch, pain, and temperature • Slowing of or change in sensory reception • Malnutrition, weight loss • ↓ Sense of smell • Poor ability to maintain balance, widened gait
Reflexes	↓ Deep tendon reflexes ↓ Sensory conduction velocity	• Below-average reflex score • Sluggish reflexes, slowed reaction time
Reticular Formation		
Reticular activating system	Modification of hypothalamic function ↓ Stage IV sleep	• Changes in sleep patterns
Autonomic Nervous System		
Sympathetic nervous system and parasympathetic nervous system	Morphologic features of ganglia Slowed autonomic nervous system responses	• Orthostatic hypotension, systolic hypertension

[a]Specific changes related to the eye are listed in Table 22.1. Specific changes related to the ear are listed in Table 23.1.

Case Study

Patient Introduction

(© TatyanaGl/ iStock/ Thinkstock.)

J.K., a 57-year-old woman, went to see her HCP for severe, persistent headaches that she has had for a few weeks. She lives alone and has a stressful job as an office manager in an engineering office. When her HCP did a neurologic assessment, he noted that she had a visual field deficit, especially in the upper left quadrant of her visual field. During the visit, J.K. had a seizure in his office. Staff called 911. She was admitted to the hospital and the on-call neurologist notified.

Discussion Questions

1. What are the possible causes of J.K.'s headaches and seizure?
2. Is her condition stable or an emergency?
3. What type of assessment would be most appropriate for J.K.: comprehensive, focused, or emergency? What would be your priority?
4. What assessment questions will you ask her?

You will learn more about J.K. and her condition as you read this assessment chapter.

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

ASSESSMENT OF NERVOUS SYSTEM

Subjective Data

Important Health Information

Health history. When performing a neurologic assessment, first determine if an emergency exists. For example, does the patient have decreasing level of consciousness? The neurologic assessment is done when an abnormality is identified during screening or can be expected based on patient history. Is the patient a reliable historian and able to give detailed information? If not, interview someone with first-hand knowledge of the patient's history and current problem. Avoid suggesting symptoms or asking leading questions.

Second, the mode of onset and course of the illness are important aspects of the history. Often these facts alone can reveal the nature of a nervous system problem. Obtain all pertinent data in the history of the present illness, especially the characteristics and progression of the symptoms. In some cases, the history may include birth injury (e.g., cerebral palsy from hypoxia) and/or other neurologic insults, such as a traumatic brain injury, stroke, or degenerative disease.

Growth and developmental history can be important in determining if a nervous system problem was present at an early age. Ask about major developmental tasks, such as walking and talking. Obtain a family history (Box 60.1).

Medications. Obtain a medication history. Include the use of sedatives, opioids, tranquilizers, and mood-elevating drugs. Many drugs have neurologic side effects. Ask the patient to describe their treatment plan to determine adherence to prescribed therapies.

Surgery or other treatments. Ask about any surgery involving any part of the nervous system, such as head, spine, or sensory organs. If a patient had surgery, determine the date, procedure, recovery, and current status. Note any history of eye surgery to determine the relevance of abnormal pupil assessment.

BOX 60.1 GENETIC RISK ALERT

- Huntington disease is a genetically transmitted, autosomal dominant disorder.
- Major neurologic disorders that may have a genetic basis include multiple sclerosis (MS), headaches, Parkinson disease, and Alzheimer disease. The presence of these problems in a family history increases the chance of similar problems occurring in the patient.
- A family history may show if a neurologic problem has a genetic basis.

Functional Health Patterns

Key questions to ask a patient with a neurologic problem are outlined in Table 60.3.

Health perception–health management pattern. Ask about the patient's health practices that affect the nervous system. Include substance use, smoking, adequate nutrition, BP management, safe participation in physical and recreational activities, and use of seat belts or helmets. Ask about hospitalizations for neurologic problems.

If the patient has an existing neurologic problem, assess how it affects daily living and the ability to perform self-care. Ask someone who knows the patient well whether they have noticed any mental or physical changes in the patient. The patient with a neurologic problem may not be aware of it or may be a poor historian.

Nutritional-metabolic pattern. Neurologic problems can result in poor nutrition. Problems related to chewing, swallowing, facial nerve paralysis, and muscle coordination could make it difficult for the patient to ingest adequate nutrients. Certain vitamins, such as thiamine (B_1), niacin, and pyridoxine (B_6), are essential for the health of the CNS. Deficiencies in any of these can result in nonspecific problems, such as depression, apathy, neuritis, weakness, confusion, and irritability. Cobalamin (vitamin B_{12}) deficiency can occur in

TABLE 60.3 HEALTH HISTORY

Nervous System

Health Perception–Health Management
- What are your usual daily activities?
- Do you use alcohol, tobacco, or recreational drugs?[a]
- What safety practices do you follow in a car? On a motorcycle? On a bicycle?
- Do you have hypertension? If so, how is it managed?
- Have you ever been hospitalized for a neurologic problem?[a]
- Do you take any medication to manage neurologic problems? If so, what?

Nutritional-Metabolic
- Are you able to feed yourself?
- Do you have any problems getting adequate nutrition because of chewing or swallowing problems, facial nerve paralysis, or poor muscle coordination?[a]
- Give a 24-hr diet recall.

Elimination
- Do you have bowel or bladder incontinence?[a]
- Do you ever have problems with urinary hesitancy, urgency, retention?[a]
- Do you postpone your bowel movements?[a]

Activity-Exercise
- Describe any problems you have with usual activities and exercise because of a neurologic problem.
- Do you have weakness or lack of coordination?[a]
- Are you able to perform your personal hygiene needs alone?[a]

Sleep-Rest
- Describe your sleep pattern.
- When you have trouble sleeping, what do you do?

Cognitive-Perceptual
- Have you noticed any changes in your memory?[a]
- Do you have dizziness, heat or cold sensitivity, numbness, or tingling?[a]
- Do you have chronic pain?[a]
- Do you have any problem with verbal or written communication?[a]
- Have you noticed any changes in vision or hearing?[a]

Self-Perception–Self-Concept
- How do you feel about yourself, about who you are?
- Describe your general emotional pattern.

Role-Relationship
- Have you had changes in roles such as spouse, parent, or primary wage earner?[a]

Sexuality-Reproductive
- Are you satisfied with your sexual function?[a]
- Are problems related to your sexual function causing tension in an important relationship?[a]
- Do you feel the need for professional counseling related to your sexual function?[a]

Coping–Stress Tolerance
- Describe your usual coping pattern.
- Do you think your present coping pattern is adequate to meet the stressors of your life?[a]
- What needs are unmet by your current support system?

Value-Belief
- Describe any culturally specific beliefs and attitudes that may influence your care.

[a]If yes, describe.

older adults. They may have problems with vitamin absorption from supplements as well as natural food sources, such as meat, fish, and poultry. Untreated, cobalamin deficiency can cause mental function decline. In the patient with brain injury, early nutrition support can markedly improve outcomes.[7]

Elimination pattern. Bowel and bladder problems often occur with neurologic problems, such as stroke, head injury, spinal cord injury, MS, and dementia. To plan appropriate interventions, determine if the bowel or bladder problem was present before or after the current neurologic event. Retention and incontinence of urine and feces are common problems. For example, nerve root compression (as occurs in cauda equina conditions) leads to a sudden onset of incontinence. Note key details, such as number of episodes, accompanying sensations or lack of sensations, and measures to control the problem.

Activity-exercise pattern. Many neurologic disorders can cause problems with mobility, strength, and coordination. These problems can affect the patient's usual activity and exercise patterns and increase the risk for falls.[6] Assess the person's activities of daily living. Neurologic problems can affect the ability to perform motor tasks, which increases the risk for injury.

Sleep-rest pattern. Sleep pattern changes can be both a cause and a response to neurologic problems. Pain and reduced ability to change position because of muscle weakness and paralysis could interfere with sleep quality. Hallucinations from dementia or drugs can interrupt sleep. Assess sleep pattern and bedtime routines.

Cognitive-perceptual pattern. Because the nervous system controls cognition and sensory integration, many neurologic problems affect these functions. Consider culture, age, and education when assessing communication because they play a role in our interaction with others. Assess memory, language, calculation ability, problem-solving ability, insight, and judgment. Ask the patient hypothetical questions, such as "What is a reasonable price for a cup of coffee?" or "What would you do if you saw a car crash outside your house?" Do the patient's plans and goals match the physical and mental capabilities? Note the presence of factors affecting intellectual capacity, such as impaired cognition, hallucinations, delusions, and dementia.

Assess a person's ability to use and understand language. Appropriateness of responses is a useful indicator of cognitive and perceptual ability. Determine the patient's understanding and ability to carry out needed treatments. Neurologic-related cognitive changes can interfere with the patient's understanding of the disease and adherence to treatment.

Pain is common with many neurologic problems. It is often the reason a patient seeks care. Carefully assess the patient's pain. Pain assessment is discussed in Chapter 9.

Self-perception–self-concept pattern. Neurologic problems can drastically change a patient's control over life and create dependency on others for meeting daily needs. Physical appearance and emotional control can be affected. Sensitively ask about the patient's evaluation of self-worth, perception of abilities, body image, and general emotional pattern.

Role-relationship pattern. Physical impairments, such as weakness and paralysis, can alter or limit participation in usual roles and activities. Cognitive changes can permanently alter a person's ability to maintain previous roles. These changes can dramatically affect the patient and caregiver. Ask the patient if a role change has occurred (e.g., spouse or breadwinner) because of neurologic problems and determine how long it has lasted. Caregivers should take part in decision making when neurologic problems affect the patient's ability to make decisions.

Sexuality-reproductive pattern. Assess the person's ability to take part in sexual activity. Many neurologic problems can affect sexual response. Cerebral lesions may inhibit the desire phase or the reflex responses of the excitement phase. The hypothalamus stimulates the pituitary gland to release hormones that influence sexual desire. Brainstem and spinal cord lesions may partially or completely interrupt the desire or ability to have intercourse. Neuropathies and spinal cord lesions may prevent reflex activities of the sexual response or affect sensation and decrease desire. Despite neurologic changes in sexual function, many persons can achieve satisfying expression of intimacy and affection.

Coping–stress tolerance pattern. The physical sequelae of a neurologic problem can strain a patient's coping ability. Often the problem is chronic, and the patient must learn new coping skills. Assess if the patient's coping skills are adequate to deal with the stress of this problem. Evaluate the patient's support system.

Value-belief pattern. Many neurologic problems have serious, long-term, life-changing effects. Determine what these effects are because they can strain the patient's belief system. Assess if any religious or cultural beliefs could affect the treatment plan.

Case Study

Subjective Data

(© TatyanaGl/ iStock/ Thinkstock.)

After her admission to the hospital, a subjective assessment of J.K. revealed the following information:

Medical History: No history of seizures, migraine, or other headache prior to the current headaches and seizure.

Medications: lisinopril 10 mg PO daily.

Health Perception–Health Management: Never smoked. Occasional social alcohol use. Reports good health other than mild hypertension.

Nutritional-Metabolic: J.K. is 5 ft, 5 in tall; weight 145 lb.

Activity-Exercise: Moderate activity. No formal exercise or participation in sports.

Cognitive-Perceptual: Says her headaches led her to get her eyes tested. Has had only minor decrease in visual acuity.

Coping–Stress Tolerance: Is depressed and fearful. She is worried that something serious is wrong. Denies dizziness, change in hearing, or memory deficits.

Discussion Questions

1. Which subjective assessment findings concern you the most?
2. Based on these subjective assessment findings, what should be included in the physical assessment?

You will learn more about the physical assessment of the neurologic system in the next section.

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

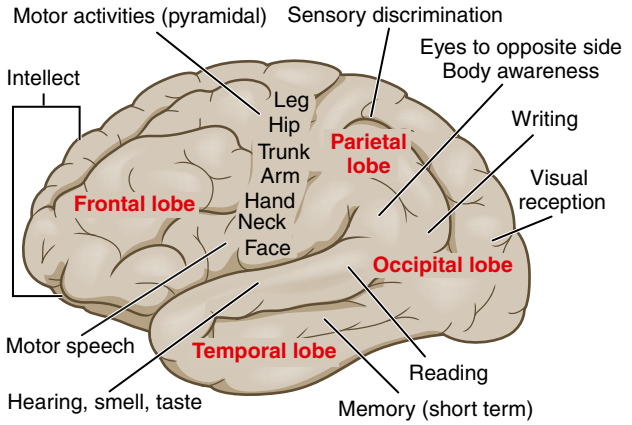

Fig. 60.14 Each area of the brain controls a particular activity.

Objective Data

Physical Assessment

The standard neurologic assessment helps determine the presence, location, and nature of nervous system disease (Fig. 60.14). The assessment looks at 6 categories of function: mental status, CN function, motor function, sensory function, cerebellar function, and reflexes.[8] Develop a consistent pattern of completing the neurologic assessment to remember to include each element for every patient encounter.

Mental status. Assessing mental status (cerebral function) gives a general impression of how the patient is functioning. It involves determining complex and high-level cerebral functions governed by many areas of the cerebral cortex. The mental status assessment begins during the start of the interview. It is ongoing throughout your interaction with the patient. For example, assess language and memory when asking the patient for details of the illness and past events. Consider the patient's age, cultural background, and level of education when evaluating mental status.

The components of the mental status assessment include:

- *General appearance and behavior:* Assess level of consciousness (awake, asleep, comatose), motor activity, body posture, dress and hygiene, facial expression, and speech pattern. Begin your assessment when you first see the patient. A patient who has deficits in self-care as shown by poor grooming is more likely to have other cognitive problems.
- *Cognition:* Note orientation to time, place, person, and situation. Note memory, general knowledge, insight, judgment, problem solving, and calculation. Common questions are "Who were the last 3 presidents?" "What do people use to cut paper?" "Can you count backward from 100 by 7s?" We often use a structured mental status questionnaire to assess these functions and provide baseline data for evaluating changes over time. Common tools include the Mini-Mental State Examination (MMSE)[8] (see Table 64.10) and Montreal Cognitive Assessment (MoCA). Delirium is an acute and transient disorder of cognition that can occur at any time during a patient's illness. As discussed in Chapter 64, delirium is often an early indicator of various illnesses (see Table 64.17). The Confusion Assessment Method tool is used to assess for delirium (see Table 64.19).
- *Mood and affect:* Note any agitation, anger, depression, or euphoria, and the appropriateness of these states. Use suitable questions to reveal the patient's feelings.

Cranial nerves. Testing each CN is an essential part of the neurologic assessment (Table 60.4).

Olfactory nerve. Chronic rhinitis, sinusitis, and heavy smoking may decrease the sense of smell. Problems with smell may occur with a tumor involving the olfactory bulb or a basilar skull fracture that has damaged the olfactory fibers. *Anosmia* (loss of sense of smell) and *hyposmia* (reduced sense of smell) is an early sign in Parkinson disease and Alzheimer disease.[9]

Optic nerve. Visual field defects may arise from lesions of the optic nerve, optic chiasm, or tracts that extend through the temporal, parietal, or occipital lobes. Visual field changes resulting from brain lesions include *hemianopsia* (half of the visual field is affected), *quadrantanopia* (1/4 of the visual field is affected), *bitemporal hemianopsia* (bilateral peripheral vision is affected), or monocular vision. It may be hard to test acuity if the patient does not read English or is aphasic.

Oculomotor, trochlear, and abducens nerves. Because the oculomotor (CN III), trochlear (CN IV), and abducens (CN VI) nerves help move the eye, we test them together (Table 60.4). With weakness or paralysis of an eye muscle, the eyes do not move together, and the patient has a *disconjugate gaze.* Note the presence and direction of *nystagmus* (fine, rapid jerking movements of the eyes), even though this condition most often indicates vestibulocerebellar problems (Fig. 60.15).

Because the oculomotor nerve exits at the top of the brainstem at the tentorial notch, it can be compressed easily by expanding mass lesions. When this occurs, sympathetic input to the pupil is unopposed; the pupil changes shape and becomes dilated. The lack of pupillary constriction is an early sign of central herniation (see Chapter 61).

Two abbreviations we often use to record the reaction of the pupils are *PERRL* (*P*upils are *E*qual [in size], *R*ound, and *R*eactive to *L*ight) and *PERRLA* (*P*upils are *E*qual, *R*ound, and *R*eactive to *L*ight and *A*ccommodation). The *PERRL* abbreviation is appropriate when accommodation cannot be assessed, as in an unconscious patient. Test convergence and accommodation by having the patient focus on your finger as it moves toward the patient's nose.

Another function of the oculomotor nerve is to keep the eyelid open. Damage to the nerve can cause *ptosis* (drooping eyelid), pupillary abnormalities, and eye muscle weakness.

Motor system. The motor system assessment includes strength, tone, coordination, and symmetry of the major muscle groups. Test muscle strength by asking the patient to push and pull against the resistance of your arm as it opposes flexion and extension of the patient's muscle. Test all 4 extremities and note any asymmetry in strength or movement. Ask the patient to offer resistance at the shoulders, elbows, wrists, hips, knees, and ankles. Mild arm weakness is demonstrated by downward drifting of the arm or pronation of the palm *(pronator drift).*

The pronator drift test is an excellent measure of strength in the upper extremities. It is especially sensitive when the patient has a potential for vasospasm or increasing edema in 1 cerebral hemisphere. Ask the patient to close the eyes and hold the arms

TABLE 60.4 Cranial Nerves

Function and Assessment

Nerve	Function	Assessment
I Olfactory	*Sensory:* from olfactory (smell)	Ask patient to close 1 nostril at a time and identify easily recognized odors (e.g., coffee). Any asymmetry in sense of smell is important.
II Optic	*Sensory:* from retina of eyes (vision)	Examine each eye separately. *Visual fields:* Position yourself opposite the patient. Ask them to look at the bridge of your nose and indicate when an object (finger, pencil tip) presented from the periphery of each of the visual fields is seen (Fig. 60.15). *Visual acuity:* Ask patient to read a Snellen chart. Record the number on the lowest line the patient can read with 50% accuracy. The patient who wears glasses should wear them during testing unless they are used only for close reading. If a Snellen chart is not available, ask the patient to read newsprint for gross assessment of acuity. Record the distance from patient to newsprint needed for accurate reading.
III Oculomotor	*Motor:* to 4 eye movement muscles and levator palpebrae muscle *Parasympathetic:* smooth muscle in eyeball	Ask the person to hold the head steady and to follow the movement of your finger, pen, or penlight only with the eyes. Hold the target back about 12 inches so that the person can focus on it comfortably. Move the target to each of the 6 positions (right and up, right, right and down, left and up, left, left and down), hold it momentarily, and then move back to center. Progress clockwise. A normal response is parallel tracking of the object with both eyes. Check for pupillary constriction and *accommodation* (pupils constricting with near vision). To test pupillary constriction, shine a light into the pupil of 1 eye; look for ipsilateral constriction of the same pupil and contralateral (consensual) constriction of the opposite eye. Note the size and shape of the pupils. The optic nerve must be intact for this reflex to occur.
IV Trochlear	*Motor:* to 1 eye movement muscle, the superior oblique muscle	See testing for CN III. Because the oculomotor (CN III), trochlear (CN IV), and abducens (CN VI) nerves help move the eye, they are tested together.
V Trigeminal		
• Ophthalmic branch	*Sensory:* from forehead, eye, superior nasal cavity	*Sensory:* Have patient close eyes and identify light touch (cotton wisp) and pinprick in each of the 3 divisions (ophthalmic, maxillary, and mandibular) of nerve on both sides of face.
• Maxillary branch	*Sensory:* from inferior nasal cavity, face, upper teeth, mucosa of superior mouth	*Motor:* Ask patient to clench teeth and then palpate masseter muscles just above the mandibular angle. Muscles should feel equally strong on both sides.
• Mandibular branch	*Sensory:* from surfaces of jaw, lower teeth, mucosa of lower mouth, and anterior tongue *Motor:* to muscles of mastication	*Corneal (blink) reflex:* Assesses CN V and CN VII simultaneously. Sensory component (corneal sensation) is innervated by the ophthalmic division of CN V. The motor component (eye blink) is innervated by the facial nerve (CN VII). Have patient look up and away. Then from the other side, lightly touch the cornea with cotton wisp. Look for normal blink reaction of both eyes. Repeat on other side.
VI Abducens	*Motor:* to the lateral rectus muscle of the eye (1 eye movement)	See testing for CN III. Because CN III, CN IV, and CN VI nerves help move the eye, they are tested together.
VII Facial	*Motor:* to facial muscles of expression and cheek muscle *Sensory:* taste from anterior 2/3 of tongue	Ask patient to raise eyebrows, close eyes tightly, purse lips, draw back the corners of mouth in an exaggerated smile, and frown. Note any asymmetry in the facial movements because this can indicate damage to nerve.
VIII Vestibulocochlear		
• Vestibular branch	*Sensory:* from equilibrium sensory organ (vestibular apparatus)	Not routinely tested unless the patient has dizziness, vertigo, unsteadiness, or auditory problems.
• Cochlear branch	*Sensory:* from auditory sensory organ (cochlea), hearing	Have patient close eyes and indicate when they hear the rustling of your fingertips. For more precise assessment of hearing, perform the Weber and Rinne tests or use an audiometer (see Table 23.6).
IX Glossopharyngeal	*Sensory:* from pharynx and posterior tongue, including taste *Motor:* to superior pharyngeal muscles	Glossopharyngeal and vagus nerves (CN IX and CN X) are tested together because both innervate the pharynx. To test the gag reflex, touch the sides of the posterior pharynx or soft palate with a tongue blade. If the reflex is weak or absent, the patient is in danger of aspirating food or secretions. For the awake, cooperative patient, ask the patient to say "ah." Note the bilateral symmetry of elevation of the soft palate. If a patient has an endotracheal tube, the cough reflex (elicited when the suction catheter contacts the *carina* of the respiratory tree) is a method of assessing the vagus nerve.

TABLE 60.4 Cranial Nerves—cont'd

Function and Assessment

Nerve	Function	Assessment
X Vagus	*Sensory:* from much of viscera of thorax and abdomen *Motor:* to larynx and middle and inferior pharyngeal muscles *Parasympathetic:* to heart, lungs, most of digestive system	See testing for CN IX. Glossopharyngeal and vagus nerves (CN IX and CN X) are tested together because both innervate the pharynx.
XI Accessory	*Motor:* to sternocleidomastoid and trapezius muscles	Ask patient to shrug the shoulders and to turn head to either side against resistance. Sternocleidomastoid and trapezius muscles should contract smoothly. Note symmetry, atrophy, or fasciculation of muscle.
XII Hypoglossal	*Motor:* to muscles of tongue	Ask to protrude tongue. It should protrude in midline. Next ask the patient to move the tongue up and down and side to side. Finally, the patient should be able to push the tongue to either side against the resistance of a tongue blade. Note any asymmetry, atrophy, or fasciculation.

Fig. 60.15 (A) Nurse checking visual fields. (B) Nurse checking extraocular movement (EOM). (Courtesy DaiWai Olson, RN, PhD, CCRN, Dallas, TX.)

out with palms facing up (like they are holding a large pizza). The patient should hold this position for 30 seconds. Downward drift with palm pronation indicates a problem in the opposite motor cortex. Asking the patient to raise the foot from the bed or to bend the knees up in bed is a good assessment of lower extremity strength.

Test muscle tone by passively moving the limbs through their range of motion. You should identify a slight resistance to these movements. Abnormal tone is described as *hypotonia* (flaccidity) or *hypertonia* (spasticity). Note any involuntary movements, such as tics, tremor, *myoclonus* (spasm of muscles), *athetosis* (slow, writhing, involuntary movements of extremities), *chorea* (involuntary, purposeless, rapid motions), and *dystonia* (impaired muscle tone).

Test cerebellar function by assessing balance and coordination. A good screening test for both balance and muscle strength is to observe stature (posture while standing) and gait. Note the pace and rhythm of the gait. Observe for normal symmetric and oppositional arm swing. The patient's ability to ambulate helps to determine the level of nursing care needed and the risk for falling.

The finger-to-nose test (having the patient alternately touch the nose, then touch the examiner's finger) and the heel-to-shin test (having the patient stroke the heel of 1 foot up and down the shin of the opposite leg) assess coordination and cerebellar function. Reposition your finger while the patient is touching the nose so that the patient must adjust to a new distance each time your finger is touched. These movements should be performed smoothly and accurately. Other tests include asking the patient to pronate and supinate both hands rapidly and to do a shallow knee bend, first on 1 leg and then on the other. Note dysarthria or slurred speech because it is a sign of incoordination of the speech muscles.

Sensory system. We evaluate several modalities in the somatic sensory assessment. Each modality is carried by a specific ascending pathway in the spinal cord before it reaches the sensory cortex. As a rule, perform the assessment with the patient's eyes closed and avoid providing the patient with clues. Ask "How does this feel?" rather than "Is this sharp?" In the routine assessment, sensory testing of the anterior torso, posterior torso, and all extremities is sufficient. However, if you identify a problem in sensory function, delineate the boundaries of that dysfunction carefully along the dermatome.

Touch, pain, and temperature. Light touch is usually tested first using a cotton wisp or light pinprick. Gently touch each extremity. Ask the patient to indicate when they feel the stimulus. Test pain by alternately touching the skin with the sharp and dull end of a pin. Tell the patient to respond "sharp" or "dull." Assess each limb separately.

Extinction is assessed by simultaneously touching both sides of the body symmetrically. Normally, the simultaneous stimuli are both perceived (sensed). An abnormal response occurs when the patient perceives the stimulus on only 1 side. The other stimulus is *extinguished*.

Test the sensation of temperature by applying tubes of warm and cold water to the skin and asking the patient to identify the stimuli with the eyes closed. If pain sensation is intact, you do not have to assess temperature sensation because the same ascending pathways carry both sensations.

Vibration sense. Assess vibration sense by applying a vibrating tuning fork to the fingernails and bony prominences of the hands, legs, and feet. Ask the patient if the vibration or "buzz" is felt. Then ask the patient to indicate when the vibration ceases.

Position sense. Assess position sense *(proprioception)* by placing your thumb and forefinger on either side of the patient's

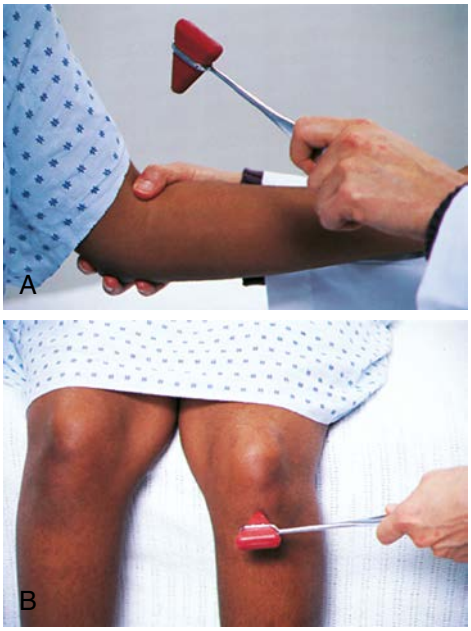

Fig. 60.16 The examiner strikes a swift blow over a stretched tendon to elicit a stretch reflex. (A) Biceps reflex. (B) Patellar reflex.

forefinger or great toe and gently moving their digit up or down. Ask the patient to close the eyes and state the direction in which the digit is moved.

Another test of proprioception is the Romberg test. Ask the patient to stand with feet together and then close their eyes. If the patient can maintain balance with the eyes open but sways or falls with the eyes closed (i.e., a positive Romberg test), vestibulocochlear problems in the posterior columns of the spinal cord may be present. Be aware of patient safety during this test.

Cortical sensory functions. Several tests assess cortical integration of sensory perceptions (which occurs in the parietal lobes). Explain these tests to the patient beforehand, while their eyes are still open. Assess *2-point discrimination* by placing the 2 points of a calibrated compass on the tips of the fingers and toes. The minimum recognizable separation is 4 to 5 mm in the fingertips and a greater degree of separation elsewhere. This test is important in diagnosing diseases of the sensory cortex and PNS.

Test *graphesthesia* (ability to feel writing on skin) by having the patient identify numbers traced on the palm of the hands. Test *stereognosis* (ability to perceive the form and nature of objects) by having the patient close the eyes and identify the size and shape of easily recognized objects (e.g., coins, keys, safety pin) placed in the hands.

Reflexes. Tendons have receptors that are sensitive to stretch. A reflex contraction of the skeletal muscle occurs when the tendon is stretched. In general, we test the biceps, triceps, brachioradialis, patellar, and Achilles tendon reflexes. Initiate a simple muscle stretch reflex by briskly tapping the tendon of a stretched muscle, usually with a reflex hammer (Fig. 60.16). Measure the response (muscle contraction of the corresponding muscle) on a 0 to 5 scale as follows: 0 = absent reflex; 1 = weak response, seen only with reinforcement; 2 = normal response; 3 = brisk response; 4 = hyperreflexia with nonsustained clonus; and 5 = hyperreflexia with sustained clonus. *Clonus,* an abnormal response, is a continued rhythmic contraction of the muscle with continuous application of the stimulus.

Elicit the *biceps reflex,* with the patient's arm partially flexed and palm up, by placing your thumb over the biceps tendon in the antecubital space and striking the thumb with a hammer. The normal response is flexion of the arm at the elbow or contraction of the biceps muscle that you can feel with your thumb.

Elicit the *triceps reflex* by striking the triceps tendon above the elbow while the patient's arm is flexed. The normal response is extension of the arm or visible contraction of the triceps.

Elicit the *brachioradialis reflex* by striking the radius 3 to 5 cm above the wrist while the patient's arm is relaxed. The normal response is flexion and supination at the elbow or visible contraction of the brachioradialis muscle.

Elicit the *patellar reflex* by striking the patellar tendon just below the patella. The patient can be sitting or lying, as long as the leg being tested hangs freely. The normal response is extension of the leg with contraction of the quadriceps.

Gently dorsiflex the patient's foot at the ankle. Elicit the *Achilles tendon reflex* by striking the Achilles tendon while the patient's leg is flexed at the knee. The normal response is plantar flexion at the ankle.

A *focused assessment* is used to assess the status of previously identified neurologic problems and to monitor for signs of new problems. A focused assessment of the neurologic system is shown in Box 60.2.

BOX 60.2 FOCUSED ASSESSMENT

Nervous System

Use this checklist to make sure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Blackouts/loss of memory	Y	N
Weakness, numbness, tingling in arms or legs	Y	N
Headaches, especially new onset	Y	N
Loss of balance/coordination	Y	N
Orientation to person, place, time, and situation	Y	N

Objective: Diagnostic

Check the following diagnostic results for critical values.

Lumbar puncture	✓
CT or MRI of brain	✓
EEG	✓

Objective: Physical Assessment

Inspect/Observe

General level of consciousness/orientation	✓
Oropharynx for gag reflex and soft palate movement	✓
Peripheral sensation of light touch and pinprick (face, hands, feet)	✓
Smell with coffee or soap	✓
Eyes for extraocular movements, PERRLA, peripheral vision, nystagmus	✓
Gait for smoothness and coordination	✓

Palpate

Strength of neck, shoulders, arms, and legs for fullness and symmetry	✓

Percuss

Reflexes	✓

TABLE 60.5 Normal Physical Assessment of the Nervous System

Parameter	Findings
Mental status	• Alert and oriented, orderly thought processes • Appropriate mood and affect
Cranial nerves May be recorded as "CN I to XII intact"	• Smell intact to soap or coffee • Visual fields full to confrontation • Intact extraocular movements • No nystagmus. PERRLA • Intact facial sensation to light touch and pinprick • Full facial movements • Hearing intact bilaterally • Intact gag and swallow reflexes. Symmetric smile. Midline protrusion of tongue • Full strength with head turning and shoulder shrugging
Motor system	• Normal gait and station. Normal tandem walk. Negative Romberg test • Normal and symmetric muscle bulk, tone, strength • Smooth performance of finger-nose, heel-shin movements
Sensory system	• Intact sensation to light touch, position sense, pinprick, heat, and cold
Reflexes  	• Biceps, triceps, brachioradialis, patellar, and Achilles tendon reflexes 2/5 bilaterally • Toes pointed down with plantar stimulation

Table 60.5 is an example of a normal neurologic physical assessment. Abnormal assessment findings of the neurologic system are shown in Table 60.6.

Case Study

Objective Data: Physical Assessment

(© TatyanaGl/ iStock/ Thinkstock.)

A physical assessment of J.K. reveals the following:

- BP 145/80, HR 78, RR 20, T 98.6°F (37°C)
- Alert, oriented, and appropriate, but anxious
- Strength 5/5 on all extremities
- Visual field deficits in upper left quadrant of visual field

Discussion Questions

1. Which physical assessment findings concern you most?
2. Based on the results of the subjective and physical assessment, what diagnostic studies do you think may be ordered for J.K.?

You will learn more about diagnostic studies related to the neurologic system in the next section.

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

DIAGNOSTIC STUDIES OF NERVOUS SYSTEM

Many diagnostic studies are available to assess the nervous system. CSF analysis provides information about a variety of CNS diseases. Normal CSF is clear, colorless, odorless, and free of red blood cells. It contains little protein. Normal CSF values are listed in Table 60.7. CSF may be obtained through LP or, on occasion, ventriculostomy.

TABLE 60.6 ASSESSMENT ABNORMALITIES

Nervous System

Finding	Description	Possible Cause and Significance
Cranial Nerves		
Dysphagia	Difficulty swallowing	Lesions involving motor pathways of CN IX and CN X (including lower brainstem)
Ophthalmoplegia	Paralysis of eye muscles	Lesions in brainstem
Eyes		
Anisocoria	Inequality of pupil size	Oculomotor nerve injury Sympathetic pathway injury
Diplopia	Double vision	Lesions affecting nerves of extraocular muscles, cerebellar damage
Homonymous hemianopsia	Loss of vision in 1 side of visual field	Lesions in the contralateral occipital lobe
Papilledema	"Choked disc," swelling of optic nerve head	Increased intracranial pressure
Mental Status		
Altered consciousness	Stuporous, mute, ↓ response to verbal cues or pain	Intracranial lesions, metabolic problem, psychiatric disorders
Anosognosia	Inability to recognize bodily defect or disease	Lesions in right parietal cortex
Motor System		
Apraxia	Inability to perform learned movements despite having desire and physical ability to perform them	Cerebral cortex lesion
Ataxia	Lack of coordination of movement	Lesions of sensory or motor pathways, cerebellum Antiseizure drugs, sedatives, hypnotic drug toxicity (including alcohol)
Dyskinesia	Impaired voluntary movement, resulting in fragmentary or incomplete movements	Disorders of basal ganglia, idiosyncratic reaction to psychotropic drugs
Hemiplegia	Paralysis on 1 side	Stroke and other lesions involving contralateral motor cortex

Continued

TABLE 60.6 ASSESSMENT ABNORMALITIES—cont'd

Nervous System

Finding	Description	Possible Cause and Significance
Nystagmus	Jerking or bobbing of eyes as they track moving object	Lesions in cerebellum, brainstem, vestibular system Antiseizure drugs, sedatives, hypnotic toxicity (including alcohol)
Reflexes		
Deep tendon reflexes	↓ or absent motor response	Lower motor neuron lesions
Extensor plantar response	Toes pointing up with plantar stimulation	Suprasegmental or upper motor neuron lesion
Sensory System		
Analgesia	Loss of pain sensation	Lesion in spinothalamic tract or thalamus. Analgesic drugs
Anesthesia	Absence of sensation	Lesions in spinal cord, thalamus, sensory cortex, or peripheral sensory nerve. Anesthesia drugs
Astereognosis	Inability to recognize form of object by touch	Lesions in parietal cortex
Paresthesia	Abnormal sensation, such as numbness or tingling	Lesions in the posterior column or sensory cortex
Speech		
Aphasia, dysphasia	Loss of or impaired language faculty (comprehension, expression, or both)	Left cerebral cortex lesion
Dysarthria	Lack of coordination in articulating speech	Cerebellar or CN lesion Antiseizure drugs, sedatives, hypnotic drug toxicity (including alcohol)
Spinal Cord		
Bladder dysfunction		
• Atonic (autonomous)	Absence of muscle tone and contractility, enlargement of capacity, no sensation of discomfort, overflow with large residual, inability to voluntarily empty	Early stage of spinal cord injury
• Hypertonic	↑ Muscle tone, ↓ capacity, reflex emptying, dribbling, incontinence	Lesions in pyramidal tracts (efferent pathways)
• Hypotonic	More ability than atonic bladder but less than normal	Interruption of afferent pathways from bladder
Paraplegia	Paralysis of lower extremities	Spinal cord transection or mass lesion (thoracolumbar region)
Tetraplegia (quadriplegia)	Paralysis of all extremities	Spinal cord transection or mass lesion (cervical region)

TABLE 60.7 Cerebrospinal Fluid Analysis

Parameter	Normal Value
Specific gravity	1.007
pH	7.35
Appearance	Clear, colorless
RBCs	None
WBCs	0–5 cells/μL (0–5 × 10^6 cells/L)
Protein	
• Lumbar	15–45 mg/dL (0.15–0.45 g/L)
• Cisternal	15–25 mg/dL (0.15–0.25 g/L)
• Ventricular	5–15 mg/dL (0.05–0.15 g/L)
Glucose	40–70 mg/dL (2.2–3.9 mmol/L)
Microorganisms	None
Pressure	60–150 mm H_2O

During LP, the HCP aspirates CSF through a needle inserted into the L3-4 or L4-5 interspace. A manometer attached to the needle is used to obtain CSF pressure. CSF is withdrawn in a series of tubes and sent for analysis. LP is contraindicated in the presence of increased intracranial pressure because of the risk for downward herniation from CSF removal or if there is infection at the intended puncture site. Nursing care of the patient undergoing LP is outlined in Table 60.8.

Tables 60.9 and 60.10 describe a number of other studies. Nerve, muscle, brain, and arterial tissues biopsies are useful in diagnosing several disorders (e.g., tumors, infectious disease, degenerative diseases). A brain biopsy is usually done using a stereotactic procedure.

TABLE 60.8 NURSING MANAGEMENT

Care of the Patient Undergoing Lumbar Puncture

Preprocedure

- Obtain vital signs and a baseline neurologic assessment. Notify HCP of signs of increased intracranial pressure (see Chapter 61).
- Assess coagulation studies to reduce the risk for epidural hematoma.
- Teach patient and caregiver about procedure. Tell the patient they may feel temporary, sharp pain or tingling radiating down the leg as a sterile needle is passed between 2 lumbar vertebrae.
- Give sedative and analgesia, as ordered.
- Have patient void.
- Place patient in a side-lying or sitting position. (Fig. 60.17)

Postprocedure

- Monitor neurologic signs and vital signs.
- Monitor for headache intensity and drainage from the puncture site.
- Apply pressure and a pressure dressing to the puncture site.
- Keep the patient in a reclining position for 1 hour or up to several hours to decrease the risk for spinal headache. The patient may to turn from side to side as long as the head is not raised.
- Properly label CSF specimens and send to laboratory.
- Teach the patient to report numbness, tingling, and movement of the extremities; pain at the injection site; and the inability to void.
- Encourage fluids with a straw to replace the CSF that was removed.
- Give ordered analgesia, as needed.

TABLE 60.9 Radiologic Studies

Nervous System

Study	Description and Purpose	Nursing Responsibility
Cerebral angiography	Serial x-ray visualization of intracranial and extracranial blood vessels done to detect vascular lesions (aneurysms, hematomas, arteriovenous malformations) and brain tumors. Catheter is inserted into the femoral (sometimes brachial) artery and passed through the aortic arch into the base of a carotid or a vertebral artery for injection of contrast medium. Timed-sequence radiographic images obtained as contrast flows through arteries, smaller vessels, and veins.	*Before:* Assess patient for stroke risk because thrombi may be dislodged during procedure. May need to be NPO. *During:* Warn patient that contrast injection may cause a feeling of being warm and flushed. Patient must lie completely still during scan. *After:* Monitor neurologic signs and VS every 15–30 min for first 2 hr, every hour for next 6 hr, then every 2 hr for 24 hr. Maintain bed rest for 6 hr (1 hr if a closure device is used). Assess for bleeding. Report any neurologic status changes.
CT scan	Provides a rapid means of obtaining radiographic images of the brain (Fig. 60.18A). Computer-assisted x-ray of multiple cross sections of body parts to detect problems such as hemorrhage, tumor, cyst, edema, infarction, brain atrophy, and other abnormalities. Contrast medium may be used to enhance visualization of brain structures.	*Before:* Note renal function before contrast medium used. Assess if patient is allergic to shellfish since the contrast is iodine based. Patient may need to be NPO 4 hr prior. If the patient is taking metformin, hold it the day of the test to prevent kidney damage. *During:* Warn patient that contrast injection may cause a feeling of being warm and flushed. Patient must lie completely still during scan. *After:* Encourage patient to drink fluids to avoid renal problems with any contrast.
• CT angiography (CTA)	Noninvasive imaging of vascular system (e.g., aneurysms). Evaluates blood volume, flow, and mean transit time as a measure of perfusion. Has fewer complications than cerebral angiography and is less expensive.	Similar to CT (see above).
MRI	Imaging of brain, spinal cord, and spinal canal by means of magnetic energy (Fig. 60.18B). Used to detect strokes, MS, tumors, trauma, herniation, and seizures. Provides greater detail than CT and improved resolution (detail) of intracranial structures. Takes a longer time to complete and may not be appropriate in life-threatening emergencies. Contrast medium may be used to enhance visualization. The contrast agent *gadolinium* has a lower incidence of allergy than iodine used in CT.	*Before:* Oral and/or IV contrast injection may be used. Check for pregnancy, allergies, and renal function. Have patient remove all metal objects. Ask about any history of surgical insertion of staples, plates, dental bridges, or other metal appliances. Remove metallic foil patches. Patient may need to be fasting. Assess for claustrophobia and the need for antianxiety medication. *During*: Patient must lie completely still.
• Magnetic resonance angiography (MRA)	Uses differential signal characteristics of flowing blood to evaluate extracranial and intracranial blood vessels. Provides both anatomic and hemodynamic information. Can be done with contrast medium.	Similar to MRI (see above).
• Functional MRI (fMRI)	MRI technique that provides time-related images that evaluate how the brain responds to various stimuli. Makes it possible to detect the brain areas that are involved in a task, process, or an emotion.	Similar to MRI (see above).

Continued

TABLE 60.9 Radiologic Studies—cont'd

Nervous System

Study	Description and Purpose	Nursing Responsibility
• MR spectroscopy (MRS)	Noninvasive test. Measures biochemical changes in the brain, especially the presence of tumors. Compares chemical composition of normal brain tissue with abnormal tumor tissue. Can detect tissue changes in stroke and epilepsy.	Similar to MRI (see above).
Myelogram	X-ray of spinal cord and vertebral column after injection of contrast medium into subarachnoid space. Used to detect spinal lesions (e.g., herniated or ruptured disc, spinal tumor).	*Before:* Give sedative as ordered. Have patient empty bladder. Tell patient that test is done with patient on tilting table that is moved during test. *After:* Patient should lie flat for 1–2 hr to prevent spinal headache. Encourage fluids. Monitor neurologic signs and VS. Headache, nausea, and vomiting may occur.
Positron emission tomography (PET)	Measures metabolic activity of brain to assess cell death or damage. Uses radioactive material that shows up as a bright spot on the image. Used to diagnose stroke, Alzheimer disease, seizure disorders, Parkinson disease, tumors.	*Before:* Explain procedure to patient. Tell patient not to take sedatives or tranquilizers. Have patient empty bladder. Insert 2 IV lines. *During:* Patient may be asked to perform different activities during test.
Single-photon emission computed tomography (SPECT)	Method of scanning similar to PET but uses more stable substances and different detectors. Radiolabeled compounds are injected, and their photon emissions can be detected. Resulting images are accumulation of labeled compound. Assesses blood flow and O_2 and glucose metabolism in the brain. Used to diagnose strokes, brain tumors, and seizure disorders.	Similar to PET (see above).
Skull and spine x-rays	Simple x-ray of skull and spinal column. Done to detect fractures, bone erosion, calcifications, abnormal vascularity.	*Before:* Remove any radiopaque objects that can interfere with results. Explain procedure to patient. *During:* Avoid excessive exposure of patient and self.
Ultrasound		
Carotid artery duplex scan	Noninvasive study. Assesses the degree of stenosis of carotid and vertebral arteries. Combines ultrasound and Doppler technology. Probe is placed over the carotid artery and slowly moved along the course of common carotid artery. Frequency of reflected ultrasound signal corresponds to blood velocity. Increased blood flow velocity can indicate stenosis of a vessel.	*Before:* Explain procedure to patient.
Transcranial Doppler	Same technology as carotid duplex but evaluates blood flow velocities of intracranial blood vessels. Probe placed on skin at various "windows" in the skull (areas in the skull that have only a thin bony covering) to record velocities of the blood vessels.	*Before:* Explain procedure to patient.

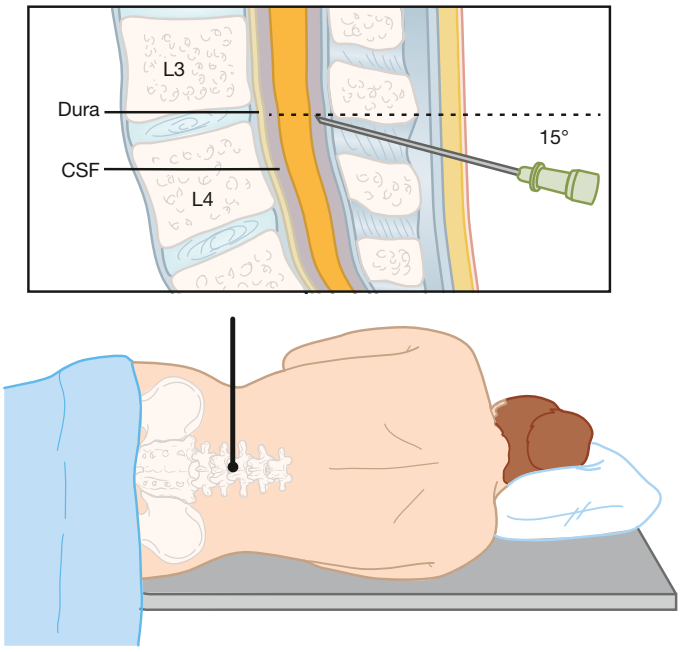

Fig. 60.17 The lateral position for a LP. The hips, knees, and neck are flexed with the knees bent up towards the chest.

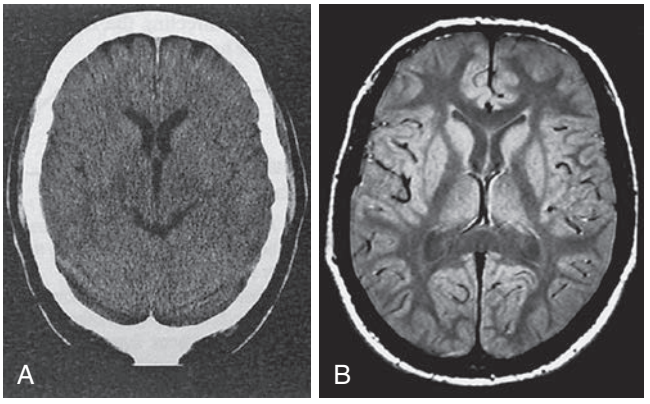

Fig. 60.18 Normal images of the brain. (A) CT scan. (B) MRI. (From Fuller G, Manford M: *Neurology: an illustrated colour text,* ed 3, New York, 2010, Churchill Livingstone.)

TABLE 60.10 Electrographic Studies

Nervous System

Study	Description and Purpose	Nursing Responsibility
Electroencephalography (EEG)	Electrical activity of brain recorded using scalp electrodes. Evaluates seizure disorders, cerebral disease, CNS effects of systemic diseases, brain injury, brain death. Specific tests may be done to evaluate brain's electrical response to lights and loud noises.	*Before:* Tell patient procedure is noninvasive and without danger of electric shock. Determine if any medications (e.g., tranquilizers, antiseizure drugs) should be withheld. *After:* Resume medications. Have patient wash electrode paste out of hair.
Electromyography (EMG)	Recording of electrical activity associated with innervation of skeletal muscle. Needle electrodes are inserted into the muscle to record specific motor units. Normal muscle at rest shows no electrical activity. Electrical activity occurs only when the muscle contracts. Activity may be altered in muscle diseases (e.g., myopathic conditions), disorders of muscle innervation (e.g., segmental or LMN lesions, peripheral neuropathic conditions).	*Before:* Explain procedure. Tell patient that pain and discomfort are common with insertion of needles. HCPs may restrict stimulants (e.g., caffeine) 2–3 hr prior. *After:* Assess needle sites for hematoma or inflammation. Give as-needed analgesics.
Electroneurography (nerve conduction studies)	Measures nerve conduction velocity of peripheral nerves. Involves applying a brief electrical stimulus to a distal portion of a sensory nerve and recording the resulting wave of depolarization at a point proximal to the stimulation. The time between the stimulus onset and the first wave of depolarization at the recording electrode is measured. Damaged nerves have slower conduction velocities.	*Before:* Explain procedure to patient. For example, a stimulus can be applied to the forefinger and a recording electrode placed over the median nerve at the wrist will detect the speed of the conduction.
Evoked potentials	Electrical activity associated with nerve conduction along sensory pathways is recorded by electrodes placed on skin and scalp. A stimulus generates the impulse. Increases in the normal time from stimulus onset to a given peak (latency) indicate slowed nerve conduction or nerve damage. Used to diagnose disease (e.g., MS), locate nerve damage, and monitor function during surgery. Can diagnose disorders of the visual or auditory systems because it shows if a sensory impulse is reaching the right part of brain.	*Before:* Explain procedure to patient. Have patient shampoo hair before test.
Magnetoencephalography (MEG)	Uses a biomagnetometer to detect magnetic fields generated by neural activity. Can accurately pinpoint the part of the brain involved in a stroke, seizure, or other disorder or injury. Measures extracranial magnetic fields and scalp electric field (EEG).	*Before:* Explain procedure to patient. MEG, a passive sensor, does not make physical contact with patient.

Case Study

Objective Data: Diagnostic Studies

(© TatyanaGI/ iStock/ Thinkstock.)

MRI/MRA results show a temporal-parietal glioblastoma that has extended into margins of the occipital lobes.

Discussion Questions

1. Are these the diagnostic studies that you expected to be ordered?
2. Why are these diagnostic study results of concern to you?

This case study is continued in Chapter 62.

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. In a patient with a disease that affects the myelin sheath of nerves, such as multiple sclerosis, the glial cells affected are the
   a. microglia.
   b. astrocytes.
   c. ependymal cells.
   d. oligodendrocytes.
2. A patient taking a drug that impairs function of the extrapyramidal system may have loss of
   a. sensations of pain and temperature.
   b. regulation of the autonomic nervous system.
   c. integration of somatic and special sensory inputs.
   d. automatic movements associated with skeletal muscle activity.

3. During the neurologic assessment, the nurse finds the patient has speech problems with weakness of the right arm and lower face. The nurse would expect a CT scan to show pathology in the distribution of the
   a. basilar artery.
   b. left middle cerebral artery.
   c. right anterior cerebral artery.
   d. left posterior communicating artery.
4. A patient is seen in the emergency department after diving into the pool and hitting the bottom with a blow to the face that hyperextended the neck and scraped the skin off the nose. The patient reports double vision when looking down. During the neurologic assessment, the nurse finds the patient is unable to abduct either eye. The nurse recognizes this finding is related to
   a. a basal skull fracture.
   b. an injury to CN VI on both sides.
   c. a stiff neck from the hyperextension injury.
   d. facial swelling from the scrape on the bottom of the pool.
5. Stimulation of the parasympathetic nervous system results in *(select all that apply)*
   a. constriction of the bronchi.
   b. dilation of skin blood vessels.
   c. increased secretion of insulin.
   d. increased blood glucose levels.
   e. relaxation of the urinary sphincters.
6. When assessing the muscle strength of an older adult, the nurse cannot compare the findings with those of a younger adult because
   a. nutrition status is better in young adults.
   b. muscle tone and strength decrease in older adults.
   c. muscle strength should be the same for all adults.
   d. most young adults exercise more than older adults.
7. A patient is admitted with a headache, fever, and general malaise. The HCP has asked that the patient be prepared for a lumbar puncture. What is a *priority* nursing action to avoid complications?
   a. Review laboratory results for changes in the white cell count.
   b. Give acetaminophen for the headache and fever before the procedure.
   c. Notify the provider if signs of increased intracranial pressure are present.
   d. Administer antibiotics before the procedure to treat the potential meningitis.
8. During neurologic testing, the patient can perceive pain elicited by pinprick. Based on this finding, the nurse may omit testing for
   a. position sense.
   b. patellar reflexes.
   c. temperature perception.
   d. heel-to-shin movements.
9. A patient's eyes jerk while the patient looks to the left. The nurse records this finding as
   a. nystagmus.
   b. CN VI palsy.
   c. ophthalmic dyskinesia.
   d. oculocephalic response.
10. The nurse is caring for a patient with peripheral neuropathy who is scheduled for EMG studies tomorrow morning. The nurse should
    a. ensure the patient has an empty bladder.
    b. instruct the patient about the risk for electric shock.
    c. ensure the patient has no metallic jewelry or metal fragments.
    d. teach the patient that pain may be experienced during the study.

1. d; 2. d; 3. b; 4. b; 5. a, b, c, e; 6. b; 7. c; 8. c; 9. a; 10. d.

Mobility
Safety
Sensory Perception

LEARNING OUTCOMES

1. Explain the mechanisms that maintain normal intracranial pressure.
2. Describe the common etiologies, clinical manifestations, and interprofessional care of the patient with increased intracranial pressure.
3. Describe the nursing management of the patient with increased intracranial pressure.
4. Compare types of head injury by mechanism of injury and clinical manifestations.
5. Describe the interprofessional and nursing management of the patient with a head injury.
6. Compare the types, clinical manifestations, and interprofessional care of patients with brain tumors.
7. Discuss the nursing management of the patient with a brain tumor.
8. Describe the nursing management of the patient undergoing cranial surgery.
9. Distinguish among the primary causes and interprofessional and nursing management of brain abscess, meningitis, and encephalitis.

KEY TERMS

cerebral edema
coma
concussion
contusion
diffuse axonal injury (DAI)
encephalitis
epidural hematoma
Glasgow Coma Scale (GCS)
head injury
intracerebral hematoma
intracranial pressure (ICP)
meningitis
nuchal rigidity
subdural hematoma
unconsciousness

The body has various mechanisms by which it regulates the intracranial space to promote optimal brain function. Acute intracranial problems can disrupt these processes, leading to increased intracranial pressure (ICP), reduced blood flow to the brain, and brain tissue damage. This chapter discusses the mechanisms that maintain normal ICP and problems that lead to increased ICP.

INTRACRANIAL REGULATION

Understanding the dynamics of ICP is important in caring for patients with neurologic problems. The skull is an enclosed space with 3 essential volume components: brain tissue, blood, and cerebrospinal fluid (CSF) (Fig. 61.1). Brain tissue makes up about 78% of this volume. Blood in the arterial, venous, and capillary network makes up 12% of the volume. The remaining 10% is the volume of CSF.

We categorize brain injury in 2 phases, primary and secondary injury. *Primary injury* occurs at the initial time of an injury (e.g., impact of car accident, blunt-force trauma). It results in displacement, bruising, or damage to any cranial component (brain tissue, blood, CSF).

Secondary injury is the resulting hypoxia, ischemia, hypotension, edema, or increased ICP that follows the primary injury. Secondary injury can occur several hours to days after the initial injury. It is the modifiable concern when managing brain

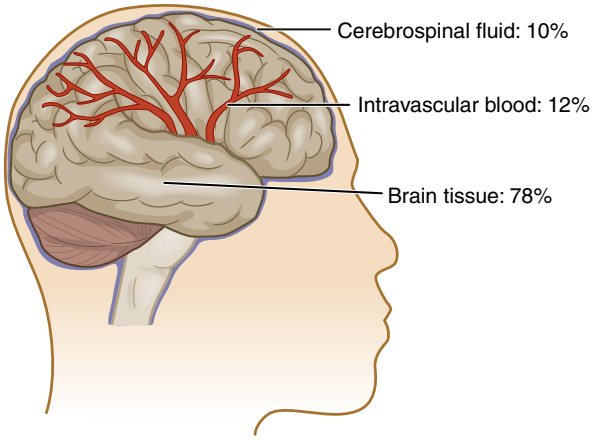

Fig. 61.1 Components of the brain.

injury. Management of the patient with an acute intracranial problem must include managing secondary injury and preventing increased ICP.

Normal Intracranial Pressure

Intracranial pressure (ICP) is the hydrostatic force measured in the brain CSF compartment. Under normal conditions in which intracranial volume stays relatively constant, the balance among the 3 components (brain tissue, blood, CSF) maintains ICP. Factors that influence ICP under normal conditions are changes in (1) arterial pressure, (2) venous pressure, (3) intraabdominal and intrathoracic pressure, (4) posture, (5) temperature, and (6) blood gases, especially CO_2 levels. The degree to which these factors increase or decrease the ICP depends on the brain's ability to adapt to changes.

The Monro-Kellie doctrine states that the 3 components must stay at a relatively constant volume within the closed skull. If the volume of any 1 of the 3 components increases within the skull and the volume from another component is displaced, the total intracranial volume will not change.[1] This hypothesis is applicable only in situations in which the skull is closed. The hypothesis does not apply in persons with displaced skull fractures or craniectomy (removal of part of the skull).

We can measure ICP in the ventricles, subarachnoid space, subdural space, epidural space, or brain tissue with a pressure transducer.[2] Normal ICP ranges from 5 to 15 mm Hg. A sustained pressure greater than 20 mm Hg is abnormal.

Normal Compensatory Adaptations

In applying the Monro-Kellie doctrine, the body can adapt to volume changes within the skull in 3 different ways to maintain a normal ICP. The first compensatory mechanisms can include changes in CSF volume. CSF volume can be changed by altering CSF absorption or production, and by displacing CSF into the spinal subarachnoid space. Second, changes in intracranial blood volume can occur through the collapse of cerebral veins and dural sinuses, regional cerebral vasoconstriction or dilation, and changes in venous outflow. Third, brain tissue volume compensates through distention of the dura or compression of brain tissue.

Initially an increase in volume does not increase ICP because of these compensatory mechanisms. However, there is a limited ability to compensate for changes in volume. As the volume increase continues, ICP rises. Decompensation occurs. This results in compression and ischemia.

Cerebral Blood Flow

Cerebral blood flow (CBF) is the amount of blood in milliliters passing through 100 g of brain tissue in 1 minute. The global CBF is about 50 mL/min/100 g of brain tissue. Maintaining blood flow to the brain is critical because the brain requires a constant supply of O_2 and glucose. The brain uses 20% of the body's O_2 and 25% of its glucose.[3]

Autoregulation of Cerebral Blood Flow

The brain regulates its own blood flow in response to its metabolic needs despite wide fluctuations in systemic arterial pressure. *Cerebral autoregulation* is the automatic adjustment in the diameter of the cerebral blood vessels by the brain to maintain a constant blood flow with changes in arterial BP. The purpose of autoregulation is to ensure a consistent CBF to provide for the metabolic needs of brain tissue and maintain cerebral perfusion pressure (CPP) within normal limits.

The lower limit of systemic arterial pressure at which autoregulation is effective is a mean arterial pressure (MAP) of 70 mm Hg. Below this, CBF decreases, and symptoms of cerebral ischemia, such as syncope and blurred vision, occur. The upper limit of systemic arterial pressure at which autoregulation is effective is a MAP of 150 mm Hg. When this pressure is exceeded, the vessels are maximally constricted and further vasoconstrictor response is lost.

The *cerebral perfusion pressure* is the pressure needed to ensure blood flow to the brain. CPP is equal to the MAP minus the ICP (CPP = MAP − ICP). See the example in Table 61.1. Normal CPP is 60 to 100 mm Hg. As CPP decreases, autoregulation fails and CBF decreases. A CPP of less than 50 mm Hg is associated with ischemia and neuron death. A CPP of less than 30 mm Hg results in ischemia. It is incompatible with life. This is why it is important to maintain MAP when ICP is increased.

Although CPP is clinically useful, it does not consider the effect of cerebrovascular resistance. Cerebrovascular resistance is generated by the arterioles within the cranium. It links CPP and blood flow as follows:

$$\text{CPP} = \text{Flow} \times \text{Resistance}$$

When cerebrovascular resistance is high, blood flow to brain tissue is impaired. Normally, autoregulation maintains an adequate CBF and CPP by adjusting the diameter of cerebral blood vessels and metabolic factors that affect ICP.

CPP may not reflect perfusion pressure in all parts of the brain. There may be local areas of swelling and compression that limit perfusion pressure. Thus these patients may need a higher CPP to prevent localized tissue damage. For example, a patient with an acute stroke may need a higher BP, increasing MAP and CPP, to increase perfusion to the brain and prevent further tissue damage.

TABLE 61.1 Calculating Cerebral Perfusion Pressure (CPP)

$CPP = MAP - ICP$

$MAP = DBP + 1/3\,(SBP - DBP)$

OR

$$MAP = \frac{SBP + 2\,(DBP)}{3}$$

Example: Systemic BP = 122/84 mm Hg
MAP = 97 mm Hg
ICP = 12 mm Hg
CPP = 85 mm Hg

Factors Affecting Cerebral Blood Flow

CO_2, O_2, and hydrogen ion concentration affect cerebral blood vessel tone. An increase in the partial pressure of CO_2 in arterial blood ($PaCO_2$) relaxes smooth muscle, dilates cerebral vessels, decreases cerebrovascular resistance, and increases CBF. A decrease in $PaCO_2$ constricts cerebral vessels, increases cerebrovascular resistance, and decreases CBF.

Cerebral O_2 tension of less than 50 mm Hg results in cerebrovascular dilation. Dilation decreases cerebrovascular resistance, increases CBF, and increases O_2 tension. However, if O_2 tension is not increased, anaerobic metabolism begins, resulting in a buildup of lactic acid. As lactic acid increases and hydrogen ions accumulate, the environment becomes more acidic. Within this acidic environment, further vasodilation occurs in a continued attempt to increase blood flow. The combination of a severely low partial pressure of O_2 in arterial blood (PaO_2) and increased hydrogen ion concentration (acidosis), which are both potent cerebral vasodilators, may produce a state in which autoregulation is lost and compensatory mechanisms do not meet tissue metabolic demands.

CBF can be affected by cardiac or respiratory arrest, systemic bleeding, and other pathophysiologic states (e.g., diabetic coma, infections, toxicities). Regional CBF can be affected by trauma, tumors, cerebral bleeding, or stroke. When regional or global autoregulation is lost, CBF is no longer maintained at a constant level but is directly influenced by changes in systemic BP, hypoxia, or catecholamines.

PATHOPHYSIOLOGY MAP

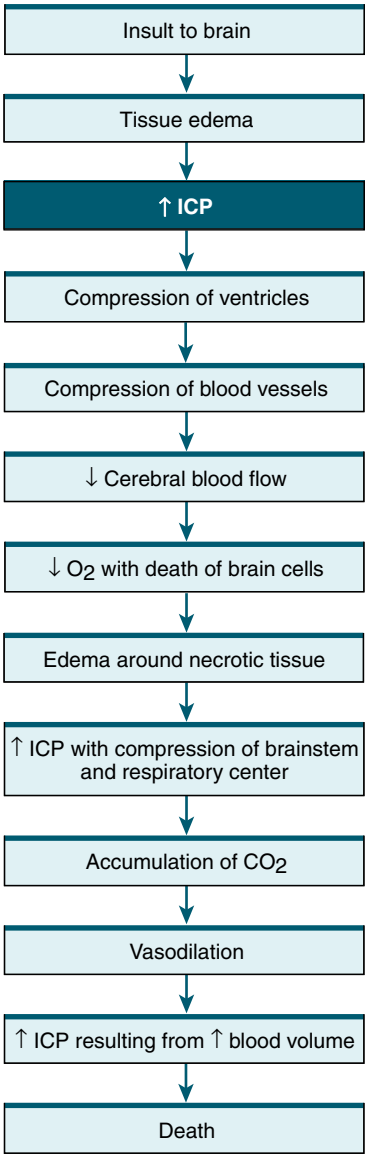

Fig. 61.2 Progression of increased ICP.

INCREASED INTRACRANIAL PRESSURE

Mechanisms of Increased Intracranial Pressure

Increased ICP is a potentially life-threatening situation that results from an increase in any or all the 3 components (brain tissue, blood, CSF) within the skull. Increased ICP is clinically significant because it decreases CPP and increases risks for brain ischemia and infarction. It has a poor prognosis.[4] Common causes of increased ICP include a mass (e.g., hematoma, contusion, abscess, tumor) and cerebral edema (from brain tumors, hydrocephalus, head injury, brain inflammation).

These cerebral insults increase the formation and spread of cerebral edema. This may result in hypercapnia, cerebral acidosis, impaired autoregulation, and systemic hypertension. Edema distorts brain tissue, further increasing the ICP, and leads to even more tissue hypoxia and acidosis. Fig. 61.2 shows the progression of increased ICP.

It is critical to maintain CBF to preserve tissue and thus minimize secondary injury. Sustained increases in ICP result in brainstem compression and brain herniation. *Herniation* occurs as the brain tissue is forcibly shifted from a compartment of greater pressure to a compartment of less pressure.

Displacement and herniation of brain tissue can cause a potentially reversible process to become irreversible. Ischemia and edema are further increased, compounding the preexisting problem. Compression of the brainstem and cranial nerves (CNs) may be fatal. Fig. 61.3 shows types of herniation. Herniation forces the cerebellum and brainstem downward through the foramen magnum. If compression of the brainstem is unrelieved, respiratory arrest will occur due to compression of the respiratory control center in the medulla. In this situation, intense pressure is placed on the brainstem. If herniation continues, brainstem death is imminent.

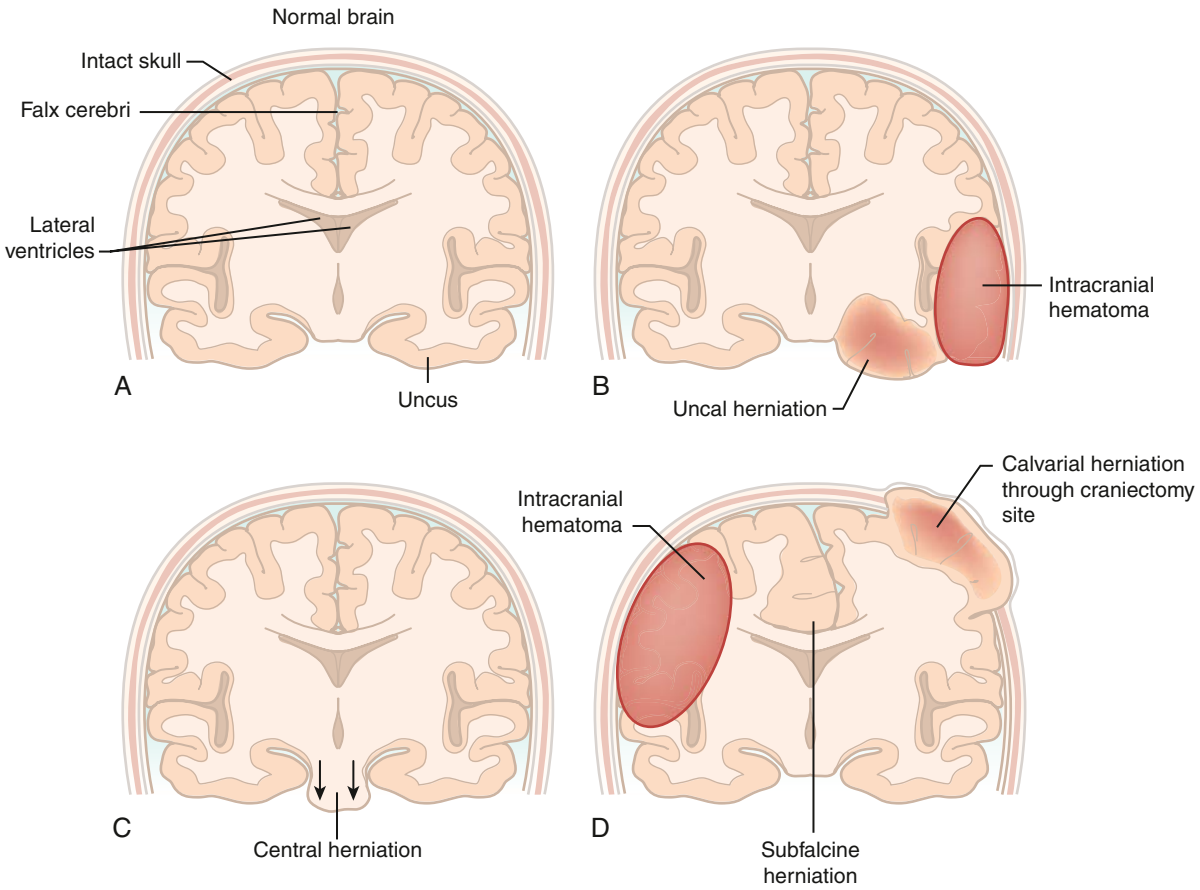

Fig. 61.3 Herniation. (A) Normal relationship of intracranial structures. (B, C, and D) Shifts of intracranial structures.

TABLE 61.2 Causes of Cerebral Edema

Cerebral Infections
- Encephalitis
- Meningitis

Head Injuries and Brain Surgery
- Contusion
- Hemorrhage
- Posttraumatic brain swelling

Mass Lesions
- Brain abscess
- Brain tumor (primary, metastatic)
- Hematoma (intracerebral, subdural, epidural)
- Hemorrhage (intracerebral, cerebellar, brainstem)

Toxic or Metabolic Encephalopathies
- Hepatic encephalopathy
- Lead or arsenic intoxication
- Uremia

Vascular Insult
- Anoxic and ischemic episodes
- Cerebral infarction (thrombotic or embolic)
- Venous sinus thrombosis

Cerebral Edema

There are a variety of causes of **cerebral edema** (increased accumulation of fluid in the extravascular spaces of brain tissue) (Table 61.2). Cerebral edema results in an increase in tissue volume that can increase ICP. The extent and severity of the original insult are factors that determine the degree of cerebral edema.

There are 3 types of cerebral edema: vasogenic, cytotoxic, and interstitial. A patient may have more than 1 type.

Vasogenic Cerebral Edema

Vasogenic cerebral edema is the most common type of cerebral edema. It occurs mainly in the white matter. It results from disruption of the blood-brain barrier. This allows large molecules (protein, blood products) to enter brain tissue. This exposes brain cells to toxic products from the blood and results in an osmotic gradient that causes fluid to flow from the intravascular to extravascular space. The result is an increase in the extracellular fluid volume. Systemic BP, site of the brain injury, and extent of the blood-brain barrier defect influence the extent of the spread of edema.

Edema may produce a continuum of symptoms. These range from headache to a decrease in consciousness, including **coma** (profound state of unconsciousness) and focal (specific to a certain area of the brain) neurologic deficits. In cases of cerebral edema, a headache can quickly progress to coma and death. So, you must be vigilant in your assessment.

Cytotoxic Cerebral Edema

Cytotoxic cerebral edema results from disruption of the integrity of the cell membranes. It develops from destructive lesions or trauma to brain tissue, resulting in cerebral hypoxia or anoxia and syndrome of inappropriate antidiuretic hormone (SIADH) secretion. In this type of edema, the blood-brain barrier stays

intact. Cerebral edema occurs from fluid and protein shifts from the extracellular space directly into the cells, with subsequent swelling and loss of cellular function.

Interstitial Cerebral Edema

Interstitial cerebral edema is usually a result of hydrocephalus. *Hydrocephalus* is a buildup of fluid in the brain. It is manifested by ventricular enlargement. It can be due to excess CSF production, obstruction of flow, or an inability to reabsorb the CSF.

Clinical Manifestations

The manifestations of increased ICP can take many forms, depending on the cause, location, and rate of increases in ICP. Any patient who becomes unconscious acutely, regardless of the cause, should be suspected of having increased ICP.

Change in Level of Consciousness

Level of consciousness (LOC) is the most sensitive and reliable indicator of neurologic status. Changes in LOC are a result of impaired CBF, which causes O_2 deprivation to the cells of the cerebral cortex and reticular activating system (RAS). The RAS is found in the brainstem, with neural connections to many parts of the nervous system. An intact RAS can maintain a state of wakefulness even in the absence of a functioning cerebral cortex. Interruptions of impulses from the RAS or changes in functioning of the cerebral hemispheres can cause **unconsciousness,** an abnormal state of complete or partial unawareness of self or environment.

The patient's state of consciousness is defined by their clinical responses and pattern of brain activity (recorded by an electroencephalogram [EEG]). A change in consciousness may be dramatic (as in coma) or subtle (e.g., flattening of affect, change in orientation, decrease in level of attention). In the deepest state of unconsciousness (e.g., coma), the patient does not respond to painful stimuli. Corneal and pupillary reflexes are absent. The patient cannot swallow or cough and is incontinent of urine and feces. The EEG pattern shows suppressed or absent neuronal activity.

Changes in Vital Signs

Increasing pressure on the thalamus, hypothalamus, pons, and medulla causes changes in vital signs.

Manifestations such as *Cushing triad* (systolic hypertension with a widening pulse pressure, bradycardia with a full and bounding pulse, irregular respirations) may be present. They often do not appear until ICP has been increased for some time or is suddenly and markedly increased (e.g., head trauma). Cushing triad as a medical emergency. It is a sign of brainstem compression and impending death. A change in body temperature may occur because increased ICP affects the hypothalamus.

CHECK YOUR PRACTICE

You are monitoring vital signs of an 82-year-old woman who has a head injury. She fell while walking on the sidewalk, hitting her head on a fire hydrant. She was confused on admission with stable vital signs: BP 150/86, pulse 84, respirations 14/min; 2 hr after admission, her vital signs are BP 166/74, pulse 54, respirations 10 to 16/min.

- What is your interpretation of her vital signs?

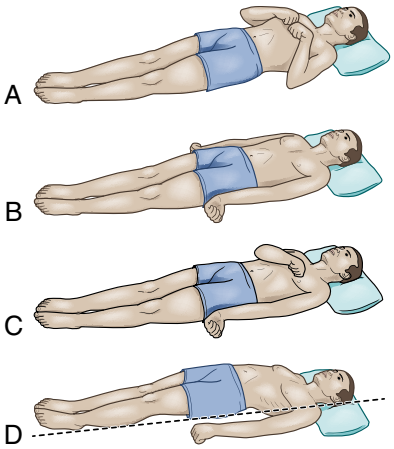

Fig. 61.4 Decorticate and decerebrate posturing. (A) Decorticate response. Flexion of arms, wrists, and fingers with adduction in upper extremities. Extension, internal rotation, and plantar flexion in lower extremities. (B) Decerebrate response. All 4 extremities in rigid extension, with hyperpronation of forearms and plantar flexion of feet. (C) Decorticate response on right side of body and decerebrate response on left side of body. (D) Opisthotonic posturing.

Ocular Signs

Compression of CN III, the oculomotor nerve, results in pupil dilation on the same side *(ipsilateral)* as the mass lesion. There may be sluggish or no pupil response to light, inability to move the eye upward and adduct, and ptosis of the eyelid. These signs result from the brain shifting from midline, compressing the trunk of CN III, and paralyzing the muscles controlling pupillary size and shape. In this situation, a fixed, unilateral, dilated pupil is a neurologic emergency that indicates brain herniation.

Other CNs may be affected, including the optic (CN II), trochlear (CN IV), and abducens (CN VI) nerves. Signs of problems with these CNs include blurred vision, diplopia, and changes in extraocular eye movements. *Central herniation* may initially manifest as sluggish but equal pupil response. *Uncal herniation* may cause a dilated unilateral pupil. *Papilledema* (an edematous optic disc seen on retinal examination) is a nonspecific sign of persistent increases in ICP.

Decrease in Motor Function

As the ICP continues to rise, the patient has changes in motor ability. A *contralateral* (opposite side of the mass lesion) hemiparesis or hemiplegia may develop depending on the location of the source of the increased ICP. If painful stimuli are used to elicit a motor response, the patient may localize to the stimuli or withdraw from it.

Noxious stimuli may elicit *decorticate* (flexor) or *decerebrate* (extensor) posturing (Fig. 61.4). Decorticate posture consists of internal rotation and adduction of the arms with flexion of the elbows, wrists, and fingers. It is a result of interruption of voluntary motor tracts in the cerebral cortex. Extension of the legs may be seen. A decerebrate posture may indicate more serious damage. It results from disruption of motor fibers in the midbrain and brainstem. In this position, the arms are stiffly extended, adducted, and hyperpronated. There is hyperextension of the legs with plantar flexion of the feet.

Headache

Although the brain itself is insensitive to pain, compression of other intracranial structures, such as arteries, veins, and CNs, can cause a headache. A nocturnal headache and/or a headache in the morning is cause for concern. It may indicate a tumor or other space-occupying lesion that is causing increased ICP. Straining, agitation, or movement may worsen the pain.

Vomiting

Vomiting, not preceded by nausea, is called *unexpected vomiting*. It is often a nonspecific sign of increased ICP that is related to pressure changes in the cranium. Projectile vomiting may occur. It is related to increased ICP.

Complications

The major complications of uncontrolled increased ICP are inadequate cerebral perfusion and cerebral herniation (Fig. 61.3). To help you understand cerebral herniation, we are going to describe 2 important structures in the brain. The *falx cerebri* is a thin wall of dura that folds down between the cortex, separating the 2 cerebral hemispheres. The *tentorium cerebelli* is a rigid fold of dura that separates the cerebral hemispheres from the cerebellum (Fig. 61.3). It is called the *tentorium* (meaning tent) because it forms a tent-like cover over the cerebellum.

Tentorial herniation (central herniation) occurs when a mass lesion in the cerebrum forces the brain to herniate downward through the opening created by the brainstem (the foramen magnum). Uncal herniation occurs when there is lateral and downward herniation. Cingulate herniation occurs when there is lateral displacement of brain tissue beneath the falx cerebri.

Diagnostic Studies

Diagnostic studies can be used to identify the cause of increased ICP (Table 61.3). CT and MRI can discover many conditions that can cause increased ICP and assess the effect of treatment.

Other tests include EEG, cerebral angiography, ICP measurement, brain tissue oxygenation measurement via the LICOX catheter (described later), positron emission tomography (PET), transcranial Doppler studies, and evoked potential studies. In general, a lumbar puncture (LP) is contraindicated when we suspect increased ICP. The reason is that cerebral herniation could occur from the sudden release of the pressure in the skull from the area above the LP.

In some agencies, a hand-held near-infrared scanner (Infrascanner) is used to detect life-threatening intracranial bleeding. The scanner directs a wavelength of light that can penetrate tissue and bone. Blood from intracranial hematomas absorbs the light differently from other areas of the brain. Transcranial doppler can monitor changes in cerebrovascular resistance.

Monitoring ICP and Cerebral Oxygenation

Indications for Intracranial Pressure Monitoring

ICP monitoring is used to guide care when the patient is at risk for or has increased ICP.[4] It may be used in patients with a variety of neurologic problems, including stroke, hemorrhage, tumor, infection, or traumatic brain injury (TBI). ICP should be monitored in patients admitted with a *Glasgow Coma Scale* (GCS) score of 8 or less and an abnormal CT scan or MRI. These results indicate that the patient may have bleeding, contusion, edema, or other problems.

TABLE 61.3 Interprofessional Care

Increased Intracranial Pressure

Diagnostic Assessment

- History and physical assessment
- Vital signs, neurologic assessments, ICP measurements
- Skull, chest, and spinal x-ray studies
- CT scan, MRI, cerebral angiography, EEG, PET
- Transcranial Doppler studies
- Infrascanner
- ECG
- Evoked potential studies
- Lumbar puncture (not done if there is a risk for herniation)
- Laboratory studies, including CBC, coagulation profile, electrolytes, serum creatinine, ABGs, ammonia level, drug and toxicology screen
- CSF analysis (protein, WBC, glucose)

Management

- Elevate head of bed to 30 degrees with head in a neutral position
- Mechanical ventilation
- ICP monitoring
- Cerebral oxygenation monitoring ($PbtO_2$, $SjvO_2$)
- Maintain PaO_2 ≥100 mm Hg
- Maintain fluid balance and assess osmolality
- Maintain systolic arterial pressure between 100 and 160 mm Hg
- Maintain CPP >60 mm Hg
- Reduction of cerebral metabolism (e.g., high-dose barbiturates)

Drug Therapy

- Osmotic diuretic (mannitol)
- Hypertonic saline
- Antiseizure drugs (e.g., phenytoin)
- Corticosteroids for brain tumors, bacterial meningitis
- Histamine (H_2)-receptor antagonist (e.g., cimetidine) or proton pump inhibitor (e.g., pantoprazole to prevent GI ulcers and bleeding)

Methods of Measuring ICP

Patients with conditions known to increase ICP, except those with irreversible problems or advanced neurologic disease, usually undergo ICP monitoring in an ICU. Multiple methods and devices are available to monitor ICP (Fig. 61.5).

The gold standard for monitoring ICP is the *ventriculostomy,* in which a specialized catheter is inserted into the lateral ventricle and coupled to an external transducer (Figs. 61.6 and 61.7). This technique directly measures the pressure within the ventricles, facilitates removal and/or sampling of CSF, and allows for intraventricular drug administration. The transducer is external. We must ensure that the transducer is level with the foramen of Monro (interventricular foramen). The system must also be at the ideal height (Fig. 61.8A). A reference point for this foramen is the tragus of the ear. Every time the patient is repositioned, assess the system to ensure it is level.

The *fiberoptic catheter,* an alternative technology, uses a sensor transducer found within the catheter tip. The sensor tip is

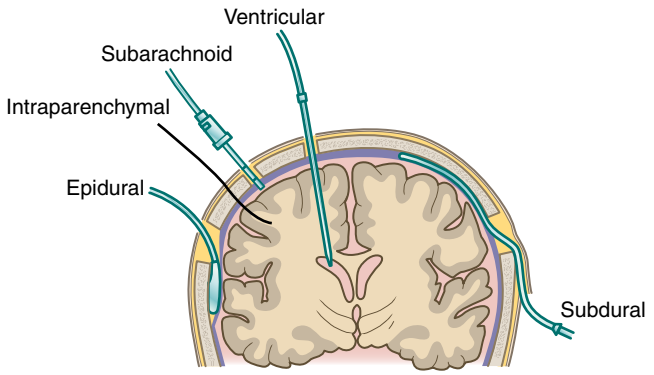

Fig. 61.5 Coronal section of brain showing potential sites for placement of ICP monitoring devices.

placed within the ventricle or the brain tissue and gives a direct measurement of brain pressure.

The *air pouch/pneumatic technology* uses an air-filled pouch to measure ICP. The pouch is at the of a catheter that maintains a constant volume. The pressure changes within the cranium are transmitted through the changes exerted on this pouch to the monitor.

ICP is represented on the monitor as a mean pressure in millimeters of mercury (mm Hg). If a CSF drainage device is in place, the drain must be closed for at least 6 minutes to ensure an accurate reading. Record the waveform strip along with other pressure monitoring waveforms. The normal ICP waveform has 3 phases (Fig. 61.6 and Table 61.4). It is important to monitor the ICP waveform and the mean CPP. When ICP is normal, P1, P2, and P3 resemble a staircase. As ICP increases, P2 rises above P1. This indicates poor ventricular compliance (Fig. 61.6). Consider the rate at which changes occur and the patient's condition. Neurologic deterioration may not occur until the ICP increase is pronounced and sustained. Immediately report to the HCP any increase in ICP, either as a mean increase in pressure or as an abnormal waveform configuration.

Causes of inaccurate ICP readings include CSF leaks around the monitoring device, obstruction of the intraventricular catheter (from tissue or blood clot), a difference between the height of the catheter and the transducer, kinks in the tubing, and incorrect height of the drainage system relative to the patient's reference point. Bubbles or air in the tubing can dampen the waveform.

Infection is a serious complication with ICP monitoring. Factors that contribute to infection include ICP monitoring more than 5 days, use of a ventriculostomy, a CSF leak, and a concurrent systemic infection. Routinely assess the insertion site and use aseptic technique. Monitor the CSF for a change in drainage color or clarity.

Cerebrospinal Fluid Drainage

With a ventricular catheter, it is possible to control ICP by removing CSF (Fig. 61.7). The HCP typically orders a specific level at which to start drainage (e.g., if ICP is greater than 20 mm Hg) and the frequency of drainage (intermittent or continuous). Draining CSF relieves pressure inside the skull (Fig. 61.8B).

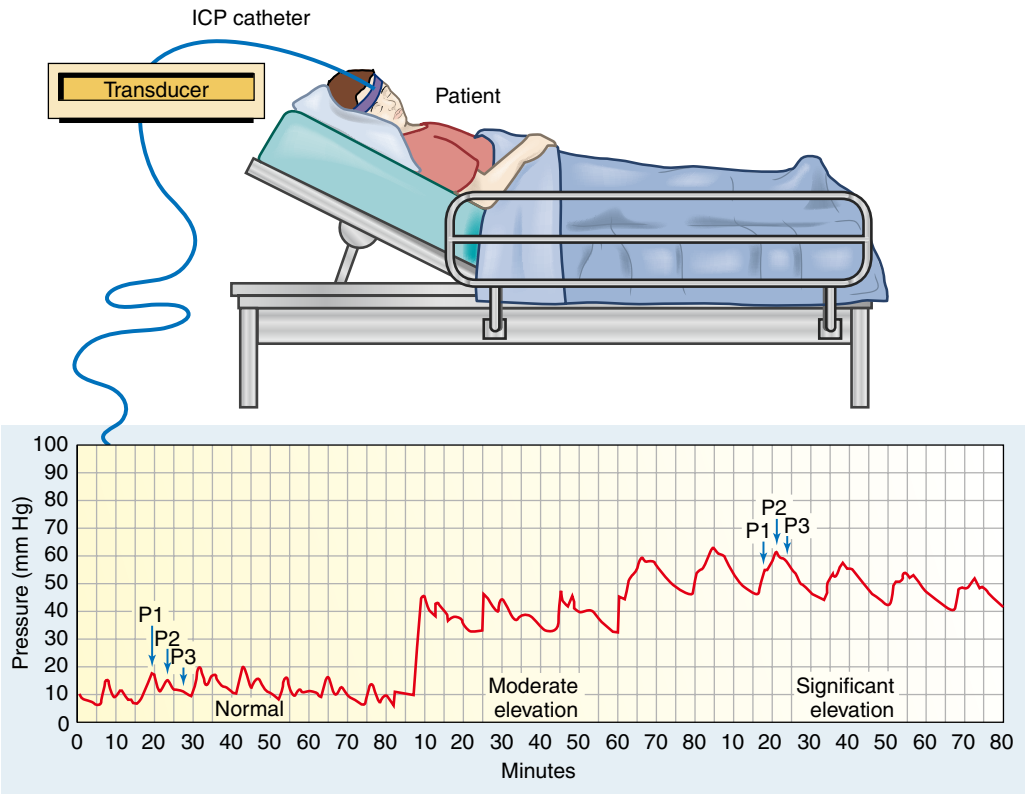

Fig. 61.6 ICP monitoring can continuously measure ICP. The ICP tracing shows normal, elevated, and plateau waves. At high ICP, the P2 peak is higher than the P1 peak, and the peaks become less distinct and plateau. (Modified from Copstead-Kirkhorn LC, Banasik JL: *Pathophysiology,* ed 5, St Louis, 2013, Mosby.)

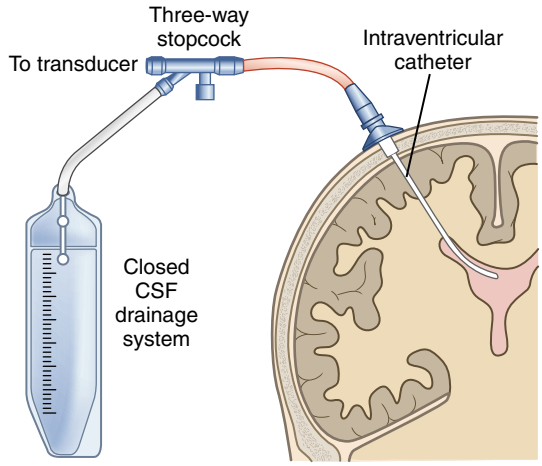

Fig. 61.7 Ventriculostomy in place. Cerebrospinal fluid *(CSF)* can be drained via a ventriculostomy when ICP exceeds the upper pressure parameter set by the HCP. Intermittent drainage involves opening the 3-way stopcock to allow CSF to flow into the drainage bag for brief periods (30 to 120 seconds) until the pressure is less than the upper pressure parameters.

Although CSF removal decreases ICP and improves CPP, there are no universal guidelines for CSF removal. Guidelines are typically based on agency or HCP preference.[5]

The 2 options for CSF drainage are intermittent or continuous. With intermittent drainage, you open the system at the indicated ICP and allow CSF to drain for 2 to 3 minutes. Then close the stopcock to return the ventriculostomy to a closed system. With continuous ICP drainage, carefully monitor the volume of CSF drained. Keep in mind that normal CSF production is about 20 to 30 mL/hr. There is a total CSF volume of about 150 mL within the ventricles and subarachnoid space. Post a sign above the patient's bed to notify anyone before turning, moving, or suctioning the patient, to prevent the removal of too much CSF. This can result in serious complications.

Complications include ventricular collapse, infection, and herniation or subdural hematoma formation from rapid decompression. Use strict aseptic technique during dressing changes or sampling of CSF to prevent infection. Keep the system intact to ensure that the ICP readings are accurate because treatment is based on the pressures.

TABLE 61.4 Normal Intracranial Pressure Waveforms

Waveform (Fig. 61.6)	Meaning
P1 Percussion wave	Represents arterial pulsations. Normally the highest of the 3 waveforms.
P2 Rebound wave or tidal wave	Reflects intracranial compliance or relative brain volume. When P2 is higher than P1, intracranial compliance is compromised.
P3 Dicrotic wave	Follows dicrotic notch. Represents venous pulsations. Normally the lowest waveform.

Cerebral Oxygenation Monitoring

Technology is available to measure cerebral oxygenation and assess perfusion. Three intracranial devices used in ICU settings are the LICOX catheter, Neurovent catheter, and jugular venous bulb catheter.

The LICOX and Neurovent catheters are placed in healthy white matter of the brain (Fig. 61.9). These catheters measure brain oxygenation and temperature. They provide continuous monitoring of the O_2 pressure in brain tissue ($PbtO_2$). The normal range for $PbtO_2$ is 20 to 40 mm Hg. A low $PbtO_2$ level indicates ischemia or regional tissue hypoxia.[4] These catheters can also measure brain temperature. A cooler brain temperature (96.8°F [36°C]) may produce better outcomes.

Jugular venous bulb oximetry measures global O_2 extraction. The jugular venous bulb catheter is placed in the internal jugular vein and positioned so that the catheter tip is in the jugular bulb. An x-ray verifies placement. This catheter measures jugular venous O_2 saturation ($SjvO_2$), which indicates total venous

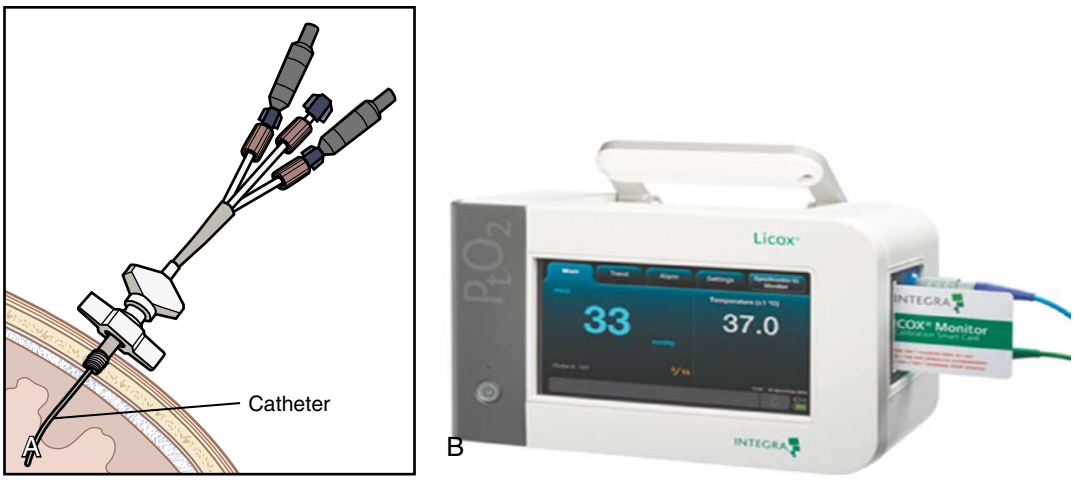

Fig. 61.9 (A) The LICOX brain tissue O_2 system involves insertion of a catheter. (B) The system measures O_2 in the brain ($PbtO_2$), brain tissue temperature, and ICP. (B, Courtesy of Integra LifeSciences Corporation, Plainsboro, NJ.)

brain tissue extraction of O_2. This is a measure of cerebral O_2 supply and demand. The normal $SjvO_2$ range is 60% to 75%. Values less than 50% indicate impaired cerebral oxygenation.[4]

In addition to measuring ICP and brain oxygenation, many HCPs are now looking at multimodality monitoring in TBI and intracranial hypertension. This technology includes brain microdialysis (measurement of small molecules), continuous EEG, and blood flow monitoring.

Interprofessional Care

The goals of interprofessional care (Table 61.3) are to (1) identify and treat the underlying cause of increased ICP and (2) support brain function. The earlier the condition is recognized and treated, the better the patient outcome. A careful history is important in the search for the underlying cause. The underlying cause of increased ICP is usually an increase in blood (bleeding), brain tissue (tumor or edema), or CSF (hydrocephalus) in the brain.

For any patient with increased ICP, it is important to maintain adequate oxygenation to support brain function and prevent secondary injury. An endotracheal tube or tracheostomy may be needed to maintain adequate ventilation. Arterial blood gas (ABG) analysis guides the O_2 therapy. The goal is to maintain the PaO_2 at 100 mm Hg or greater and to keep $PaCO_2$ in normal range at 35 to 45 mm Hg. The patient may need mechanical ventilation to ensure adequate oxygenation.

If increased ICP is caused by a mass (e.g., tumor, hematoma), surgical removal of the mass is the best treatment. In aggressive situations, a craniectomy (removal of part of skull) may be done to reduce ICP and prevent herniation.

Drug Therapy

Drug therapy plays an important part in managing increased ICP. Mannitol (Osmitrol) (25%) is an osmotic diuretic given IV. It decreases ICP through plasma expansion and an osmotic effect. The immediate plasma-expanding effect reduces the hematocrit and blood viscosity. This increases CBF and cerebral O_2 delivery. Mannitol creates a vascular osmotic gradient. The decrease in the total brain fluid content causes fluid to move from the tissues into the blood vessels, reducing the ICP. Monitor fluid and electrolyte status when osmotic diuretics are used. Mannitol may be contraindicated with renal disease and increased serum osmolality.

Hypertonic saline solution is another option. It produces massive movement of water out of edematous swollen brain cells and into blood vessels. This movement can reduce swelling and improve CBF. During an infusion, monitor BP and serum sodium levels because intravascular fluid volume excess can occur. Hypertonic saline infusion is just as effective as mannitol when treating increased ICP. They are often used concurrently when caring for a patient with a severe brain injury.[4]

Corticosteroids (e.g., dexamethasone) are used to treat vasogenic edema around tumors and abscesses. These drugs are not recommended for TBI. Corticosteroids stabilize the cell membrane and inhibit prostaglandin synthesis (see Fig. 12.2), preventing the formation of proinflammatory mediators. Corticosteroids also improve neuronal function by improving CBF and restoring autoregulation.

Complications of corticosteroids include hyperglycemia, infections, and gastrointestinal (GI) bleeding. Monitor fluid intake, electrolyte, and glucose levels. Perform blood glucose monitoring at least every 6 hours. Patients receiving corticosteroids should receive a histamine (H_2)-receptor blocker (e.g., cimetidine, ranitidine) or proton pump inhibitor (e.g., pantoprazole) to prevent GI ulcers and bleeding.

IV 0.9% sodium chloride is the preferred solution for giving secondary medications. If 5% dextrose in water or 0.45% sodium chloride is used, serum osmolality decreases and an increase in cerebral edema may occur.

Metabolic demands, such as fever (greater than 100.4°F [38°C]), agitation, shivering, pain, and seizures, can increase ICP. Implement measures to reduce these metabolic demands to lower the ICP in the at-risk patient. Monitor patients for seizure activity. They may need prophylactic antiseizure medication. Maintain the temperature at 96.8°F to 98.6°F (36°C to 37°C) by using antipyretics (e.g., acetaminophen), cool baths,

cooling blankets, ice packs, or intravascular cooling devices as needed. Do not let the patient shiver, because this increases the metabolic workload on the brain. If this occurs, the patient may need sedatives or a different cooling method.

Drug therapy for reducing cerebral metabolism may be an effective way to control ICP. Reducing the metabolic rate decreases the CBF and therefore the ICP. High doses of barbiturates (e.g., pentobarbital, thiopental) are used in patients with increased ICP refractory to other treatments. Barbiturates decrease cerebral metabolism, causing a decrease in ICP and a reduction in cerebral edema. With this treatment, monitor the patient's ICP, blood flow, and EEG. Barbiturate dosing is typically based on analysis of the bedside EEG tracing and the ICP. The HCP orders the barbiturate infusion at a rate that achieves a desired level of brain wave suppression to control ICP. *Total burst suppression,* recognized by the absence of spikes showing brain activity on the EEG monitor, shows that maximal therapeutic effect has been achieved.

Nutrition Therapy

Because malnutrition promotes continued cerebral edema, maintaining optimal nutrition is important. The patient with increased ICP is in a hypermetabolic and hypercatabolic state that increases the need for glucose as fuel for metabolism of the injured brain. If the patient cannot maintain an adequate oral intake, we should start other means of meeting nutrition needs, such as enteral feedings or parenteral nutrition.

Early feeding after brain injury may improve patient outcome.[5] Nutrition replacement should meet caloric needs by at least day 5 after injury.[5] Fluid and electrolyte status and metabolic needs should guide feedings or supplements. The patient should be kept in a euvolemic fluid state. Continuously evaluate the patient based on clinical factors such as urine output, insensible fluid loss, serum and urine osmolality, and serum electrolytes.

❖ NURSING MANAGEMENT: INCREASED INTRACRANIAL PRESSURE

◆ Assessment

You can obtain subjective data about the patient with increased ICP from the patient, caregiver, or family member who is familiar with the patient. Describe LOC by noting the specific behaviors seen. Assess LOC, body functions, and vital signs.

◆ Glasgow Coma Scale

The **Glasgow Coma Scale (GCS)** is a quick, practical, and standard system for assessing the LOC. The 3 areas assessed in the GCS are the patient's ability to (1) open the eyes when a verbal or painful stimulus is applied, (2) speak, and (3) obey commands. Specific assessments evaluate the patient's response to varying degrees of stimulus. Three indicators of response are evaluated: (1) opening of the eyes, (2) best verbal response, and (3) best motor response (Table 61.5).

Specific behaviors observed as responses to the testing stimulus are given a numeric value. Your responsibility is to elicit the best response on each of the scales. The subscale scores are especially important if a patient is untestable in an area. For example, severe periorbital edema may make eye opening impossible.

TABLE 61.5 Glasgow Coma Scale

Appropriate Stimulus	Response	Score
Eyes Open		
• Approach to bedside	Spontaneous response.	4
• Verbal command	Opening of eyes to name or command.	3
• Pain	Lack of opening of eyes to previous stimuli but opening to pain.	2
	Lack of opening of eyes to any stimulus.	1
	Untestable.[a]	U
Best Verbal Response		
• Verbal questioning with maximum arousal	Appropriate orientation, conversant. Correct identification of self, place, year, and month.	5
	Confusion. Conversant, but disorientation in 1 or more spheres.	4
	Inappropriate or disorganized use of words (e.g., cursing), lack of sustained conversation.	3
	Incomprehensible words, sounds (e.g., moaning).	2
	Lack of sound, even with painful stimuli.	1
	Untestable.[a]	U
Best Motor Response		
• Verbal command (e.g., "raise your arm, hold up 2 fingers")	Obedience of command.	6
• Pain (pressure on proximal nail bed)	Localizes pain, lack of obedience but presence of attempts to remove offending stimulus.	5
	Flexion withdrawal,[a] flexion of arm in response to pain without abnormal flexion posture.	4
	Abnormal flexion, flexing of arm at elbow and pronation, making a fist.	3
	Abnormal extension, extension of arm at elbow usually with adduction and internal rotation of arm at shoulder.	2
	Lack of response.	1
	Untestable.[a]	U

[a]Added to the original scale by some centers.

The total GCS score is the sum of the numeric values assigned to each of the 3 areas. The higher the scores, the higher the level of brain functioning. The highest GCS score is 15 for a fully alert person. The lowest possible score is 3. A GCS score of 8 or less generally indicates coma. Plot the results of the GCS scores on a graph. Use the data to determine if the patient is stable, improving, or deteriorating.

The GCS offers several advantages in the assessment of the unconscious patient. It allows different health care professionals to arrive at the same conclusion about the patient's status. It can be used to determine between different or changing states.

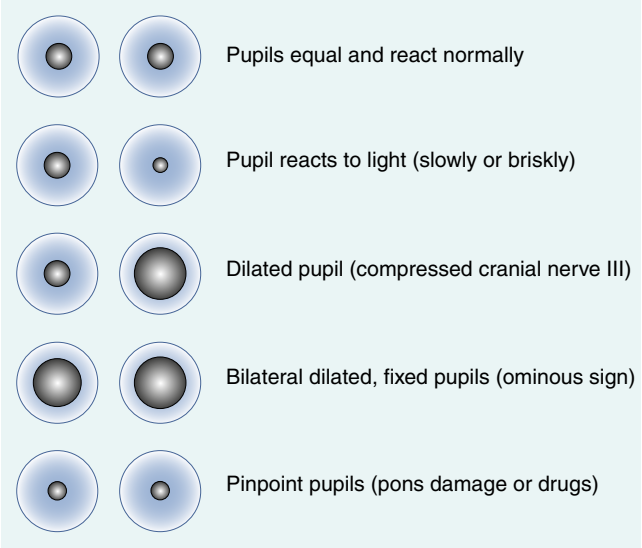

Fig. 61.10 Pupillary check for size and response.

Although the GCS is the standard assessment tool for LOC, we sometimes use other scales, such as the *Full Outline of Unresponsiveness (FOUR) scale*.[6] In cases of stroke or hemorrhage with increased ICP, use the NIH Stroke Scale (see Table 62.12). Other key neurologic assessments include CN assessment and motor and sensory testing. CN assessment is outlined in Table 60.4.

Neurologic Assessment

Compare the pupils for size, shape, movement, and reactivity (Fig. 61.10). If the oculomotor nerve (CN III) is compressed, the pupil on the affected side *(ipsilateral)* becomes larger until it fully dilates. If ICP continues to increase, both pupils dilate.

Test pupillary reaction with a penlight. The normal reaction is brisk constriction when the light is shone directly into the eye. Note a consensual response (slight constriction in the opposite pupil) at the same time. A sluggish reaction can indicate early pressure on CN III. A fixed pupil unresponsive to light stimulus usually indicates increased ICP. However, there are other causes of a fixed pupil. These include direct injury to CN III, previous eye surgery, atropine administration, and mydriatic eye drops.

In some agencies, HCPs are using a hand-held device *(pupillometer)* to measure the pupil reactivity and size. The device removes any subjectivity from the pupil evaluation.

Assess eye movements controlled by CN III, CN IV, and CN VI in the patient who is awake and able to follow commands. They can be used to assess brainstem function. Testing the corneal reflex gives information about CN V and CN VII. If this reflex is absent, start routine eye care to prevent corneal abrasion (see Chapter 22).

We can test the eye movements of the uncooperative or unconscious patient with the use of head movements (oculocephalic) and caloric stimulation (oculovestibular). To test the oculocephalic reflex (doll's eye reflex), turn the patient's head briskly to the left or right while holding the eyelids open. A normal response is movement of the eyes across the midline in the direction opposite that of the turning. Next, quickly flex and then extend the neck. Eye movement should be opposite to the direction of head movement—up when the neck is flexed and down when it is extended. Abnormal responses can help locate an intracranial lesion. We usually only do this test as part of the evaluation of brain death.

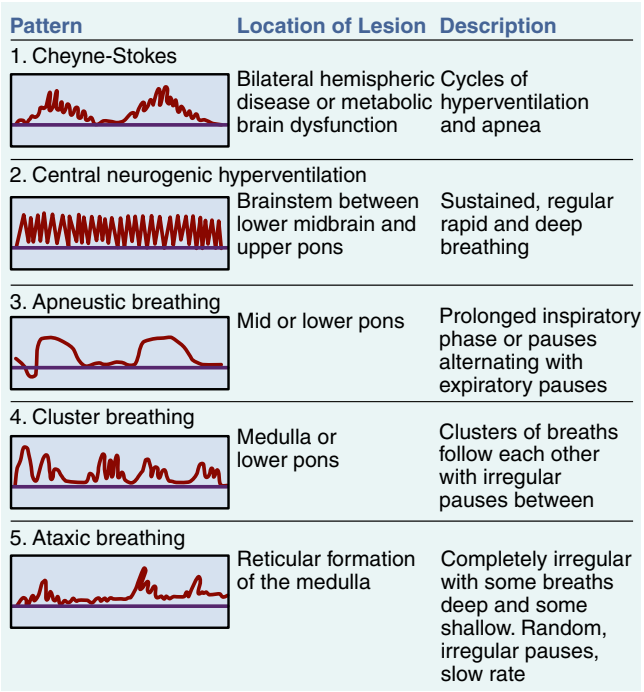

Fig. 61.11 Common abnormal respiratory patterns associated with coma.

To test the oculovestibular reflex (cold caloric), position the patient with the head of bed elevated. Instill a syringe of ice-cold water into the external auditory ear canal. Then, assess the patient's eyes for a total of 1 minute. The absence of eye movement or response indicates severe neurologic demise. This test requires patent external auditory ear canals and tympanic membranes.

Test all 4 extremities for strength. Note any asymmetry in strength or movement. Assess the motor response of the unconscious or uncooperative patient by observation of spontaneous movement. If no spontaneous movement is possible, apply a pain stimulus to the patient and note the response. Resistance to movement during passive range of motion exercises is another measure of strength. Do not include hand squeezing as part of the assessment of motor movement in the unconscious or uncooperative patient. This is a reflex action and can misrepresent the patient's status.

Record vital signs, including BP, pulse, respiratory rate, and temperature. Be aware of Cushing triad, which indicates severely increased ICP. Note the respiratory pattern. Specific respiratory patterns are associated with severely increased ICP (Fig. 61.11).

Clinical Problems

Clinical problems for the patient with increased ICP include:

- Increased intracranial pressure
- Inadequate tissue perfusion
- Risk for injury

Additional information on clinical problems and interventions for patients with increased ICP is presented in eNursing Care Plan 61.1 (available on the website for this chapter).

Planning

The overall goals for the patient with increased ICP are to (1) maintain a patent airway, (2) have ICP within normal limits, (3) have normal fluid, electrolyte, and nutrition balance, and (4) prevent complications from immobility and decreased LOC.

Implementation

Acute Care

Respiratory function. Maintaining a patent airway is critical in the patient with increased ICP. It is a major nursing responsibility. As the LOC decreases, the patient is at an increased risk for airway obstruction from the tongue dropping back and occluding the airway or from accumulation of secretions.

! SAFETY ALERT

Altered Breathing

- Be alert to altered breathing in a patient with increased ICP.
- Snoring sounds indicate obstruction and require immediate intervention.

Remove secretions by suctioning as needed. An oral airway facilitates breathing and provides an easier suctioning route in the comatose patient. In general, any patient with a GCS of 8 or less or an altered LOC who is unable to maintain a patent airway or effective ventilation needs intubation and mechanical ventilation.

Frequently monitor and evaluate the ABG values. Take measures to maintain the levels within prescribed or acceptable parameters. Appropriate ventilatory support can be ordered based on PaO_2 and $PaCO_2$ values.

Prevent hypoxia and hypercapnia to minimize secondary injury. Suctioning and coughing cause transient decreases in PaO_2 and increase ICP. Keep suctioning to a minimum and less than 10 seconds in duration. Give 100% O_2 before and after to prevent decreases in the PaO_2. To avoid cumulative increases in the ICP with suctioning, limit suctioning to 2 passes per suction procedure, if possible. Patients with increased ICP are at risk for lower CPP during suctioning.

Try to prevent abdominal distention, since it can interfere with respiratory function. Inserting a nasogastric (NG) tube to aspirate the stomach contents can prevent distention, vomiting, and aspiration. However, in patients with facial and skull fractures, an NG tube is contraindicated due to risk for inadvertent intracranial placement. Oral insertion of a gastric tube is preferred.

Sedation. Pain, anxiety, and fear related to the primary injury, therapeutic procedures, or noxious stimuli can increase ICP and BP, thus complicating the patient's management and recovery. The appropriate choice or combination of sedatives, paralytics, and analgesics for symptom management is a challenge. Giving these agents may alter the neurologic state, thus masking true neurologic changes. We may need to temporarily stop drug therapy to appropriately assess neurologic status. The choice, dose, and combination of agents may vary depending on the patient's history, neurologic state, and overall clinical presentation.

Opioids, such as morphine sulfate and fentanyl, are rapid-onset analgesics with minimal effect on CBF or O_2 metabolism. The IV sedative propofol (Diprivan) is used to manage anxiety and agitation in the ICU because of its rapid onset and short half-life. We can do an accurate neurologic assessment soon after stopping an infusion of propofol.

Dexmedetomidine (Precedex), an α_2-adrenergic agonist, is used for continuous IV sedation of mechanically ventilated patients in the ICU setting for up to 24 hours. When using continuous IV sedatives, be aware of the side effects of these drugs, especially hypotension. Hypotension can lower CPP.

Nondepolarizing neuromuscular blocking agents (e.g., vecuronium) are useful for achieving complete ventilatory control in the treatment of refractory intracranial hypertension. Because these agents paralyze muscles without blocking pain or noxious stimuli, they must be used in combination with sedatives, analgesics, or benzodiazepines.

Benzodiazepines, although useful for sedation, are usually avoided when managing the patient with increased ICP because of the hypotensive effect and long half-life. They are usually given as an adjunct to neuromuscular blocking agents.

The patient should be in a quiet, calm environment with minimal noise and interruptions. Observe the patient for signs of agitation, irritation, or frustration. Teach the caregiver and family about decreasing stimulation. Coordinate with team members to minimize procedures that may cause agitation.

Fluid and electrolyte balance. Fluid and electrolyte problems can have an adverse effect on ICP. Closely monitor IV fluids with the use of an accurate IV infusion control device or pump. Intake and output, accounting for insensible losses, and daily weights are important parameters in assessing fluid balance.

Monitor serum electrolytes, especially glucose, sodium, potassium, magnesium, and osmolality. Discuss abnormal values with the HCP.

Monitor urine output to detect problems related to diabetes insipidus and inappropriate secretion of antidiuretic hormone (SIADH). Diabetes insipidus is caused by a decrease in antidiuretic hormone (ADH). It results in increased urine output and hypernatremia. The usual treatment of diabetes insipidus is fluid replacement, vasopressin, or desmopressin acetate (DDAVP) (see Chapter 54). If it is not quickly identified and treated, severe dehydration will occur.

SIADH is caused by excess secretion of ADH. SIADH results in decreased urine output and dilutional hyponatremia. It may result in cerebral edema, changes in LOC, seizures, and coma. SIADH is described in Chapter 54.

Monitoring ICP. ICP monitoring is used with other parameters to guide the care of the patient and assess their response to treatment. Suctioning, hypoxemia, and arousal from sleep are factors that can increase ICP. Be alert to these factors and try to minimize them. Increased intrathoracic pressure can increase ICP by impeding the venous return. So, the patient should avoid coughing, straining, sneezing, and the Valsalva maneuver.

Body position. Proper head positioning is important. Maintain the patient in the head-up position. Keep the head

in a midline position, avoiding extreme neck flexion. Flexion can cause venous obstruction and contribute to increased ICP. Adjust the body position to decrease the ICP and improve the CPP. Elevating the head of the bed promotes drainage from the head and decreases the vascular congestion that can produce cerebral edema. However, raising the head of the bed more than 30 degrees can decrease the CPP by lowering systemic BP. Carefully evaluate the effects of elevating the head of the bed on both ICP and CPP. Position the bed so that it lowers the ICP while optimizing the CPP and other indices of cerebral oxygenation.

Turn the patient with slow, gentle movements. Rapid changes in position may increase ICP. Prevent discomfort when turning and positioning the patient because pain or agitation increases pressure. Avoid extreme hip flexion to decrease the risk for raising the intraabdominal pressure, which increases ICP. Decorticate or decerebrate posturing is a reflex response in some patients with increased ICP. Turning, skin care, and even passive range of motion can elicit these posturing reflexes.

Provide the physical care to minimize complications of immobility, such as atelectasis and contractures. Turn the patient at least every 2 hours.

Protection from injury. The patient with increased ICP and decreased LOC needs protection from self-injury. Confusion, agitation, and the possibility of seizures increase the risk for injury. Use restraints carefully in the agitated patient. If restraints are necessary to keep the patient from removing tubes or falling out of bed, they should be secure enough to be effective. Observe the skin area under the restraints regularly for irritation. Agitation may increase with the use of restraints, which indicates the need for other measures to protect the patient from injury. Light sedation with sedative agents may be needed. Having a family member stay with the patient may have a calming effect.

Place the patient with or at risk for seizures on seizure precautions. These include padded side rails, an Ambu bag at the bedside, readily available suction, accurate and timely administration of antiseizure drugs, and close observation. Antiseizure prophylaxis against early seizures (within the first 7 to 10 days) is recommended in severe brain injury. This practice is controversial for mild to moderate brain injury.[7]

The patient can benefit from a quiet, nonstimulating environment. Use a calm, reassuring approach. Touch and talk to the patient, even one who is in a coma.

Psychologic considerations. Be aware of the psychologic well-being of patients and their families. There is a need for support, information, and teaching of both patients and families. Anxiety over the diagnosis and prognosis can be distressing to the patient, caregiver, family, and nursing staff. Your competent and assured manner in performing care is reassuring to everyone involved. Short, simple explanations are appropriate. Allow the patient and caregiver to acquire the amount of information they desire. Assess the family members' desires to help with providing care for the patient and allow for their participation as appropriate. Encourage interprofessional management (e.g., social work, chaplain) involving the patient and family in decision making as much as possible.

◆ Evaluation

The expected outcomes are that the patient with increased ICP will:

- Maintain ICP and cerebral perfusion within normal parameters
- Have no serious increases in ICP during or after care activities
- Have no complications of immobility

HEAD INJURY

Head injury includes any injury or trauma to the scalp, skull, or brain. A serious form of head injury is *traumatic brain injury* (TBI). Statistics about head injuries are incomplete because many victims die at the injury scene, or the condition is minor so the patient does not seek health care. Around 2.8 million persons are treated each year in US emergency departments (EDs) for TBI. Of those, 57,000 die and 282,000 are hospitalized. Of those hospitalized, 20% will die.[8] At least 5.3 million Americans (2% of the US population) currently live with disabilities resulting from TBI.

The most common causes of head injury are falls and motor vehicle accidents. Other causes include firearms, assaults, sports-related trauma, recreational injuries, and war-related injuries.[8] Men are twice as likely to sustain a TBI.

Head trauma has a high potential for a poor outcome (Box 61.1). Deaths from head trauma occur at 3 points after injury: immediately after the injury, within 2 hours after injury, and about 3 weeks after injury.[9] Most deaths occur immediately after the injury, either from the direct head trauma or from massive bleeding and shock. Deaths occurring within a few hours of the trauma are caused by progressive worsening of the brain injury or bleeding.[10]

Deaths occurring 3 weeks or more after the injury result from multisystem failure. Expert nursing care in the weeks after the injury is crucial in decreasing mortality and optimizing outcomes.[11]

Types of Head Injuries

Scalp Lacerations

Scalp lacerations are an easily recognized type of external head trauma. Because the scalp contains many blood vessels with poor constrictive abilities, profuse bleeding occurs with most scalp lacerations. Even relatively small wounds can bleed significantly. The major complications with scalp laceration are blood loss and infection.

Skull Fractures

Skull fractures often occur with head trauma. Skull fractures are described in several ways: (1) linear or depressed, (2) simple, comminuted, or compound, and (3) closed or open (Table 61.6). Fractures may be closed or open, depending on the presence of a scalp laceration or extension of the fracture into the air sinuses or dura. The type and severity of a skull fracture depend on the velocity, momentum, direction, and shape (blunt or sharp) of the injuring agent and site of impact.

The location of the fracture determines the manifestations (Table 61.7). For example, a basilar skull fracture is a special type

BOX 61.1 ETHICAL/LEGAL DILEMMAS

Brain Death

Situation

The emergency nurse receives a call from emergency response system (ERS) personnel, who are in route with R.G., a young man involved in a motorcycle crash. He was not wearing a helmet and has a large open skull fracture. Transport from the accident scene was delayed by 45 min because of a severe thunderstorm and the location. R.G. has fixed, dilated pupils and is in cardiac arrest. Estimated arrival at the hospital is still another 30 min because of the weather. ERS personnel request permission to stop resuscitation efforts.

Ethical/Legal Points for Consideration

- Criteria for brain death include coma or unresponsiveness, absence of brainstem reflexes, and apnea (see Chapter 10).
- In a situation in which the professional responsible for determining a state of death is in remote contact with the patient but the monitoring devices available provide virtual contact with the patient, a remote diagnosis of death may be legally acceptable.
- CPR is not appropriate when survival is not expected or the patient is expected to survive without the ability to communicate. Quantitative futility implies that survival is not expected after CPR under given circumstances. In the absence of mitigating factors, prolonged resuscitative efforts are unlikely to be successful and can be stopped if there is no return of spontaneous circulation at any time during 30 minutes of cumulative advanced life support.
- It is ethical for ED personnel to stop treatment started by ERS personnel in the prehospital setting if there is valid, after-the-fact evidence that these interventions are now inappropriate.

Discussion Questions

1. What are your feelings about cessation of brain function versus cessation of heart and lung function as the criteria for death?
2. What are your state's laws or practices about stopping CPR efforts by ERS personnel in the field?

TABLE 61.6 Types of Skull Fractures

Type	Description	Cause
Comminuted	Multiple linear fractures with fragmentation of bone into many pieces	Direct, high-momentum impact
Compound	Depressed skull fracture and scalp laceration with communicating pathway to intracranial cavity	Severe head injury
Depressed	Inward indentation of skull	Powerful blow
Linear	Break in continuity of bone without change of relationship of parts	Low-velocity injuries
Simple	Linear or depressed skull fracture without fragmentation or communicating lacerations	Low to moderate impact

TABLE 61.7 Manifestations of Skull Fractures

Fracture Location	Manifestations
Basilar	CSF or brain otorrhea, bulging of tympanic membrane caused by blood or CSF, Battle sign, tinnitus or hearing difficulty, rhinorrhea, facial paralysis, conjugate deviation of gaze, vertigo
Frontal	Exposure of brain to contaminants through frontal air sinus, possible association with air in forehead tissue, CSF rhinorrhea, pneumocranium (air between cranium and dura mater)
Orbital	Periorbital bruising (raccoon eyes), optic nerve injury
Parietal	Deafness, CSF or brain otorrhea, bulging of tympanic membrane caused by blood or CSF, facial paralysis, loss of taste, Battle sign
Posterior fossa	Occipital bruising resulting in cortical blindness, visual field defects, rare appearance of ataxia or other cerebellar signs
Temporal	Boggy temporal muscle because of extravasation of blood, oval-shaped bruise behind ear in mastoid region (Battle sign), CSF otorrhea, middle meningeal artery disruption, epidural hematoma

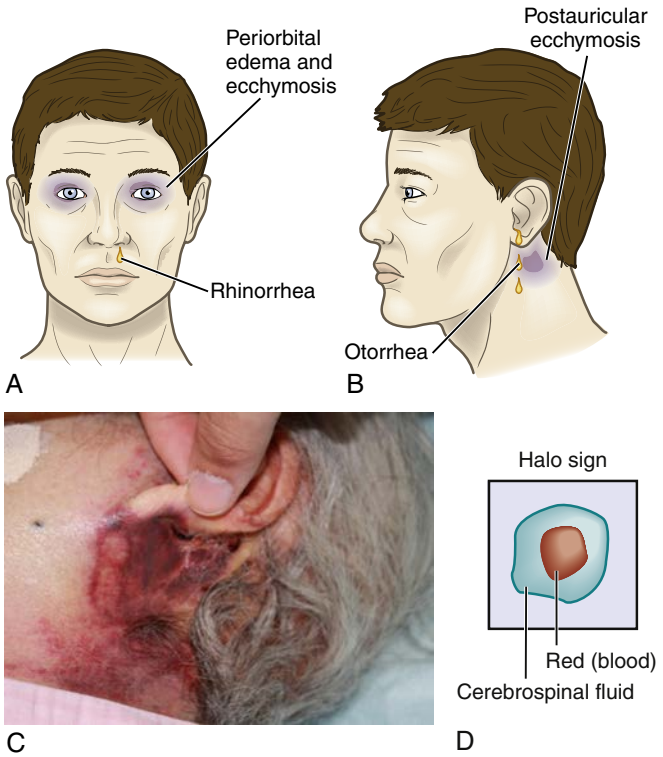

Fig. 61.12 (A) Raccoon eyes and rhinorrhea. (B) Battle sign (postauricular bruising) with otorrhea. (C) Battle sign. (D) Halo or ring sign (see text). (C, From Takahashi C, Okudera H, Kobayashi K, et al.: An extensive retropharyngeal haematoma associated with pyramidal fracture, *Injury Extra* 40:162, 2009.)

of linear fracture involving the base of the skull. Manifestations can evolve over the course of several hours. They vary with the location and severity of fracture. These may include CN deficits, Battle sign (postauricular bruising), and periorbital bruising (raccoon eyes) (Fig. 61.12). This fracture is often due to a tear in the dura and subsequent leakage of CSF.

Rhinorrhea (CSF leakage from the nose) or *otorrhea* (CSF leakage from the ear) can confirm that a fracture has traversed the dura (Fig. 61.12). Rhinorrhea may also manifest as postnasal sinus drainage. Rhinorrhea may be overlooked unless we assess

the patient for this finding. The risk for meningitis is high with a CSF leak. Antibiotics should be given as a preventive measure.

We use 2 ways to test whether fluid leaking from the nose or ear is CSF. One method is to test the leaking fluid with a Dextrostix or Tes-Tape strip to see if glucose is present. CSF gives a positive reading for glucose. If blood is present in the fluid, testing for glucose is unreliable because blood also contains glucose. In this event, look for the *halo* or *ring* sign (Fig. 61.12D). Allow the leaking fluid to drip onto a white gauze pad (4 × 4) or towel, and then observe the drainage. Within a few minutes, the blood coalesces into the center, and a yellowish ring encircles the blood if CSF is present. Note the color, appearance, and amount of leaking fluid because both tests can give false-positive results.

The major complications of skull fractures are intracranial infections, hematoma, and meningeal and brain tissue damage.

Head Trauma

We categorize brain injuries as diffuse (generalized) or focal (localized). In a *diffuse* injury (e.g., concussion, diffuse axonal injury), damage to the brain is not localized to 1 area. In a *focal injury* (e.g., contusion, hematoma), damage is localized to a specific area of the brain. We also classify brain injury as *minor* (GCS 13 to 15), *moderate* (GCS 9 to 12), or *severe* (GCS 3 to 8).

Diffuse injury. A **concussion** is a sudden transient mechanical head injury with disruption of neural activity and a change in the LOC. It is a minor diffuse head injury. Typical signs include a brief disruption in LOC, amnesia about the event (retrograde amnesia), and headache. The patient may or may not lose total consciousness. The manifestations are often of short duration. It usually resolves spontaneously. A concussion is usually considered benign.

For some, the signs and symptoms may be the beginning of a more serious, progressive problem, especially in a patient with a history of a concussion or head injury. If the patient has not lost consciousness or if the loss of consciousness lasts less than 5 minutes, the patient is usually discharged with instructions to notify the HCP if symptoms persist or if behavior changes occur. Give the patient and caregiver instructions for observation and accurate reporting of symptoms or changes in neurologic status.

Postconcussion syndrome may develop in some patients, usually from 2 weeks to 2 months after the injury. Manifestations include persistent headache, lethargy, personality and behavior changes, shortened attention span, decreased short-term memory, and changes in intellectual ability. This syndrome can significantly affect the patient's abilities to perform activities of daily living.

Diffuse axonal injury. **Diffuse axonal injury (DAI)** is widespread axonal damage occurring after a mild, moderate, or severe TBI. The damage occurs primarily around axons in the subcortical white matter of the cerebral hemispheres, basal ganglia, thalamus, and brainstem.[12] Initially, we thought DAI occurred because the tensile forces of trauma sheared axons, resulting in axonal disconnection. There is increasing evidence that axonal damage is not preceded by an immediate tearing of the axon from the traumatic impact. Instead, the trauma changes the function of the axon, resulting in axon swelling and disconnection. This process takes 12 to 24 hours to develop. It may persist longer.

The clinical signs of DAI vary. They may include a decreased LOC, increased ICP, decortication or decerebration, and global cerebral edema. Patients with DAI who survive the initial event are admitted to ICU. There, they will be vigilantly watched for signs of increased ICP and treated accordingly. Patients with severe injury have a poor functional prognosis.[13]

Focal injury. Focal injury can be minor to severe and localized to an area of injury. Focal injury consists of lacerations, contusions, hematomas, and CN injuries.

Lacerations involve actual tearing of the brain tissue. They often occur in depressed and open fractures and penetrating injuries. Tissue damage is severe. Surgical repair of the laceration is impossible because of the nature of brain tissue. Management consists of antibiotics (until meningitis is ruled out) and preventing secondary injury from increased ICP. If bleeding is deep into the brain tissue, focal and generalized signs develop.

With major head trauma, many delayed responses can occur. These include bleeding, hematoma formation, seizures, and cerebral edema. Intracerebral hemorrhage is generally due to a cerebral laceration. This bleeding manifests as a space-occupying lesion accompanied by unconsciousness, hemiplegia on the contralateral side, and a dilated pupil on the ipsilateral side. As the hematoma expands, signs of increased ICP become more severe. Subarachnoid hemorrhage and intraventricular hemorrhage can occur from head trauma.

A **contusion** is bruising of the brain tissue within a focal area. It is usually associated with a closed head injury. A contusion often occurs at a fracture site. There may be areas of bleeding, infarction, necrosis, and edema.

With contusion, the phenomenon of *coup-contrecoup injury* may occur (Fig. 61.13). Injuries can range from minor to severe. Damage from coup-contrecoup injury occurs when the brain moves inside the skull due to high-energy or high-impact injury mechanisms. Contusions or lacerations occur both at the site of the direct impact of the brain on the skull *(coup)* and at a second area of damage on the opposite side away from injury *(contrecoup),* leading to multiple contused areas. *Contrecoup* injuries tend to be more severe. The overall prognosis depends on the amount of bleeding around the contusion site.

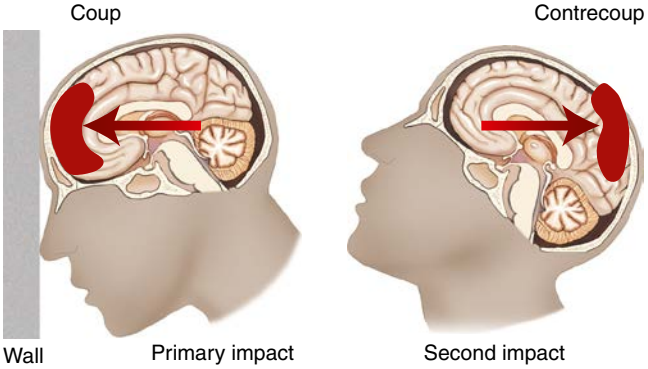

Fig. 61.13 Coup-contrecoup injury. After the head strikes the wall, a coup injury occurs as the brain strikes the skull (primary impact). The contrecoup injury (the second impact) occurs when the brain strikes the skull surface opposite the site of the original impact.

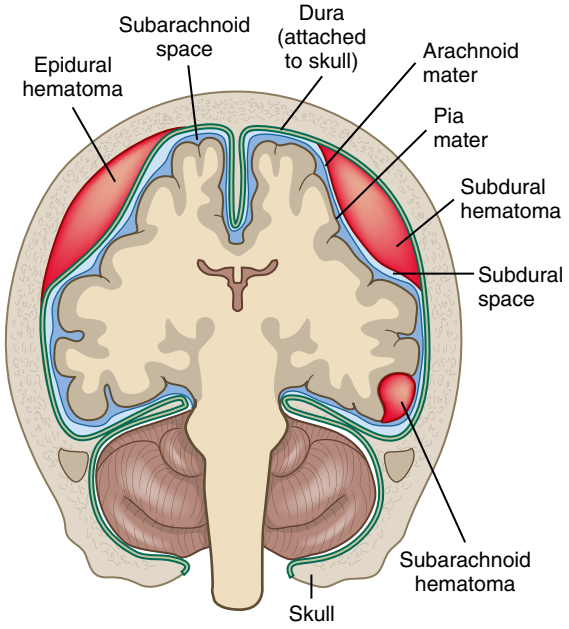

Fig. 61.14 Locations of epidural, subdural, and subarachnoid hematomas. (From Copstead-Kirkhorn LC, Banasik JL: *Pathophysiology,* ed 4, St Louis, 2010, Mosby.)

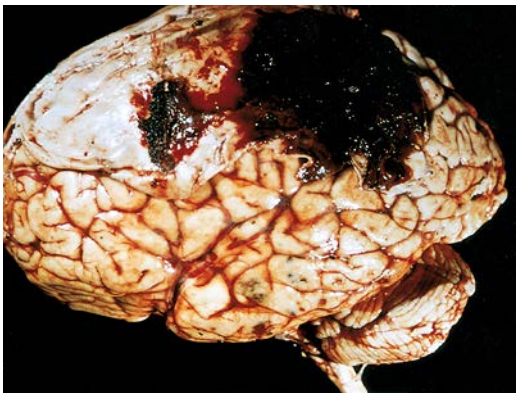

Fig. 61.15 Epidural hematoma covering a portion of the dura. Multiple small contusions are seen in the temporal lobe. (From Kumar V, Abbas AK, Aster JC, et al.: *Robbins and Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.)

Contusions may continue to bleed or rebleed and appear to "blossom" on subsequent CT scans. Bleeding worsens the neurologic outcome. Neurologic assessment may show focal and generalized manifestation, depending on the contusion's size and location. Seizures can occur, especially when the injury involves the frontal or temporal lobes. Anticoagulant use and coagulopathy are associated with increased bleeding, more severe head injury, and an increased mortality rate.[14] This is especially important with older adults who are taking anticoagulants. If they fall, their contusion is likely to be more severe due to anticoagulant use. Assess for risk of falls in all patients taking anticoagulants.

Complications

Epidural Hematoma

An **epidural hematoma** results from bleeding between the dura and inner surface of the skull (Figs. 61.14 and 61.15). An epidural hematoma is a neurologic emergency. It is usually due to a linear fracture crossing a major artery in the dura, causing a tear. It can have a venous or arterial origin. Venous epidural hematomas are due to a tear of the dural venous sinus and develop slowly. With arterial hematomas, the middle meningeal artery lying under the temporal bone is often torn. Bleeding occurs into the epidural space, which lies between the dura and inner surface of the skull (Fig. 61.14). Because this is arterial bleeding, the hematoma develops rapidly.

Classic signs include an initial period of unconsciousness at the scene, with a brief lucid interval followed by a decrease in LOC. Other manifestations may be a headache, nausea and vomiting, or focal findings. Rapid surgical treatment to evacuate the hematoma and prevent cerebral herniation, along with medical management for increasing ICP, dramatically improves outcomes.

TABLE 61.8 Types of Subdural Hematomas

Occurrence After Injury	Progression of Symptoms	Treatment
Acute		
24–48 hr after severe trauma	Immediate deterioration	Craniotomy, evacuation, and decompression
Subacute		
48 hr–2 weeks after severe trauma	Decline in mental status as hematoma develops. Progression dependent on size and location of hematoma	Evacuation and decompression
Chronic		
Weeks or months, usually >20 days after injury. Often injury seemed trivial or was forgotten by patient	Nonspecific, nonlocalizing progression. Progressive change in LOC	Evacuation and decompression, membranectomy

Subdural Hematoma

A **subdural hematoma** occurs from bleeding between the dura mater and arachnoid layer of the meninges (Fig. 61.14). A subdural hematoma usually results from injury to the brain tissue and its blood vessels. The veins that drain from the surface of the brain into the sagittal sinus are the source of most subdural hematomas. Because it is usually venous in origin, a subdural hematoma may be slower to develop. However, an arterial bleed can cause a subdural hematoma. In this case it develops more rapidly.

Subdural hematomas may be acute, subacute, or chronic (Table 61.8). An *acute subdural hematoma* manifests within hours of the injury.[14] The signs and symptoms are similar to those of brain tissue compression in increased ICP. They include decreasing LOC and headache. The size of the hematoma determines the presentation and prognosis. The patient's appearance may range from drowsy and confused to unconscious. The ipsilateral pupil dilates and becomes fixed if ICP is

significantly increased. Blunt-force injuries that produce acute subdural hematomas may cause significant underlying brain injury, resulting in cerebral edema. The resulting increase in ICP from the cerebral edema can increase morbidity and mortality despite surgery to evacuate the hematoma.

A *subacute subdural hematoma* usually occurs within 2 to 14 days of the injury. After the initial bleeding, this hematoma may appear to enlarge over time as the breakdown products of the blood draw fluid into the subdural space.

A *chronic subdural hematoma* develops over weeks or months after a seemingly minor head injury.[14] They are more common in older adults because of a potentially larger subdural space from brain atrophy. With atrophy, the brain stays attached to the supportive structures and tension is increased. This makes it subject to tearing. Because the subdural space is larger, the presenting problem is focal symptoms rather than signs of increased ICP.[14] Patients with a history of alcohol use are prone to subdural hematomas because of an increased incidence of falls.

There may be a delay in diagnosing a subdural hematoma in the older adult because symptoms mimic other health problems in this age-group, such as confusion, lethargy, and memory loss. Manifestations of a subdural hematoma are often attributed to vascular disease (stroke, transient ischemic attack [TIA]) or dementia.

CHECK YOUR PRACTICE

You are doing BP screenings in the senior center when you meet a 76-year-old man and his wife. As you perform their BP screening, the wife tells you that her husband has been getting severe headaches, is dizzy, and sometimes has difficulty talking. Based on your advice, they go to an urgent care center, where a CT scan is done. The results show he has a chronic subdural hematoma. When you find out the diagnosis, you are puzzled because you thought he was having a stroke and cannot understand how he got a subdural hematoma.

- If you had been the nurse, what would you have done differently when screening this man?

Intracerebral Hematoma

Intracerebral hematoma occurs from bleeding within the brain tissue. It occurs in about 16% of head injuries. It usually happens in the frontal and temporal lobes, possibly from rupture of intracerebral vessels at the time of injury. The size and location of the hematoma are key in determining the patient's outcome.

Diagnostic Studies

In general, the diagnostic studies are similar to those used for a patient with increased ICP (Table 61.3). CT scan is the best test to evaluate for head trauma. It allows for rapid diagnosis and intervention in the acute care setting. MRI, PET, and evoked potential studies may be used to diagnose head injuries. An MRI scan is more sensitive than the CT scan in detecting small lesions. Transcranial Doppler studies can measure CBF velocity. A cervical spine x-ray series, CT scan, or MRI of the spine may be done since cervical spine trauma often occurs at the same time as a head injury.

Interprofessional Care

Emergency management of the patient with a head injury is outlined in Table 61.9. The key treatment of head injuries is prompt diagnosis and surgery (if needed). We also institute measures to prevent secondary injury by treating cerebral edema and managing increased ICP. For the patient with concussion and contusion, observation and management of increased ICP are the main management strategies.

The treatment of skull fractures is usually conservative. For depressed fractures and fractures with loose fragments, a craniotomy is done to elevate the depressed bone and remove the free fragments. If large amounts of bone are destroyed, the bone may be removed (craniectomy). A cranioplasty will be needed later.

In cases of large acute subdural and epidural hematomas or those that have significant neurologic impairment, the blood must be removed through surgical evacuation. A craniotomy is usually done to see and allow control of the bleeding vessels. Burr-hole openings may be used in an extreme emergency for a more rapid decompression, followed by a craniotomy. A drain may be placed after surgery for several days to prevent blood from reaccumulating. When extreme swelling is expected (e.g., DAI, bleeding), a craniectomy may be done. This involves removing a piece of skull to reduce the pressure inside the skull. It reduces the risk for herniation.

NURSING MANAGEMENT: HEAD INJURY

Assessment

A patient with a head injury always has the potential to develop increased ICP, which has higher mortality rates and poorer functional outcomes. Objective data are obtained by applying the GCS (Table 61.5), assessing and monitoring neurologic status, and determining whether a CSF leak has occurred. Nursing assessment related to increased ICP is discussed later in this chapter. Assessment of the patient with a head injury is outlined in Table 61.10.

Clinical Problems

Clinical problems for the patient who has a head injury may include:

- Increased intracranial pressure
- Inadequate tissue perfusion
- Altered temperature

Planning

The overall goals are that the patient with an acute head injury will (1) maintain adequate cerebral oxygenation and perfusion, (2) stay afebrile, (3) be free of discomfort, (4) be free from infection, (5) have adequate nutrition, and (6) attain maximal cognitive, motor, and sensory function.

Implementation

Health Promotion

One of the best ways to prevent head injuries is to prevent car and motorcycle accidents. Be active in campaigns that promote driving safety (Box 61.2). Speak to driver education classes about the dangers of distracted driving and driving after drinking alcohol or using drugs. Helmets for motorcycle riders is the most effective way to increase survival after crashes.

TABLE 61.9 EMERGENCY MANAGEMENT

Head Injury

Etiology	Assessment Findings	Interventions
Blunt • Assault • Fall • Motor vehicle collision • Sports injury **Penetrating** • Arrow • Gunshot • Knife	**Central Nervous System** • Asymmetric facial movements • Combativeness • Confusion • CSF leaking from ears or nose • Decerebrate or decorticate posturing • Depressed or hyperactive reflexes • Dilated or unequal pupils, photophobia • Flaccidity • Garbled speech, abusive speech • GCS score <12 • Incontinence • Involuntary movements • ↓ LOC • Seizures **Respiratory** • Central neurogenic hyperventilation • Cheyne-Stokes respirations • ↓ O_2 saturation • Pulmonary edema **Surface Findings** • Bruises or contusions on face, Battle sign (bruising behind ears) • Fracture or depressions in skull • Raccoon eyes (dependent bruising around eyes) • Scalp lacerations	**Initial** • If unresponsive, assess circulation, airway, and breathing. • If responsive, monitor airway, breathing, and circulation. • Assume neck injury with head injury. • Stabilize cervical spine. • Apply O_2 via nonrebreather mask. • Establish IV access with 2 large-bore catheters to infuse normal saline or lactated Ringer solution. • Intubate if GCS score <8. • Control external bleeding with sterile pressure dressing. • Remove patient's clothing. **Ongoing Monitoring** • Maintain normothermia using blankets, warm IV fluids, as needed. • Monitor vital signs, LOC, O_2 saturation, cardiac rhythm, GCS score, pupil size and reactivity. • Expect intubation if gag reflex is impaired or absent. • Assess for rhinorrhea, otorrhea, scalp wounds. • Give fluids cautiously to prevent fluid overload and increasing ICP.

◆ Acute Care

Management at the scene can have a significant impact on the outcome of a head injury. Emergency management of head injury is outlined in Table 61.9. The general goal of nursing management of the patient with head injury is to maintain cerebral oxygenation and perfusion and prevent secondary cerebral ischemia.

Surveillance or monitoring for changes in neurologic status is critically important because the patient's condition may deteriorate rapidly, requiring emergency surgery. Appropriate nursing interventions are started if surgery is anticipated. Because of the close association between hemodynamic status and cerebral perfusion, be aware of any coexisting injuries or conditions.

Explain the need for frequent neurologic assessments to the patient and caregiver. Behavior manifestations can result in a frightened, disoriented patient who is combative and resists help. Your approach should be calm and gentle. A family member may be available to stay with the patient to decrease their anxiety and fear. An important need of the caregiver and family members in the acute injury phase is information about the patient's diagnosis, treatment plan, and reason for the interventions. Other teaching points are described in Table 61.11.

Perform neurologic assessments at intervals based on the patient's condition. The GCS is useful in assessing the LOC (Table 61.5). Report any signs of a deteriorating neurologic state, no matter how subtle, such as a decreasing LOC or motor strength, to the HCP. Monitor the patient's condition closely.

The major focus of nursing care for the patient with a brain injury relates to increased ICP (see eNursing Care Plan 61.1). However, some problems need specific nursing intervention.

Eye problems may include loss of the corneal reflex, periorbital bruising and edema, and diplopia. Loss of the corneal reflex may require lubricating eye drops or taping the eyes shut to prevent abrasion. Periorbital bruising and edema decrease with time. Cold and, later, warm compresses provide comfort and hasten healing. Wearing an eye patch can relieve diplopia. Consider a consult with an ophthalmologist.

Fever may occur from injury to or inflammation of the hypothalamus. Fever can increase CBF, cerebral blood volume, and ICP. Increased metabolism from fever increases metabolic waste. This causes further cerebral vasodilation. Avoid fever with a goal of a temperature of 96.8°F to 98.6°F (36°C to 37°C) as the standard of care. Use interventions to reduce fever and prevent shivering (see Table 12.5).

If CSF rhinorrhea or otorrhea occurs, inform the HCP at once. The head of the bed may be raised to decrease the CSF pressure so that a tear can seal. A loose collection pad may be placed under the nose or over the ear. Do not place a dressing in the nasal or ear cavities. Record the amount of drainage each shift. Teach the patient not to sneeze or blow the nose. Do not use NG tubes. Do not perform nasotracheal suctioning because of the high risk for meningitis.

Implement measures specific to the care of the immobilized patient, such as those related to bladder and bowel function,

TABLE 61.10 NURSING ASSESSMENT

Head Injury

Subjective Data

Important Health Information

Health history: Mechanism of injury: motor vehicle collision, sports injury, industrial incident, assault, falls

Medications: Anticoagulant drugs

Functional Health Patterns

Health perception–health management: Alcohol or recreational drugs. Risk-taking behaviors

Cognitive-perceptual: Headache, mood or behavior change, mentation changes, aphasia, dysphasia, impaired judgment

Coping–stress tolerance: Fear, denial, anger, aggression, depression

Objective Data

Cardiovascular

Impending herniation: Cushing triad (systolic hypertension with widening pulse pressure, bradycardia with full and bounding pulse, irregular respirations)

GI

Vomiting, projectile vomiting, bowel incontinence

Musculoskeletal

Motor deficit/impairment, weakness, palmar drift, paralysis, spasticity, decorticate or decerebrate posturing, muscular rigidity or increased tone, flaccidity, ataxia

Neurologic

Altered LOC, altered mental status, seizure activity, pupil dysfunction, cranial nerve deficit(s)

Respiratory

Rhinorrhea, impaired gag reflex, inability to maintain a patent airway. Impending herniation: altered/irregular respiratory rate and pattern

Skin

Lacerations, contusions, abrasions, hematoma, Battle sign, periorbital edema and bruising, otorrhea, exposed brain matter

Urinary

Bladder incontinence

Possible Diagnostic Findings

Location and type of hematoma, edema, skull fracture, and/or foreign body on CT scan and/or MRI; abnormal EEG; positive toxicology screen or alcohol level, ↓ or ↑ blood glucose level; ↑ ICP

BOX 61.2 PROMOTING POPULATION HEALTH

Reducing the Risk for Head Injuries

- Always wear car seat belts in motor vehicles.
- Do not drive after using drugs or alcohol.
- Do not text and drive or drive distracted.
- Wear helmets while bicycling, skating, skateboarding, skiing, and playing contact sports.
- Athletes should follow safe playing techniques and the rules of the game.
- Assess home safety and implement any corrective measures needed.
- Older adults should continue to exercise regularly to improve strength and balance.
- Follow workplace safety precautions, including wearing helmets and protective gear.

TABLE 61.11 PATIENT & CAREGIVER TEACHING

Head Injury

Include the following instructions when teaching the patient and caregiver about care during the first 2 or 3 days after a head injury:

1. Notify your HCP immediately if you have signs and symptoms that may indicate complications. These include:
   - Increased drowsiness (e.g., difficulty arousing, confusion)
   - Nausea or vomiting
   - Worsening headache or stiff neck
   - Seizures
   - Vision changes (e.g., blurring) or sensitivity to light (photophobia)
   - Behavior changes (e.g., irritability, anger)
   - Motor problems (e.g., clumsiness, difficulty walking, slurred speech, weakness in arms or legs)
   - Sensory problems (e.g., numbness)
   - Heart rate <60 beats/min
2. Have someone stay with you.
3. Abstain from alcohol.
4. Check with your HCP before taking drugs that may increase drowsiness, including muscle relaxants, tranquilizers, and opioid analgesia.
5. Avoid driving, using heavy machinery, playing contact sports, and taking hot baths.

skin care, and infection. Nausea and vomiting may be a problem. Administer antiemetics drugs as ordered. Acetaminophen or small doses of codeine can help to control headache.

If the patient's condition deteriorates, they may need intracranial surgery. The patient may need a burr-hole opening or craniotomy, depending on the underlying injury. The emergency nature of the surgery may hasten the usual preoperative preparation. Consult with the HCP to determine specific preoperative nursing measures.

The patient is often unconscious before surgery, making it necessary for a family member to sign the consent form for surgery. This is a difficult and frightening time for the patient's caregiver and family and requires sensitive nursing management. The suddenness of the situation makes it especially hard for the family to cope. Use a team approach, including social workers, to help the patient and family throughout the hospitalization and recovery time.

Ambulatory Care

Once their condition has stabilized, the patient is usually transferred for acute rehabilitation management. There may be chronic problems related to motor and sensory deficits, communication, memory, and intellectual functioning. Conditions we may need to manage include nutrition problems, bowel and bladder problems, spasticity, dysphagia, and hydrocephalus. Many of the principles for managing the patient with a stroke are appropriate for these patients (see Chapter 62).

Seizure disorders may occur in patients with nonpenetrating head injury. Seizures may develop during the first week after the

head injury or not until years later. Antiseizure drugs may be used prophylactically to manage posttraumatic seizure activity. However, this practice is controversial.

The mental and emotional sequelae are often the most incapacitating problems. One of the consequences of TBI is that the person may not realize that a brain injury has occurred. Many patients with head injuries who were comatose for more than 6 hours may have some personality change. They may have loss of concentration and memory and defective memory processing. Personal drive may decrease. Apathy may increase. Euphoria and mood swings, along with a seeming lack of awareness of the seriousness of the injury, may occur. The patient's behavior may indicate a loss of social restraint, judgment, tact, and emotional control.

Progressive recovery may continue for years. Specific nursing management in the posttraumatic phase depends on specific residual deficits. Being able to return to work and maintaining employment are challenges during the recovery period.[15] The patient's outward physical appearance does not necessarily reflect what has happened in the brain. It is not a good indicator of how well the patient will ultimately function in the home or work environment.

Give the family special consideration. They need to understand what is happening. The family often has unrealistic expectations of the patient as the coma begins to recede. They may expect full return to pretrauma status. In reality, the patient usually has a reduced awareness and ability to interpret environmental stimuli. Prepare the family for the patient's emergence from coma. Explain that the process of awakening often takes several weeks. Help the patient and family to remain hopeful. Arrange for social work and chaplain consults for the family.

When it is time for discharge planning, the patient, caregiver, and family may benefit from specific instructions to avoid family-patient friction. Special "no" policies may include no alcohol use, no driving, no use of firearms, no working with hazardous implements and machinery, and no unsupervised smoking. Help the family in involving the patient in family activities whenever possible. Family members, especially spouses, go through role transition as the role changes from that of spouse to that of caregiver. Provide guidance and referrals for financial aid, childcare, and other personal needs.

Evaluation

The expected outcomes are that the patient with a head injury will:

- Maintain normal CPP
- Achieve maximal cognitive, motor, and sensory function
- Have no infection or fever

BRAIN TUMORS

There are an estimated 23,400 people diagnosed each year with brain tumors in the United States. The brain is also a frequent site for metastasis from other sites.[16] Males have a slightly higher incidence of brain tumors (Box 61.3). Brain tumors most often occur in middle-aged persons, but they may be seen at any age.

BOX 61.3 PROMOTING HEALTH EQUITY

Brain Tumors

- Whites have a higher incidence of malignant brain tumors than do Blacks.
- White males have the highest incidence of malignant brain tumors.
- Blacks have the highest incidence of benign brain tumors.

Types

Brain tumors can occur in any part of the brain or spinal cord. They may be *primary,* arising from tissues within the brain, or *secondary,* resulting from a metastasis of cancer from elsewhere in the body.[16] Metastatic brain tumors are the most common brain tumor. The cancers that most often metastasize to the brain are lung and breast.

We usually classify primary brain tumors according to the tissue from which they arise (Table 61.12). Meningiomas are the most common primary brain tumor. Other common brain tumors are gliomas (e.g., astrocytoma, glioblastoma [most common form of glioma]).

More than half of brain tumors are malignant. They infiltrate the brain tissue and are not amenable to complete surgical removal. Other tumors may be histologically benign but are located such that complete removal is not possible.

Brain tumors rarely metastasize outside the central nervous system (CNS) because they are contained by structural (meninges) and physiologic (blood-brain) barriers. Table 61.12 compares the most common brain tumors. Sites of common tumors are shown in Fig. 61.16.

Clinical Manifestations and Complications

The manifestations of brain tumors depend mainly on their location and size (Table 61.13). A wide range of manifestations are possible. Headache is common. Tumor-related headaches tend to be worse at night and may awaken the patient. The headaches are usually dull and constant but sometimes throbbing. Seizures are common in gliomas and brain metastases. Brain tumors can cause nausea and vomiting from increased ICP. Cognitive dysfunction, including memory problems and mood or personality changes, is common, especially in patients with brain metastases. Muscle weakness, sensory losses, aphasia, and visual-spatial dysfunction may occur.

If the tumor mass obstructs the ventricles or occludes the outlet, ventricular enlargement (hydrocephalus) can occur. As the brain tumor expands, it may produce manifestations of increased ICP, cerebral edema, or obstruction of the CSF pathways. Unless treated, all brain tumors eventually cause death from increasing tumor volume leading to increased ICP.

Diagnostic Studies

An extensive history and a comprehensive neurologic examination are done in the workup of a patient with a suspected brain tumor. The history and physical assessment may provide data with respect to location. New onset of seizures or adult-onset migraines may indicate a brain tumor and should be assessed. Diagnostic studies are similar to those used for a patient with increased ICP (Table 61.3).

TABLE 61.12 Types of Brain Tumors

Type	Tissue of Origin	Characteristics
Acoustic neuroma (schwannoma)	Cells that form myelin sheath around nerves. Often affects cranial nerve VIII	Many grow on both sides of the brain. Usually benign or low grade.
Gliomas		
• Astrocytoma	Supportive tissue, glial cells, and astrocytes	Can range from low grade to moderate grade.
• Ependymoma	Ependymal epithelium	Range from benign to highly malignant. Most are benign and encapsulated.
• Glioblastoma	Primitive stem cell (glioblast)	Highly malignant and invasive. Among the most devastating of primary brain tumors.
• Medulloblastoma	Primitive neuroectodermal cell	Highly malignant and invasive. Metastatic to spinal cord and remote areas of brain.
• Oligodendroglioma	Oligodendrocytes	Benign (encapsulation and calcification).
Hemangioblastoma	Blood vessels of brain	Rare and benign. Surgery is curative.
Meningioma	Meninges	Can be benign or malignant. Most are benign.
Metastatic tumors	Lungs and breast (most common)	Malignant.
Pituitary adenoma	Pituitary gland	Usually benign.
Primary central nervous system lymphoma	Lymphocytes	↑ Incidence in transplant recipients and AIDS patients.

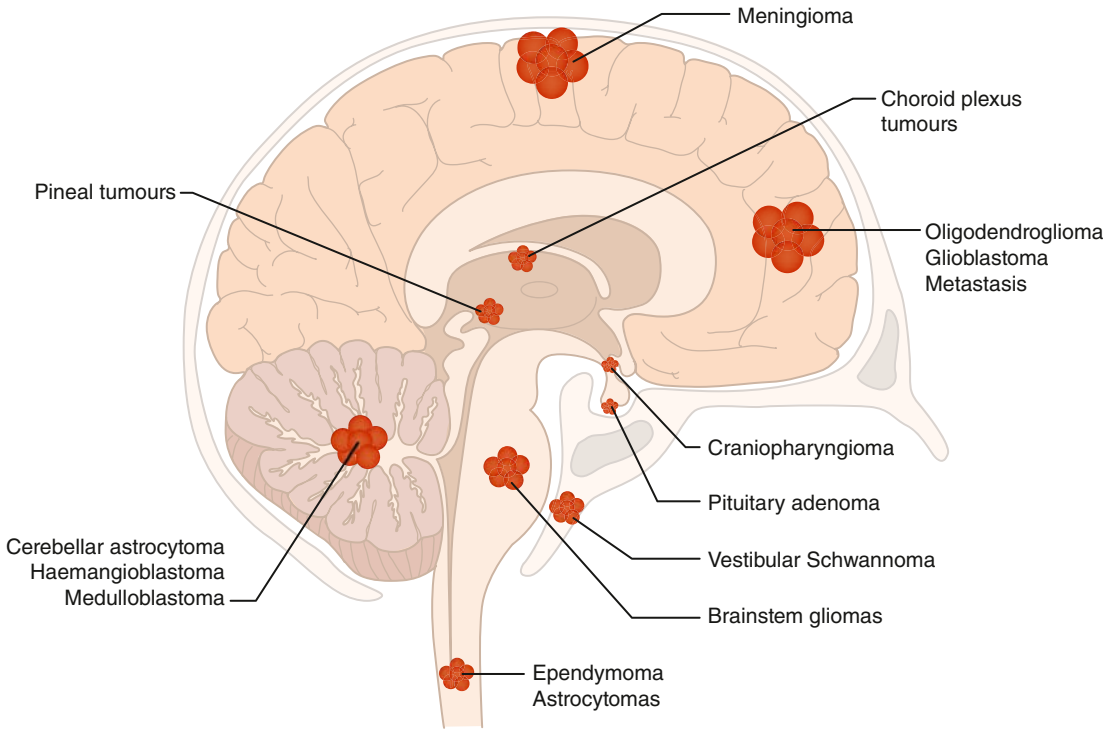

Fig. 61.16 Common sites of occurrence for CNS tumors.

CT with contrast and MRI are used to identify the lesion's location. The sensitivity of MRI and PET scans allows for detection of small tumors and may provide better diagnostic information than a CT scan. Other tests include magnetic resonance spectroscopy, functional MRI (fMRI), and single-photon emission computed tomography (SPECT). An EEG can rule out seizures but is of less importance. Cerebral angiography can assess blood flow to the tumor and further localize the tumor. Other studies are done to rule out a primary lesion elsewhere in the body. Endocrine studies are helpful when a pituitary adenoma is suspected (see Chapter 54).

The correct diagnosis of a brain tumor can be made by obtaining tissue for histologic study. In most patients, tissue is obtained at the time of surgery. Computer-guided stereotactic biopsy is also an option. A smear or frozen section can be done in the operating room for a preliminary interpretation of the histologic type. With this information, the HCP can make a better decision about the extent of surgery.

TABLE 61.13 Manifestations of Brain Tumors

Tumor Location	Manifestations
Brainstem tumors	Headache on awakening, drowsiness, vomiting, ataxic gait, facial muscle weakness, hearing loss, dysphagia, dysarthria, "crossed eyes" or other visual changes, hemiparesis
Cerebellopontine tumors	Tinnitus and vertigo, deafness
Cerebral hemisphere	
• Frontal lobe (unilateral)	Unilateral hemiplegia, seizures, memory deficit, personality and judgment changes, visual changes
• Frontal lobe (bilateral)	Symptoms of unilateral frontal lobe tumors. Ataxic gait
• Parietal lobe	Speech problems (if tumor is in the dominant hemisphere), inability to write, spatial disorders, unilateral neglect
• Occipital lobe	Vision changes and seizures
• Temporal lobe	Few symptoms. Seizures, dysphagia, hallucinations, auras
Fourth ventricle and cerebellar tumors	Headache, nausea, and papilledema (occur from ↑ ICP). Ataxic gait and changes in coordination
Meningeal tumors	Symptoms of compression of the brain and depend on tumor location
Metastatic tumors	Headache, nausea, or vomiting (occur from ↑ ICP). Other symptoms depend on tumor location
Subcortical	Hemiplegia; other symptoms may depend on area of infiltration
Thalamus and sellar tumors	Headache, nausea, vision changes, papilledema, and nystagmus (occur from ↑ ICP). Diabetes insipidus may occur

Interprofessional Care

Treatment goals are aimed at (1) identifying the tumor type and location, (2) removing or decreasing tumor mass, and (3) preventing or managing increased ICP.

Surgical Therapy

Surgical removal is the preferred treatment for brain tumors. The outcome of surgery depends on the tumor's type, size, and location. Complete removal of brain tumors is not always possible because the tumor is not always accessible or may involve vital parts of the brain. Surgery can reduce tumor mass, which decreases ICP, provides relief of symptoms, and extends survival time.

Meningiomas and oligodendrogliomas can usually be completely removed. The more invasive gliomas and medulloblastomas may be only partially removed. Stereotactic surgery is used to perform a biopsy and remove small brain tumors. Computer-guided stereotactic biopsy, ultrasound, fMRI, and cortical mapping can localize brain tumors during surgery.

Ventricular Shunts

Hydrocephalus due to a tumor obstructing the CSF flow can be treated by placing a ventricular shunt. A catheter with 1-way valves is placed in the lateral ventricle and then tunneled under the skin to drain CSF into the peritoneal cavity. Rapid decompression of ICP can cause total body collapse and weakness. Headache may be prevented by gradually introducing the patient to the upright position.

Manifestations of shunt malfunction, which are related to increased ICP, include decreasing LOC, restlessness, headache, blurred vision, or vomiting. This may require shunt revision or replacement. Infection may occur, with high fever, headache, and stiff neck. Antibiotics are used to treat the infection. In some situations, the shunt is replaced. CSF drainage is managed with an extraventricular drainage system while the infection is treated.

Radiation Therapy and Stereotactic Radiosurgery

Radiation therapy may be used as a follow-up measure after surgery. Radiation seeds can be implanted into the brain. Cerebral edema and rapidly increasing ICP may be a complication of radiation therapy. These problems can usually be managed with high doses of corticosteroids (e.g., dexamethasone, methylprednisolone). Radiation therapy is discussed in Chapter 16.

Stereotactic radiosurgery is a method of delivering a highly concentrated dose of radiation to a precise location within the brain. Stereotactic radiosurgery may be used when conventional surgery has failed or is not an option because of the tumor location.

Chemotherapy and Targeted Therapy

The effectiveness of chemotherapy is limited by the difficulty with getting drugs across the blood-brain barrier, tumor cell heterogeneity, and tumor cell drug resistance. Chemotherapy drugs called *nitrosoureas* (e.g., carmustine, lomustine) are used to treat brain tumors. Normally the blood-brain barrier prohibits the entry of most drugs into the brain. Cancer tumors can cause a breakdown of the blood-brain barrier in the area of the tumor, thus allowing chemotherapy agents to be used to treat the cancer. Chemotherapy-laden biodegradable wafers (e.g., Gliadel wafer [polifeprosan with carmustine implant]) implanted at the time of surgery can deliver chemotherapy directly to the tumor site. Other drugs being used include methotrexate and procarbazine (Matulane). One way used to deliver chemotherapy drugs directly to the CNS is intrathecal administration via an Ommaya reservoir.

Temozolomide (Temodar) is an oral chemotherapy agent that can cross the blood-brain barrier. In contrast with many chemotherapy drugs, which require metabolic activation to exert their effects, temozolomide can convert spontaneously to a reactive agent that directly interferes with tumor growth. It does not interact with other common drugs taken by patients with brain tumors, such as antiseizure drugs, corticosteroids, and antiemetics.

DRUG ALERT

Temozolomide (Temodar)

- Causes myelosuppression. Before using, the absolute neutrophil count should be ≥1500/μL and platelet count should be ≥100,000/μL.
- To reduce nausea and vomiting, take on empty stomach or at bedtime.

Bevacizumab (Avastin) is used to treat patients with glioblastoma that continues to progress after standard therapy. Bevacizumab is a targeted therapy that inhibits the action of vascular endothelial growth factor, which helps form new blood vessels. These vessels can feed a tumor, helping it to grow, and provide a pathway for cancer cells to circulate in the body.

Other Therapies

The Optune System is used to treat glioblastoma that recurs or progresses after receiving chemotherapy and radiation therapy. With this system, electrodes are placed on the surface of the patient's scalp to deliver low intensity, changing electrical fields called *tumor treatment fields* (TTFs) to the tumor site.

NURSING MANAGEMENT: BRAIN TUMORS

Assessment

Ask about the medical history, intellectual abilities and educational level, and history of nervous system infections and trauma. Is there a history of dementia? Loss of emotional control, confusion, disorientation, memory loss, impulsivity, and depression may be signs of a frontal lobe lesion. The patient often does not perceive these changes. Having the patient or caregiver explain the problem can be helpful to determine the patient's limitations and obtain information about the patient's insight into the problems. Structure the initial assessment to provide baseline data of the patient's neurologic status. Use this information to design a realistic patient-specific care plan.

Assess the patient's LOC, motor abilities, sensory perception, integrated function (including bowel and bladder function), and balance and proprioception. Determine the presence of seizures, syncope, nausea and vomiting, and headaches or other pain. Assess the coping abilities of the patient, caregiver, and family. Watching a patient perform activities of daily living and listening to the patient's conversation can be part of the neurologic assessment. Record all initial data to provide a baseline for comparison to determine whether the patient's condition is improving or deteriorating.

Clinical Problems

Clinical problems for the patient with a brain tumor may include:

- Inadequate tissue perfusion
- Pain
- Anxiety
- Neurologic problem

Planning

The overall goals are that the patient with a brain tumor will (1) maintain normal ICP, (2) maximize neurologic functioning, (3) achieve control of pain and discomfort, and (4) be aware of the long-term implications with respect to prognosis and cognitive and physical functioning.

Implementation

Help the caregiver and family understand what is happening to the patient and support the family. A tumor of the frontal lobe can cause behavior and personality changes. These changes can be disturbing and frightening to the caregiver and family. They can also cause a distancing to occur between the family and patient.

The confused patient with behavior instability can be a challenge. Protecting the patient from self-harm is an important part of nursing care. Essential interventions include close supervision of activity, use of side rails, judicious use of restraints, appropriate sedatives, padding of the rails and the area around the bed, and a calm, reassuring approach.

Tumors in the temporal lobe can cause hallucinations. Perceptual problems from frontal and parietal lobe tumors contribute to disorientation and confusion. Minimize environmental stimuli, create a routine, and use reality orientation for the confused patient.

Seizures, which often occur with brain tumors, are managed with antiseizure drugs. Use seizure precautions for the patient's protection. Some behavior changes seen in the patient are a result of seizure disorders and can improve with adequate seizure control. Patients at risk for seizures may be unable to drive. Be aware of the extra resources needed and collaborate with the social worker and family. Seizure disorders are discussed in Chapter 63.

Motor and sensory problems interfere with activities of daily living. Encourage the patient to provide as much self-care as physically possible. Self-image often depends on the patient's ability to take part in care within the limitations of the physical deficits.

Language deficits may be present. Motor (expressive) or sensory (receptive) dysphasia may occur. The problem with communication can be frustrating for the patient and may interfere with your ability to meet the patient's needs. Try to establish a communication system that both the patient and staff can use.

Nutrition intake may be decreased because of the patient's inability to eat, loss of appetite, or loss of desire to eat. Assess nutrition status and ensure adequate nutrition intake. Encourage the patient to eat. Some patients may need enteral or parenteral nutrition (see Chapter 44).

Provide help and support during the adjustment phase and in long-range planning. Social work and home health nurses may help the caregiver with discharge planning. They can help the family adjust to role changes and psychosocial and socioeconomic factors. Issues related to palliative and end-of-life care must be discussed with both the patient and family (see Chapter 10).

Evaluation

The expected outcomes are that the patient with a brain tumor will:

- Achieve control of pain, vomiting, and other discomforts
- Maintain ICP within normal limits
- Have maximal neurologic function given the location and extent of the tumor
- Maintain optimal nutrition status
- Accept the long-term consequences of the tumor and its treatment

TABLE 61.14 Indications for Cranial Surgery

Indication	Cause	Surgical Procedure
Aneurysm repair	Dilation of weak area in arterial wall (usually near anterior portion of circle of Willis)	Dissection and clipping or coiling of aneurysm
Arteriovenous (AV) malformation	Congenital tangle of arteries and veins (often in middle cerebral artery)	Excision of malformation
Brain abscess	Bacteria that caused intracranial infection	Excision or drainage of abscess
Brain tumors	Benign or malignant cell growth	Excision or partial resection of tumor
Hydrocephalus	Overproduction of cerebrospinal fluid, obstruction to flow, defective reabsorption	Placement of ventriculoperitoneal or (rarely) ventriculoatrial shunt
Intracranial bleeding	Rupture of cerebral vessels because of trauma or stroke	Surgical evacuation through burr holes or craniotomy
Skull fractures	Trauma to skull	Debridement of fragments and necrotic tissue, elevation and realignment of bone fragments

TABLE 61.15 Types of Cranial Surgery

Type	Description
Burr hole	Opening into the cranium with a drill. Used to remove localized fluid and blood beneath the dura.
Craniectomy	Excision into the cranium to cut away bone flap.
Cranioplasty	Repair of cranial defect resulting from trauma, malformation, or previous surgery. Artificial material used to replace damaged or lost bone.
Craniotomy	Opening into cranium with removal of bone flap and opening the dura to remove a lesion, repair a damaged area, drain blood, or relieve ↑ ICP.
Shunt procedures	Alternative pathway to redirect cerebrospinal fluid from one area to another using a tube or implanted device. Examples include ventricular shunt and Ommaya reservoir.
Stereotactic procedure	Precise localization of a specific area of the brain using a frame or frameless system based on 3-dimensional coordinates. Used for biopsy, radiosurgery, or dissection.

CRANIAL SURGERY

Indications for cranial surgery are related to brain tumors, CNS infection (e.g., abscess), vascular abnormalities, craniocerebral trauma, seizure disorder, or intractable pain (Table 61.14).

Types

Various cranial surgeries are outlined in Table 61.15.

Craniotomy

Depending on the location of the pathologic condition, a *craniotomy* may be frontal, parietal, occipital, temporal, suboccipital, or a combination of any of these. The HCP drills a set of burr holes and uses a saw to connect the holes to remove the bone flap (Fig. 61.17). Sometimes operating microscopes are used to magnify the site. After surgery, the bone flap is secured with small plates or wired shut. Sometimes drains are placed to remove fluid and blood. Patients usually receive care in the ICU until stable.

Stereotactic Radiosurgery

Stereotactic procedures use a precision apparatus (often computer guided) to help the HCP precisely target an area of the brain. Stereotactic biopsy can be done to obtain tissue samples for histologic examination. CT scanning and MRI image the targeted tissue. With the patient under general or local anesthesia, the HCP drills a burr hole or creates a bone flap for an entry site and then introduces a probe and biopsy needle. Stereotactic procedures are used for removal of small brain tumors and abscesses, drainage of hematomas, ablative procedures for extrapyramidal diseases (e.g., Parkinson disease), and repair of arteriovenous malformations. A major advantage of the stereotactic approach is a reduction in damage to surrounding tissue.

Stereotactic radiosurgery is not a form of surgery in the traditional sense. Instead, radiosurgery uses high-dose radiation to destroy precisely targeted tumor cells and other abnormal growths. Computers create 3-dimensional images of the brain. These images are used to guide the focused radiation while the patient's head is held still in a stereotactic frame (Fig. 61.18). The ionizing radiation can be generated by a linear accelerator, Gamma Knife, or CyberKnife. The dose of radiation is delivered in a single treatment lasting a few hours or in multiple sessions. Side effects include fatigue, headache, and nausea.

In combination with stereotactic procedures to identify and localize tumor sites, lasers can be used to destroy tumors. Lasers work by creating thermal energy, which destroys the tissue on which it is focused. Laser therapy provides the benefit of reducing damage to surrounding tissue.

❖ NURSING MANAGEMENT: CRANIAL SURGERY

◆ Implementation

◆ Acute Care

The general nursing care for the patient undergoing cranial surgery is similar regardless of the cause. It is similar to that for the patient with increased ICP. The patient (if conscious and coherent), caregiver, and family will be concerned about the potential physical and emotional problems that can result from surgery. The uncertainty about the prognosis and outcome requires compassionate nursing care in the preoperative period.

Preoperative teaching is important in allaying the fears of the patient, caregiver, and family and in preparing them for the postoperative period. Provide general information about the type of surgery and what they can expect afterwards. Explain that some hair may be shaved to allow for better exposure and to prevent contamination. The hair is usually removed in the

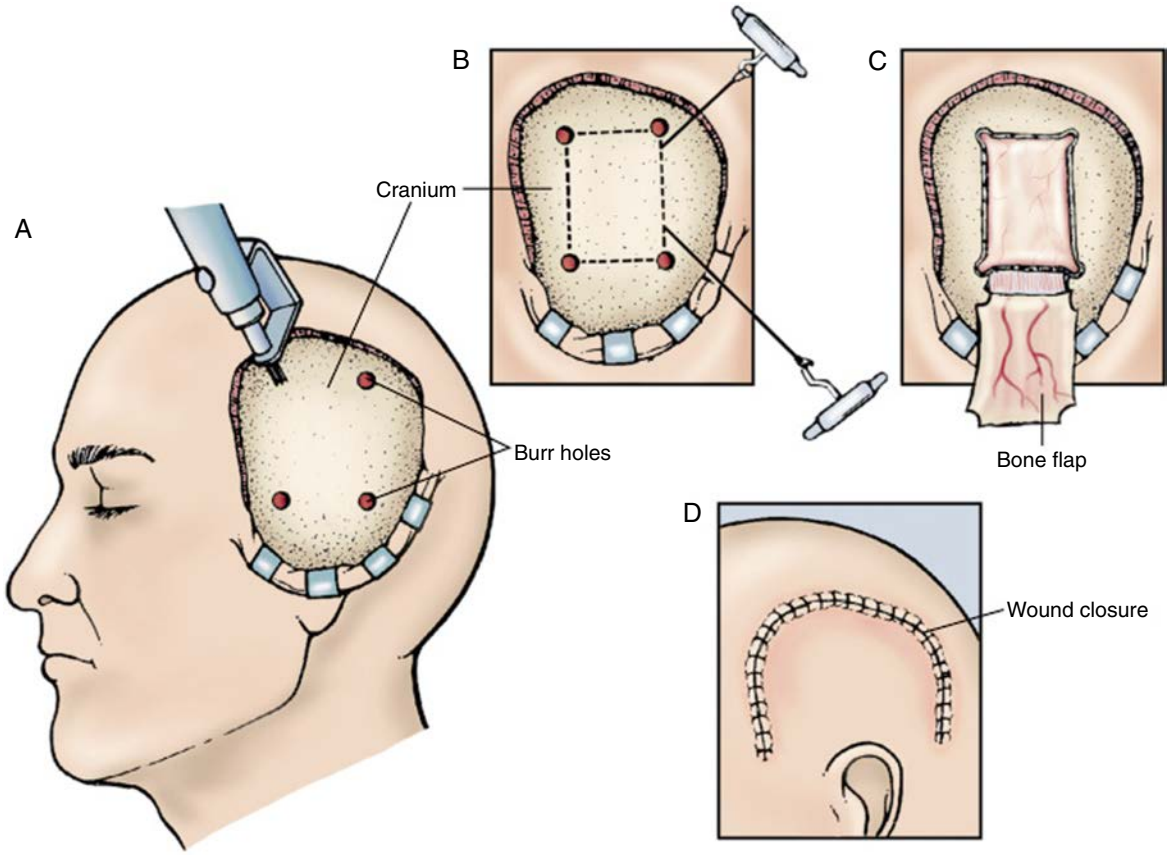

Fig. 61.17 Craniotomy. (A) Burr holes are drill into skull. (B) Skull is cut between burr holes with a surgical saw. (C) Bone flap is turned back to expose cranial contents. (D) Bone flap is replaced and wound closed. (From Monahan F, Sands J, Neighbors M, et al.: *Phipps' medical-surgical nursing: health and illness perspectives,* ed 9, St Louis, 2007, Mosby.)

operating room after induction of anesthesia. Tell them that the patient will be in an ICU or special care unit after surgery.

The main goal of care after cranial surgery is preventing increased ICP. Frequent assessment of the patient's neurologic status is essential during the first 48 hours. Closely monitor fluid and electrolyte levels and serum osmolality to detect changes in sodium regulation, the onset of diabetes insipidus, or severe hypovolemia. Manage problems associated with increased ICP.

Monitor the patient for pain and nausea. Nausea and vomiting are common after surgery. Administer antiemetic drugs as ordered. Do not give promethazine. It can increase somnolence and change the accuracy of a neurologic assessment.

Although the brain itself does not have pain receptors, patients often report headache caused by edema or pain at the incision site. Control pain with short-acting opioids and monitor neurologic status.

The dressing is usually in place for a few days. When the incision over the skull is in the anterior or middle fossa, elevate the head of the bed at least 30 degrees. If the surgical approach is in the posterior fossa or they have a burr hole, keep the patient flat or at a slight elevation (10 to 15 degrees).

Turning and positioning the patient will depend on the site of the operation. If a bone flap was removed (craniectomy), do not position the patient on the operative side. Place a sign at the head of the bed, alerting everyone of the craniectomy site and position of the surgical site. Observe the dressing for color, odor, and amount of drainage. Notify the HCP immediately of any excess bleeding or clear drainage. Check drains for placement. Assess the area around the dressing. Scalp care should include meticulous care of the incision to prevent wound infection. Cleanse the area and treat it following agency protocol or the HCP's orders. Once the dressing is removed, use an antiseptic soap for washing the scalp. The psychologic impact of hair removal can be lessened by using a wig, turban, scarves, or cap. For the patient who is receiving radiation, teach the patient to use a sunblock and head covering if any sun exposure is expected.

◆ Ambulatory Care

The patient's rehabilitative potential depends on the reason for the surgery, postoperative course, and their general state of health. Base your care on a realistic appraisal of these factors. Specific rehabilitation potential cannot be determined until cerebral edema and increased ICP subside postoperatively (Box 61.4). An overall goal is to foster independence for as long as possible and to the highest degree possible.

Take care to maintain as much function as possible through measures such as careful positioning, meticulous skin and mouth care, regular range of motion exercises, bowel and bladder care, and adequate nutrition. Address the needs and problems of each patient individually because many variables affect the plan.

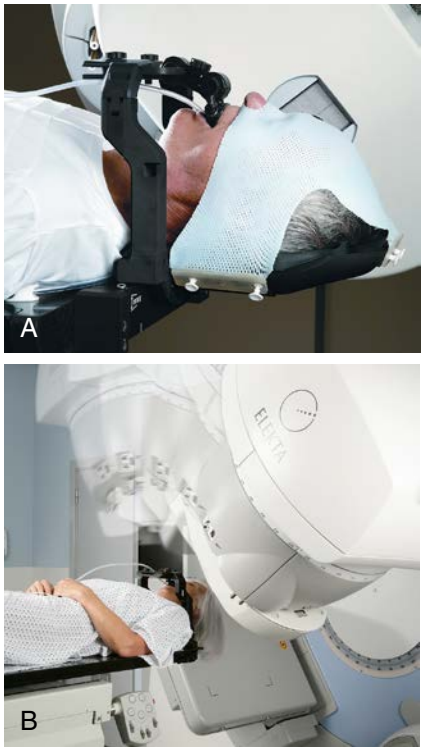

Fig. 61.18 (A) Patient in a stereotactic frame. (B) Elekta Fraxion head frame helps to ensure accuracy and precision in stereotactic radiation therapy of cancer targets in the brain and cranium. (Courtesy Elekta, Stockholm, Sweden.)

Collaborate with other specialists. The physical therapist may provide an exercise plan to regain functional deficits. A speech therapist will help the patient with communication and swallowing skills. The patient's mental and physical deterioration, including seizures, personality disorganization, apathy, and wasting, is difficult for both family and health care professionals. Cognitive and emotional residual deficits are often harder to accept than are motor and sensory losses. Social workers can help the patient and family adapt to changes in their home life, work, and financial circumstances.

BOX 61.4 ETHICAL/LEGAL DILEMMAS

Withholding Treatment

Situation

C.J., a 26-year-old patient in a permanent vegetative state after a craniotomy for brain trauma, is diagnosed with her 15th bladder infection. As the home care nurse, you must determine whether to seek antibiotics for this infection. The family members have expressed a concern that no heroic measures be used to extend her life. However, they are not willing to stop enteral nutrition. Should antibiotics be withheld?

Ethical/Legal Points for Consideration

- Patients in a persistent vegetative state do not recover.
- The main legal issue here is who has the legal right to refuse or consent to treatment for this incapacitated patient. You need to know if a guardian has been appointed by the court or if her parents retain a form of guardianship to make health care decisions for her.
- You need to know when the vegetative state began; that is, did the patient ever have the right to consent having reached the age of majority as a competent adult or did the vegetative state begin while she was a minor? If the patient did become a competent adult before the vegetative state, did she ever express any preference for quality-of-life and end-of-life decision making?
- The courts have widespread legal precedents for accepting the decision of the patient's guardian or parents or the patient's clearly expressed preferences for quality-of-life decision making.
- Life-sustaining treatment is any treatment that serves to prolong life without reversing the underlying medical condition. Common life-sustaining treatments include mechanical ventilation, dialysis, chemotherapy, antibiotics, and artificial nutrition and hydration.
- There is no ethical distinction between withdrawing and withholding life-sustaining treatment. If there is not adequate evidence of the incompetent patient's preferences and values, the decision should be based on the best interests of the patient (i.e., what outcome will promote the patient's well-being).

Discussion Questions

1. How would you approach C.J.'s family?
2. What are your feelings about providing nutrition, hydration, and treatments that will prolong life in a patient for whom there is no hope of recovery?
3. What options are available to the family for the care of their daughter once a decision is made about withholding antibiotics?

INFLAMMATORY CONDITIONS OF THE BRAIN

Brain abscesses, meningitis, and encephalitis are the most common inflammatory conditions of the brain and spinal cord (Table 61.16). Inflammation can be caused by bacteria, viruses, fungi, and chemicals (e.g., contrast media used in diagnostic tests, blood in the subarachnoid space). CNS infections may occur via the bloodstream, by extension from a primary site, or along cranial and spinal nerves.

The mortality rate for inflammatory conditions of the brain is about 10% to 15% in the general population. Rates are higher rates in older and immunosuppressed patients. Some who recover have long-term neurologic deficits, including hearing loss.[17]

BACTERIAL MENINGITIS

Meningitis is an acute inflammation of the meningeal tissues surrounding the brain and spinal cord. Meningitis usually occurs in fall, winter, or early spring. It is often related to a viral respiratory disease. Older adults and persons who are debilitated are affected more often. College students living in dormitories and people living in institutions (e.g., prisoners) have a high risk for meningitis. Untreated bacterial meningitis has a high mortality rate.[17]

Etiology and Pathophysiology

Streptococcus pneumoniae and *Neisseria meningitidis* are the leading causes of bacterial meningitis. *N. meningitides* has at least 13 different subtypes (serogroups), with 5 of them (A, B, C, Y, W) causing most cases. *Haemophilus influenzae* was once the most common cause of bacterial meningitis. *H. influenzae* vaccine has significantly decreased meningitis from this organism.

The organisms usually gain entry to the CNS through the upper respiratory tract or bloodstream. However, they may

TABLE 61.16 Comparison of Cerebral Inflammatory Conditions

	Meningitis	Encephalitis	Brain Abscess
Cause	Bacteria (*Streptococcus pneumoniae, Neisseria meningitidis*, group B streptococci, viruses, fungi)	Bacteria, fungi, parasites, herpes simplex virus (HSV), other viruses (e.g., West Nile virus)	Streptococci, staphylococci through bloodstream
Cerebrospinal Fluid (Reference Interval)			
• Pressure (<20 mm H_2O)	↑ Bacterial: 200–500 Viral: ≤250	Normal to slight ↑	↑
• WBC count (0–5 cells/μL)	Bacterial: >1000/μL (mainly neutrophils) Viral: 25–500/μL (mainly lymphocytes)	500/μL, neutrophils (early), lymphocytes (later)	25–300/μL (neutrophils)
• Protein (15–45 mg/dL [0.15–0.45 g/L])	Bacterial: >500 mg/dL Viral: 50–500 mg/dL	Slight ↑	Normal
• Glucose (50–77 mg/dL [2.2–3.9 mmol/L])	Bacterial: ↓ 5–40 Viral: Normal or low >40	Normal	↓ or absent
• Appearance	Bacterial: Turbid, cloudy Viral: Clear or cloudy	Clear	Clear

Treatment	Antibiotics, dexamethasone, supportive care, prevent ↑ ICP	Supportive care, prevent ↑ ICP, acyclovir (Zovirax) for HSV	Antibiotics, incision and drainage Supportive care

enter by direct extension from penetrating skull wounds or through fractured sinuses in basilar skull fractures.

The inflammatory response to the infection tends to increase CSF production with a moderate increase in ICP. In bacterial meningitis the purulent secretions quickly spread to other areas of the brain through the CSF and cover the CNs and other intracranial structures. If this process extends into the brain parenchyma or if concurrent encephalitis is present, cerebral edema and increased ICP become more of a problem. Closely observe all patients for manifestations of increased ICP. ICP can increase from swelling around the dura and increased CSF volume.

Clinical Manifestations

Fever, severe headache, nausea, vomiting, and **nuchal rigidity** (neck stiffness) are key signs of meningitis. Photophobia, a decreased LOC, and signs of increased ICP may be present. Coma is associated with a poor prognosis. It occurs in 5% to 10% of patients with bacterial meningitis. Seizures occur in one third of all cases. The headache becomes progressively worse. It may be accompanied by vomiting and irritability.

If the infecting organism is a meningococcus, a skin rash is common. Petechiae may be seen on the trunk, lower extremities, and mucous membranes. Perform a *tumbler test* by pressing the base of a drinking glass against the rash. The rash does not blanch or fade under pressure.

Complications

The most common acute complication of bacterial meningitis is increased ICP. Most patients have increased ICP. It is the major cause of an altered mental status.

Another complication is residual neurologic dysfunction. It often involves many CNs. CN irritation can have serious sequelae. The optic nerve (CN II) is compressed by increased ICP. Papilledema is often present. Blindness may occur. When CN III, CN IV, and CN VI are irritated, ocular movements are affected. Ptosis, unequal pupils, and diplopia are common. Irritation of CN V results in sensory losses and loss of the corneal reflex. Irritation of CN VII results in facial paresis. Irritation of CN VIII causes tinnitus, vertigo, and deafness. The dysfunction usually disappears within a few weeks. However, hearing loss may be permanent.

Hemiparesis, dysphasia, and hemianopsia may occur. These signs usually resolve over time. If they do not, suspect a cerebral abscess, subdural empyema, subdural effusion, or persistent meningitis. Acute cerebral edema may cause seizures, CN III palsy, bradycardia, hypertensive coma, and death.

Headaches may occur for months after the diagnosis of meningitis until the irritation and inflammation have completely resolved. It is important to implement pain management for chronic headaches.

A noncommunicating hydrocephalus may occur if the exudate causes adhesions that prevent the normal flow of CSF from the ventricles. CSF reabsorption by the arachnoid villi may be obstructed by the exudate. In this situation, surgical implantation of a shunt is the only treatment.

Waterhouse-Friderichsen syndrome is a complication of meningococcal meningitis. The syndrome is manifested by petechiae, disseminated intravascular coagulation (DIC), adrenal hemorrhage, and circulatory collapse. DIC and shock, which are some of the most serious complications of meningitis, are associated with meningococcemia. DIC is discussed in detail in Chapter 34.

Diagnostic Studies

When a patient has manifestations suggestive of bacterial meningitis, a blood culture and CT scan should be done. Diagnosis is usually verified by doing an LP with CSF analysis (Table 61.16). An LP should be done only after the CT scan has ruled out an obstruction in the foramen magnum to prevent a fluid shift resulting in herniation.

TABLE 61.17 Interprofessional Care

Bacterial Meningitis

Diagnostic Assessment
- History and physical assessment
- Analysis of CSF (for protein, WBC, glucose), Gram stain, and culture
- CBC, coagulation profile, electrolyte levels, glucose, platelet count
- Blood culture
- CT scan, MRI, PET scan
- Skull x-ray studies

Management
- Rest
- IV fluid
- Hypothermia

Drug Therapy
- IV antibiotics
  - ampicillin, penicillin
  - cephalosporin (e.g., ceftriaxone)
- codeine for headache
- dexamethasone
- acetaminophen or aspirin for temperature >100.4°F (38°C)
- IV phenytoin
- IV mannitol (Osmitrol) for diuresis

Specimens of the CSF, sputum, and nasopharyngeal secretions are taken for culture before the start of antibiotic therapy to identify the causative organism. A Gram stain is done to detect bacteria. The predominant white blood cell type in the CSF with bacterial meningitis is neutrophils.

X-rays of the skull may show infected sinuses. CT scans and MRI may be normal in uncomplicated meningitis. In other cases, CT scans may show signs of increased ICP or hydrocephalus.

Interprofessional Care

Bacterial meningitis is a medical emergency. Rapid diagnosis based on history and physical assessment is crucial because the patient is usually in a critical state when health care is sought. When meningitis is suspected, antibiotic therapy is begun after the collection of specimens for cultures, even before the diagnosis is confirmed (Table 61.17).

Ampicillin, penicillin, vancomycin, cefuroxime, ceftriaxone, and ceftazidime are the main drugs given to treat bacterial meningitis. Dexamethasone may be given before or with the first dose of antibiotics. Collaborate with the HCP to manage the headache, fever, and nuchal rigidity from meningitis.

❖ NURSING MANAGEMENT: BACTERIAL MENINGITIS

◆ Assessment

Initial assessment should include vital signs, neurologic assessment, fluid intake and output, and evaluation of the lungs and skin.

◆ Clinical Problems

Clinical problems for the patient with bacterial meningitis may include:
- Increased ICP
- Inadequate tissue perfusion
- Altered body temperature
- Pain

Additional information on clinical problems and interventions for the patient with bacterial meningitis is presented in eNursing Care Plan 61.2 (available on the website for this chapter).

◆ Planning

The overall goals for the patient with bacterial meningitis are to (1) return to maximal neurologic functioning, (2) resolve the infection, and (3) control pain and discomfort.

◆ Implementation

◆ Health Promotion

Prevention of respiratory tract infections through vaccination programs for pneumococcal pneumonia and influenza is important. Meningococcal vaccines are available that protect against the serogroups that occur most often in the United States. They will not prevent all cases. Two types of meningococcal vaccines are available in the United States:
- Meningococcal conjugate vaccines (MCV4) (Menactra, Menveo)
- Serogroup B meningococcal vaccines (Bexsero, Trumenba)

Early treatment of respiratory tract and ear infections is important. Persons who have close contact with anyone who has bacterial meningitis should receive prophylactic antibiotics.

◆ Acute Care

The patient with bacterial meningitis is usually acutely ill. The fever is high, and head pain is severe. Irritation of the cerebral cortex may cause seizures. Changes in mental status and LOC depend on the degree of increased ICP. Assess vital signs, neurologic status, intake and output, skin, and lung sounds at regular intervals based on the patient's condition. Administer antibiotics as scheduled to maintain therapeutic blood levels.

Head and neck pain with movement requires attention. Codeine provides some pain relief without undue sedation for most patients. Assist the patient to a position of comfort, often curled up with the head slightly extended. Elevate the head of the bed slightly. A darkened room and a cool cloth over the eyes relieve photophobia.

All patients have some degree of mental distortion and hypersensitivity. They may be frightened and misinterpret the environment. Make every attempt to minimize environmental stimuli and prevent injury. For the patient with delirium, low lighting may decrease hallucinations. A familiar person at the bedside may have a calming effect. Be efficient with care while conveying an attitude of caring and unhurried gentleness. The use of touch and a soothing voice to give simple explanations of activities is helpful. If seizures occur, assess the patient and take protective measures. Give antiseizure drugs, such as phenytoin or levetiracetam (Keppra), as ordered. Manage problems associated with increased ICP.

Fever is vigorously treated because it increases cerebral edema and the risk for seizures. In addition, neurologic damage may result from a high fever over a prolonged time. Acetaminophen

or aspirin may be used to reduce fever. If the fever is resistant to aspirin or acetaminophen, more vigorous means are needed (e.g., cooling blanket). Do not to reduce the temperature too rapidly because shivering may result, causing a rebound effect and increasing the temperature and ICP. Wrap the extremities in soft towels or a blanket covered with a sheet to reduce shivering. If a cooling blanket is not available or desirable, tepid sponge baths with water may be effective in lowering the temperature. Protect the skin from excessive drying and injury and prevent breaks in the skin.

Because high fever increases the metabolic rate and insensible fluid loss, assess the patient for dehydration and adequacy of fluid intake. Diaphoresis further increases fluid losses and should be noted on the output record. Calculate replacement fluids as 800 mL/day for respiratory losses and 100 mL for each degree of temperature greater than 100.4°F (38°C). Supplemental feeding (e.g., enteral nutrition) may be needed to maintain adequate nutrition.

Meningococcal meningitis is highly contagious. Maintain respiratory isolation until the cultures are negative. Other causes of meningitis may pose minimal to no infection risk with patient contact. They do not need isolation.

Ambulatory Care

After the acute period has passed, the patient needs several weeks of recovery before resuming normal activities. In this period, stress the importance of adequate nutrition. Encourage a high-protein, high-calorie diet in small, frequent feedings.

Muscle rigidity may persist in the neck and backs of the legs. Progressive range of motion exercises and warm baths are useful. Have the patient gradually increase activity as tolerated, but encourage adequate rest and sleep.

Residual effects can result in sequelae such as dementia, seizures, deafness, hemiplegia, and hydrocephalus. Assess vision, hearing, cognitive skills, and motor and sensory abilities after recovery. Provide the patient with appropriate referrals as needed. Throughout the acute and recovery periods, be aware of the anxiety and stress felt by the caregiver and other family members.

Evaluation

The expected outcomes are that the patient with bacterial meningitis will:

- Have appropriate cognitive function
- Maintain body temperature within normal range
- Report satisfaction with pain control

VIRAL MENINGITIS

The most common causes of viral meningitis are enteroviruses, arboviruses, human immunodeficiency virus, and herpes simplex virus (HSV). Enteroviruses most often spread through direct contact with respiratory secretions. Viral meningitis usually presents as a headache, fever, photophobia, and stiff neck.[17] The fever may be moderate or high.

The Xpert EV test can rapidly diagnose viral meningitis. A sample of CSF is used to determine if enterovirus is present. Results are available within hours of symptom onset.[17]

The CSF can be clear or cloudy, and the typical finding is lymphocytosis. Organisms are not seen on Gram stain or acid-fast smears. Polymerase chain reaction (PCR) used to detect viral-specific deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) is a sensitive method for diagnosing CNS viral infections.

Antibiotics should be given after the LP while awaiting the results of the CSF analysis. Antibiotics are the best defense for bacterial meningitis. We can easily discontinue them if the meningitis is found to be viral.

Viral meningitis is managed symptomatically because the disease is self-limiting. Full recovery is expected. Rare sequelae include persistent headaches, mild mental impairment, and incoordination.

BRAIN ABSCESS

Brain abscess is an accumulation of pus within the brain tissue from a local or systemic infection. Direct extension from an ear, tooth, mastoid, or sinus infection is the main cause. Other causes include spread from a distant site (e.g., pulmonary infection, bacterial endocarditis), skull fracture, and prior brain trauma or surgery. Streptococci and *Staphylococcus aureus* are the most common infective organisms.

Manifestations are similar to those of meningitis and encephalitis. They include headache, fever, and nausea and vomiting. Signs of increased ICP may include drowsiness, confusion, and seizures. Focal symptoms may reflect the local area of the abscess. For example, visual field defects and seizures are common with a temporal lobe abscess. Vision problems and hallucinations may accompany an occipital abscess. CT and MRI are used to diagnose a brain abscess.

Antimicrobial therapy is the main treatment. Other manifestations are treated symptomatically. If drug therapy is not effective, the abscess may have to be drained or removed if it is encapsulated.

Nursing care is similar to those for a patient with meningitis or increased ICP. If the patient had surgical drainage or removal, the nursing care is similar to that of a patient having cranial surgery.

ENCEPHALITIS

Encephalitis is an acute inflammation of the brain. It is a serious and sometimes fatal disease. Several thousand cases occur in the United States each year. It is usually caused by a virus. Many different viruses can cause encephalitis. Some are associated with certain seasons of the year or endemic to certain geographic areas.

Ticks and mosquitoes transmit epidemic encephalitis. Examples include eastern equine, La Crosse, St. Louis, West Nile, and western equine.[17] Nonepidemic encephalitis may occur as a complication of measles, chickenpox, or mumps. HSV encephalitis is the most common cause of acute nonepidemic viral encephalitis. Cytomegalovirus encephalitis occurs in patients with acquired immunodeficiency syndrome (AIDS).

Clinical Manifestations and Diagnostic Studies

Encephalitis can be acute or subacute. The onset is typically nonspecific, with fever, headache, nausea, and vomiting. CNS signs appear on day 2 or 3. They vary from minimal changes in mental status to coma. Virtually any CNS problem can occur, including hemiparesis, tremors, seizures, CN palsies, personality changes, impaired memory, amnesia, and dysphasia.

Early diagnosis and treatment of viral encephalitis are essential for favorable outcomes. Diagnostic findings are shown in Table 61.16. Brain imaging techniques include CT, MRI, and PET. PCR tests allow for early detection of HSV and West Nile encephalitis. West Nile virus should be strongly considered in adults over 50 years old who develop encephalitis or meningitis in summer or early fall. The best diagnostic test for West Nile virus is a blood test that detects viral RNA. This test is also used to screen donated blood, organs, cells, and tissues.

Interprofessional and Nursing Care

Encephalitis prevention focuses on mosquito control. Measures include cleaning rain gutters, removing old tires, draining bird baths, and removing water where mosquitoes can breed. Insect repellent should be used during mosquito season.

The management of encephalitis, including West Nile virus infection, is symptomatic and supportive. In the initial stages of encephalitis, many patients need intensive care. We treat seizure disorders with antiseizure drugs. Prophylactic treatment with antiseizure drugs may be used in severe cases of encephalitis.

Acyclovir (Zovirax) is used to treat encephalitis caused by HSV infection. Its use reduces mortality rates, although neurologic complications may still occur. For maximal benefit, it should start before the onset of coma. Treatment of cytomegalovirus encephalitis in AIDS patients is discussed in Chapter 15.

Case Study

Traumatic Brain Injury

(© Comstock/Thinkstock.)

Patient Profile

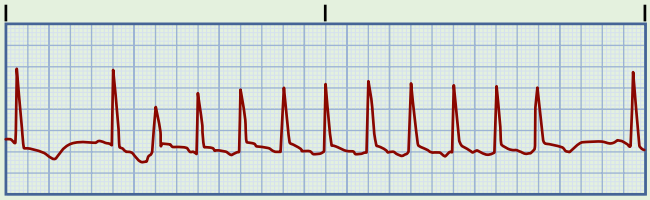
C.G. is a 30-year-old Army veteran who comes to the outpatient clinic reporting chronic headaches (rating of 8 [0 to 10 scale]) and trouble sleeping. During his service, he was deployed for 15 months to Afghanistan. His wife has noticed some personality changes since his discharge from military service. She is concerned that he has posttraumatic stress disorder (PTSD).

Subjective Data

- Reports that he has been depressed lately but attributes it to headache and difficulty returning to civilian life
- Headache is worse in the morning or when he lies down
- Uses tobacco and drinks coffee throughout the day
- Has trouble sleeping
- Reports "incidents" of heavy combat and blasts with a loss of consciousness. Cannot remember how many times
- Unable to obtain a more through history as he becomes quite agitated

Objective Data

- During your assessment, you note that C.G. is looking around the room and jumps when the phone rings next door
- Loss of short-term memory (remembers 1 of 3 items)
- Heart rate ranges from 100 to 130 beats/min
- ECG strip is shown below:



- Systolic BP ranges from 120 to 160 mm Hg
- Right pupil, 3 mm sluggishly reactive; left pupil, 3 mm briskly reactive

Diagnostic Studies

- CT of the head: negative for skull fracture, hematoma, or bleeding. Cerebral edema present, with cingulate herniation on the right side
- MRI of the head: Mild diffuse axonal injury

Discussion Questions

1. ***Recognize:*** What could be the cause of C.G.'s hypertension, tachycardia, and ECG rhythm?
2. ***Analyze:*** In addition to PTSD, what do his manifestations suggest?
3. ***Prioritize:*** Based on the assessment data presented, what are the priority clinical problems?
4. ***Prioritize:*** What priority interventions should be implemented?
5. ***Plan:*** How can the interprofessional team work together to meet his needs?
6. ***Safety:*** Are there any safety concerns for this patient or his wife?
7. ***Act:*** What interventions and support can help his wife?

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Vasogenic cerebral edema increases intracranial pressure by
- **a.** shifting fluid in the gray matter.
- **b.** disrupting the blood-brain barrier.
- **c.** leaking molecules from the intracellular fluid to the capillaries.
- **d.** altering the osmotic gradient flow into the intravascular component.

2. A patient with intracranial pressure monitoring has a pressure of 12 mm Hg. The nurse understands that this pressure reflects
- **a.** a severe decrease in cerebral perfusion pressure.
- **b.** an alteration in the production of cerebrospinal fluid.
- **c.** the loss of autoregulatory control of intracranial pressure.
- **d.** a normal balance among brain tissue, blood, and cerebrospinal fluid.

3. A nurse plans care for the patient with increased intracranial pressure with the knowledge that the *best* way to position the patient is to
   a. keep the head of the bed flat.
   b. elevate the head of the bed to 30 degrees.
   c. maintain patient on the left side with the head supported on a pillow.
   d. use a continuous-rotation bed to continuously change patient position.
4. The nurse is alert to a possible acute subdural hematoma in the patient who
   a. has a linear skull fracture crossing a major artery.
   b. has focal symptoms of brain damage with no recollection of a head injury.
   c. develops decreased level of consciousness and a headache within 48 hours of a head injury.
   d. has an immediate loss of consciousness with a brief lucid interval followed by decreasing level of consciousness.
5. During admission of a patient with a severe head injury to the emergency department, the nurse places the *highest* priority on assessment of
   a. airway patency.
   b. presence of a neck injury.
   c. neurologic status with the Glasgow Coma Scale.
   d. cerebrospinal fluid leakage from the ears or nose.
6. A patient suspected of having a brain tumor has memory deficits, visual changes, weakness of right upper and lower extremities, and personality changes. The nurse determines that the tumor is likely located in the
   a. frontal lobe.
   b. parietal lobe.
   c. occipital lobe.
   d. temporal lobe.
7. Management of a patient with a brain tumor includes *(select all that apply)*
   a. discussing with the patient methods to control inappropriate behavior.
   b. using diversion techniques to keep the patient stimulated and motivated.
   c. assisting and supporting the family in understanding any changes in behavior.
   d. limiting self-care activities until the patient has regained maximum physical functioning.
   e. planning for seizure precautions and teaching the patient and the caregiver about antiseizure drugs.
8. The nurse on the clinical unit is assigned to 4 patients. Which patient should she assess *first*?
   a. Patient with a skull fracture whose nose is bleeding
   b. A patient with an acute stroke who is confused and whose daughter is present
   c. Patient with meningitis who is suddenly agitated and reporting a headache of 10 on a 0 to 10 scale
   d. Patient 2 days postoperative after a craniotomy for a brain tumor who has had continued vomiting
9. A nursing measure that can reduce the potential for seizures and increased intracranial pressure in the patient with bacterial meningitis is
   a. administering codeine for relief of head and neck pain.
   b. controlling fever with prescribed drugs and cooling techniques.
   c. maintaining strict bed rest with the head of the bed slightly elevated.
   d. keeping the room dark and quiet to minimize environmental stimulation.

1. b; 2. d; 3. b; 4. c; 5. a; 6. a; 7. c, e; 8. c; 9. b.

CONCEPTUAL FOCUS

Family Dynamics
Functional Ability
Intracranial Regulation
Mobility
Safety
Sensory Perception

LEARNING OUTCOMES

1. Describe the incidence of and risk factors for stroke.
2. Explain mechanisms that affect cerebral blood flow.
3. Compare and contrast the etiology and pathophysiology of ischemic and hemorrhagic strokes.
4. Correlate the clinical manifestations of stroke with the underlying pathophysiology.
5. Identify diagnostic studies done for patients with strokes.
6. Distinguish the interprofessional care for patients with ischemic strokes and hemorrhagic strokes.
7. Describe the acute nursing management of a patient with a stroke.
8. Describe the rehabilitative nursing management of a patient with a stroke.
9. Explain the psychosocial impact of a stroke on the patient, caregiver, and family.

KEY TERMS

aneurysm
aphasia
cerebrovascular accident (CVA)
dysarthria
dysphasia
embolic stroke
hemorrhagic strokes
intracerebral hemorrhage
ischemic stroke
stroke
subarachnoid hemorrhage (SAH)
thrombotic stroke
transient ischemic attack (TIA)

Stroke occurs when there is (1) *ischemia* (inadequate blood flow) to a part of the brain or (2) *hemorrhage* (bleeding) into the brain that results in the death of brain cells. In a stroke, functions such as movement, sensation, thinking, talking, or emotions that were controlled by the affected area of the brain are lost or impaired. The severity of the loss of function varies based on the location and extent of the brain damage.

The terms *brain attack* and **cerebrovascular accident (CVA)** are also used to describe stroke. The term *brain attack* communicates the urgency of recognizing the warning signs of a stroke and treating it as a medical emergency, as we do with a heart attack (Table 62.1). After the onset of a stroke, immediate medical attention is crucial to decrease disability and the risk of death.

Stroke is a major public health concern. About 800,000 people have a stroke each year.[1] An estimated 7 million adults in the United States have had a stroke.[1] With an aging population, we can expect these numbers to increase. However, stroke can occur at any age. 34% of strokes occur in people younger than 65 years old.[2]

Stroke is currently the fifth most common cause of death in the United States.[1] More than 150,000 deaths occur each year from stroke.[3] While deaths due to stroke have declined, stroke is the leading cause of serious long-term disability. 15% to 30% have a permanent disability.[4]

Common long-term disabilities include *hemiparesis* (partial paralysis on 1 side), inability to walk, complete or partial dependence for activities of daily living (ADLs), *aphasia* (dysfunction in communication), and depression. In addition to the physical, cognitive, and emotional impact of the stroke on the survivor, the stroke affects the lives of the stroke patient's caregiver and family. A stroke is a lifelong change for both the stroke survivor

TABLE 62.1 PATIENT & CAREGIVER TEACHING

FAST Warning Signs of Stroke

FAST is an easy way to remember the signs of stroke. Include the following information in the teaching plan for a patient at risk for stroke and the patient's caregiver:

F	Face drooping	Does one side of the face droop, or is it numb? Ask the person to smile. Is the smile uneven?
A	Arm weakness	Is one arm weak or numb? Ask the person to raise both arms. Does one arm drift downward?
S	Speech difficulties	Is speech slurred? Is the person unable to speak or hard to understand? Ask the person to repeat a simple sentence like "The sky is blue." Is the sentence repeated correctly?
T	Time	Time is CRITICAL! If someone shows any of these signs (even if they go away), call 911 and get the person to the hospital. Note the time when the signs first appeared.

In addition, report the sudden onset of the following:

- Confusion
- Numbness or weakness, especially in 1 side of the body
- Severe headache with no known cause
- Trouble seeing in one or both eyes
- Trouble walking, dizziness, loss of balance or coordination

Source: ASA: FAST. Retrieved from www.strokeassociation.org/STROKEORG/WarningSigns/Stroke-Warning-Signs-and-Symptoms_UCM_308528_SubHomePage.jsp.

and family. Be mindful of this impact when caring for patients who survive stroke.

PATHOPHYSIOLOGY OF STROKE

Anatomy of Cerebral Circulation

Blood is supplied to the brain by 2 major pairs of arteries: internal carotid arteries (anterior circulation) and vertebral arteries (posterior circulation). The carotid arteries branch to supply most of the (1) frontal, parietal, and temporal lobes; (2) basal ganglia; and (3) part of the diencephalon (thalamus and hypothalamus). The major branches of the carotid arteries are the middle cerebral and anterior cerebral arteries. The vertebral arteries join to form the basilar artery, which branches to supply the middle and lower parts of the temporal lobes, occipital lobes, cerebellum, brainstem, and part of the diencephalon. The main branch of the basilar artery is the posterior cerebral artery. The anterior and posterior communicating arteries connect the anterior and posterior cerebral circulation at the *circle of Willis* by (Fig. 62.1). Fig. 60.10 shows the arteries at the base of the brain. Genetic variations in this area are common. All connecting vessels may not be present.

Regulation of Cerebral Blood Flow

The brain needs a continuous supply of blood to provide the O_2 and glucose that neurons need to function. Blood flow must be maintained at 750 to 1000 mL/min (55 mL/100 g of brain tissue), or 20% of the cardiac output, for optimal brain function. If blood flow to the brain is totally interrupted (e.g., cardiac arrest), neurologic metabolism is altered in

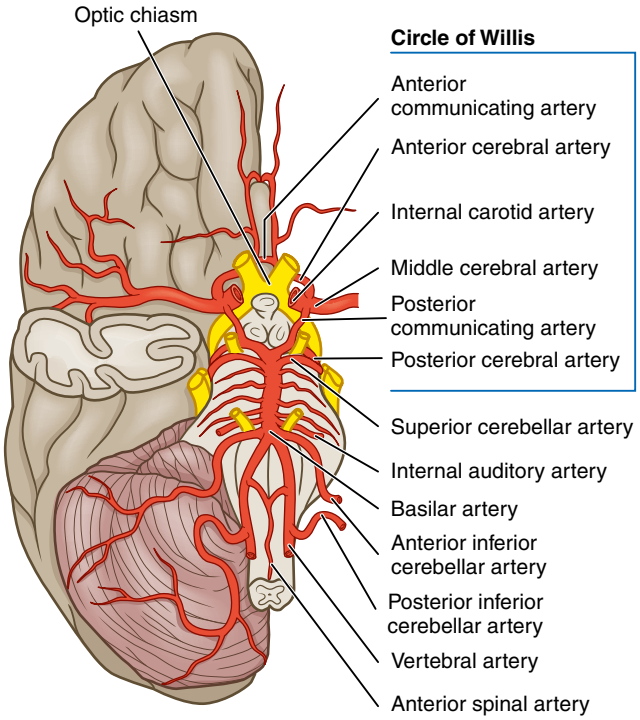

Fig. 62.1 Cerebral arteries and the circle of Willis. The top of the temporal lobe has been removed to show the course of the middle cerebral artery.

30 seconds, metabolism stops in 2 minutes, and cell death occurs in 5 minutes.

The brain is normally protected from changes in mean systemic arterial BP over a range from 50 to 150 mm Hg by a mechanism known as *cerebral autoregulation*. This involves changes in the diameter of cerebral blood vessels in response to changes in pressure so that the blood flow to the brain stays constant. When cerebral ischemia occurs, autoregulation may be impaired, making the brain dependent on systemic BP. CO_2 is a potent cerebral vasodilator. Changes in arterial CO_2 levels have a huge effect on cerebral blood flow (CBF). Increased CO_2 levels increase CBF. Decreased CO_2 levels decrease CBF. Very low arterial oxygen (O_2) levels (partial pressure of arterial O_2 less than 50 mm Hg) or increases in hydrogen ion concentration also increase CBF.

Factors that affect blood flow to the brain include systemic BP, cardiac output, and blood viscosity. During normal activity, O_2 requirements vary. Changes in cardiac output, vasomotor tone, and distribution of blood flow normally maintain adequate blood flow to the brain. Cardiac output must be reduced by one-third before CBF is reduced. Changes in blood viscosity affect CBF, with decreased viscosity increasing blood flow.

Collateral circulation may develop over time to compensate for a decrease in CBF. An area of the brain can potentially receive blood supply from another blood vessel even if blood supply from the original vessel has been cut off (e.g., because of thrombosis). In other words, the vessels in the brain make an "alternative route" for blood flow to reach damaged areas, thus preventing a stroke.

Intracranial pressure (ICP) influences CBF. Increased ICP causes brain compression and reduced CBF. A major goal when

BOX 62.1 PROMOTING HEALTH EQUITY

Stroke

Blacks

- Have the highest incidence of strokes
- Have a rate of first strokes that is twice that of any other ethnic group
- Are 3 times more likely than Whites to have an ischemic stroke and 4 times more likely to have a hemorrhagic stroke
- Have increased rates of hypertension, diabetes, and sickle cell anemia, which may be related to the high incidence of strokes
- Have high rates of smoking and obesity, 2 risk factors for stroke
- Are twice as likely to die from a stroke as Whites

Other Ethnicities

- Hispanics, Native Americans, and Asian Americans have a higher incidence of strokes than Whites
- Hispanics have a high incidence of diabetes, an important risk factor
- Native Americans are more likely than Whites to have at least 2 risk factors for stroke

caring for a patient after a stroke is to reduce secondary injury from increased ICP (see Chapter 61).

RISK FACTORS FOR STROKE

The most effective way to decrease the burden of stroke is prevention and teaching, especially about risk factors. We divide risk factors into nonmodifiable and modifiable. Stroke risk increases with multiple risk factors. Thus, primary prevention focuses on reducing modifiable risk factors. This can dramatically reduce the chance of stroke.[5]

Nonmodifiable Risk Factors

Nonmodifiable risk factors include age, gender, ethnicity or race, and family history or heredity. Stroke risk increases with age, doubling each decade after 55 years of age. Two-thirds of all strokes occur in persons older than 65 years. Strokes are more common in men, but more women die from stroke than men. Because women tend to live longer than men, they have more opportunity to have a stroke.[2]

Blacks have twice the incidence of stroke and a higher death rate from stroke compared to any other ethnic group (Box 62.1). This may be related in part to higher rates of hypertension, obesity, and diabetes.[2]

Genetic risk factors are important in the development of vascular disease, including stroke. A person with a family history of stroke has an increased risk of having a stroke. We think that genes encoding products involved in lipid metabolism, thrombosis, and inflammation are genetic factors for stroke. People who have at least 2 first-degree relatives with a history of subarachnoid hemorrhage (SAH) or aneurysm should be screened to rule out anomalies in their cerebral vasculature.[5]

Modifiable Risk Factors

Modifiable risk factors are those that can potentially be altered through lifestyle changes and medical treatment, thus reducing the risk for stroke. They include hypertension, heart disease, diabetes, smoking, obesity, sleep apnea, metabolic syndrome, lack of physical exercise, poor diet, and drug and alcohol use. We think modifiable risk factors cause 90% of strokes.[6]

Hypertension is the single most important modifiable risk factor. It is often undetected and inadequately treated. Increases in systolic BP (SBP) and diastolic BP (DBP) independently increase stroke risk. Treating hypertension reduces stroke risk up to 50%. New recommendations by the American Heart Association (AHA) include home BP monitoring with a goal of SBP less than 140 mm Hg.[4]

Heart disease, including atrial fibrillation, myocardial infarction (MI), cardiomyopathy, cardiac valve abnormalities, and congenital heart defects, is a risk factor for stroke. Atrial fibrillation causes about 25% of strokes.[6] People with atrial fibrillation are 5 times more likely to have a stroke than people with a regular heart rhythm. The incidence of atrial fibrillation increases with age. Oral anticoagulants (e.g., warfarin, dabigatran) and adherence to their therapy play a key role in stroke prevention.

Diabetes is a significant risk factor for stroke. Stroke risk in people with diabetes is 5 times higher than in those without diabetes.[6]

Smoking nearly doubles the risk for ischemic stroke. Smokers are 4 times as likely to have a hemorrhagic stroke than nonsmokers.[5] The risk from smoking decreases substantially over time after the smoker quits. After 5 to 10 years of no tobacco use, former smokers have the same risk for stroke as nonsmokers.

The effect of alcohol on stroke risk depends on the amount consumed. Women who drink more than 1 alcoholic drink per day and men who drink more than 2 alcoholic drinks per day are at higher risk for hypertension, which increases their chance of stroke. Illicit drug use, especially cocaine use, increases stroke risk.[6]

A waist circumference to hip circumference ratio equal to or above the mid-value for the population increases the risk for ischemic stroke 3-fold. Obesity is associated with hypertension, high blood glucose, and increased blood lipid levels, all of which increase stroke risk.[6] Physical inactivity increases stroke risk. Benefits of physical activity can occur with even light to moderate regular activity. The AHA recommends 150 minutes of moderate-intensity exercise or 75 minutes of vigorous-intensity exercise per week to reduce stroke risk.[4] Nutrition teaching is important. A diet high in fat and low in fruits and vegetables may increase stroke risk.

The early forms of birth control pills that had high levels of progestin and estrogen increased a woman's chance of having a stroke, especially if the woman smoked. Newer, low-dose oral contraceptives have lower risks for stroke except in those who have hypertension and smoke. The AHA recommends smoking cessation and alternatives to estrogen oral contraceptives for those women to reduce their risk of stroke.[4]

Women who have migraines with aura have an increased risk for stroke. Other conditions that may increase stroke risk include inflammatory conditions (e.g., rheumatoid arthritis), sickle cell disease, and blood clotting disorders, such as factor V Leiden mutation.[5]

Transient Ischemic Attack

Another risk factor associated with stroke is a history of a **transient ischemic attack (TIA)**. A TIA is a transient episode

of neurologic dysfunction caused by focal brain, spinal cord, or retinal ischemia, but without acute infarction of the brain. Symptoms typically last less than 1 hour.

Teach the patient to seek treatment for any stroke symptoms since there is no way to predict if a TIA will resolve or if it will progress to a stroke. In general, one-third of those who had a TIA do not have another, one-third have more TIAs, and one-third progress to stroke.[7] TIAs may be due to microemboli that temporarily block the blood flow. TIAs are a warning sign of progressive cerebrovascular disease. The signs and symptoms of a TIA depend on the blood vessel that is involved and the area of the brain that is ischemic. If the carotid system is involved, patients may have a temporary loss of vision in 1 eye *(amaurosis fugax),* transient hemiparesis, numbness or loss of sensation, or a sudden inability to speak. Signs of a TIA involving the vertebrobasilar system may include tinnitus, vertigo, darkened or blurred vision, diplopia, ptosis, dysarthria, dysphagia, ataxia, and unilateral or bilateral numbness or weakness.

CHECK YOUR PRACTICE

You are talking with your uncle at your family reunion. He knows that you are a nurse and seems very eager to talk with you. He tells you that earlier this morning, he was having problems talking, got dizzy, and then "blanked" out for a while. He found himself just lying on the floor in his room. He says, "I think it is just all the excitement of the reunion."

- How would you respond?

A TIA is considered a medical emergency since it can lead to an ischemic stroke. Teach people at risk for TIAs to seek medical attention at once with any stroke-like symptoms and to identify the time of onset of symptoms. The ABCD^2 score is a tool used to predict stroke risk after a TIA (Table 62.2).[8]

TYPES OF STROKE

Unlike a TIA, in which ischemia occurs without infarction, a stroke results in infarction (cell death). We classify strokes as ischemic or hemorrhagic based on the cause and underlying pathophysiologic findings (Fig. 62.2 and Table 62.3).

Ischemic Stroke

An **ischemic stroke** results from inadequate blood flow to the brain from partial or complete occlusion of an artery.[9] We classify ischemic strokes as thrombotic or embolic strokes.

Thrombotic Stroke

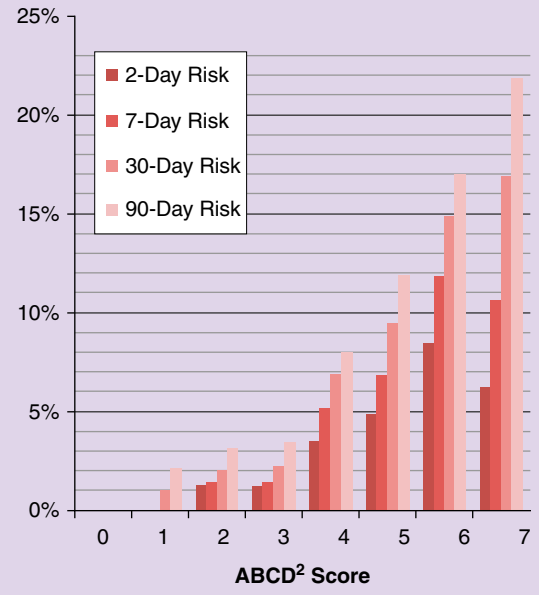
A **thrombotic stroke** occurs from injury to a blood vessel wall and formation of a blood clot (Fig. 62.2A). The lumen of the blood vessel becomes narrowed, and, if it becomes occluded, infarction occurs. Thrombosis develops readily where atherosclerotic plaques have already narrowed blood vessels. Thrombotic stroke is the most common cause of stroke. It accounts for about 60% of strokes.[2] They are more common in older adults, especially those with high cholesterol, atherosclerosis, or diabetes. Most thrombotic strokes are associated with hypertension or diabetes, both of which accelerate atherosclerosis. Many times, a TIA precedes thrombotic strokes.

TABLE 62.2 ABCD^2 Score

The ABCD^2 score is a risk assessment tool. It is designed to predict the risk for stroke 2 days after a transient ischemic attack (TIA). Calculate the score by adding up points for 5 factors.

Risk Factor	Points
Age ≥60 year	1
Systolic BP ≥140 mm Hg *OR* diastolic BP ≥90 mm Hg	1
Clinical features of TIA (choose 1)	
Unilateral weakness with or without impaired speech *OR*	2
Impaired speech without unilateral weakness	1
Duration	
TIA duration ≥60 min *OR*	2
TIA duration 10–59 min	1
Diabetes	1
Total ABCD^2 Score	0–7

ABCD^2 Score	2-Day Stroke Risk (%)	Care Needed
0–3	1.0	Hospitalization not needed unless there is another indication (e.g., new atrial fibrillation)
4–5	4.1	Hospitalization in most situations
6–7	8.1	Hospitalization

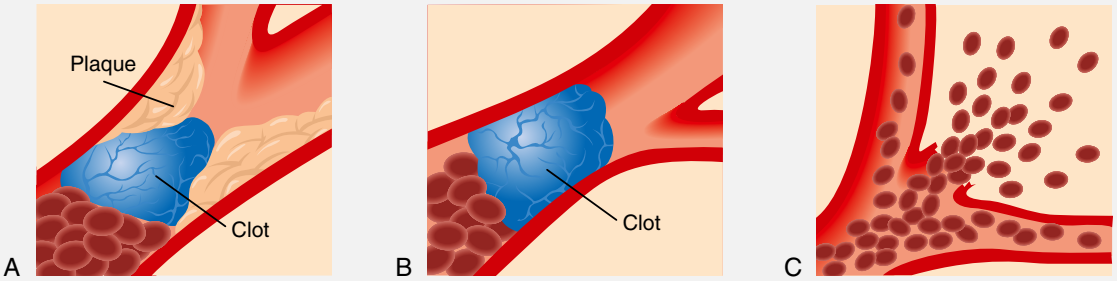


Permission obtained from National Stroke Association. Retrieved from https://www.stroke.org.

The extent of the stroke depends on rapidity of onset, size of the damaged area, and presence of collateral circulation. Most patients with ischemic stroke do not have a decreased level of consciousness (LOC) in the first 24 hours, unless it is due to a brainstem stroke or other condition, such as seizure, increased ICP, or hemorrhage. Manifestations of ischemic stroke may progress in the first 72 hours as infarction and cerebral edema increase.

Embolic Stroke

Embolic stroke occurs when an embolus lodges in and occludes a cerebral artery, resulting in infarction and edema of the area



Thrombotic stroke. The process of clot formation (thrombosis) results in a narrowing of the lumen, which blocks the passage of the blood through the artery.

Embolic stroke. An embolus is a blood clot or other debris circulating in the blood. When it reaches an artery in the brain that is too narrow to pass through, it lodges there and blocks the flow of blood.

Hemorrhagic stroke. A burst blood vessel may allow blood to seep into and damage brain tissues until clotting shuts off the leak.

Fig. 62.2 Major types of stroke.

TABLE 62.3 Types of Stroke

Gender and Age	Warning and Onset	Prognosis
Ischemic		
Incidence: 87% of strokes		
Embolic		
Men more than women	*Warning:* TIA (uncommon) *Onset:* Sudden onset, most likely to occur during activity	Single event, signs, and symptoms develop quickly, usually some improvement, recurrence common without aggressive treatment of underlying disease.
Thrombotic		
Men more than women Oldest median age	*Warning:* TIA (30%–50% of cases) *Onset:* Often during or after sleep	Stepwise progression, signs, and symptoms develop slowly, usually some improvement, recurrence in 20%–25% of survivors.
Hemorrhagic		
Incidence: 13% of strokes		
Intracerebral		
Slightly higher in women	*Warning:* Headache (25% of cases) *Onset:* Activity (often)	Progression over 24 h. Poor prognosis, fatality more likely with presence of coma.
Subarachnoid		
Slightly higher in women Youngest median age	*Warning:* Headache (common) *Onset:* Activity (often), sudden onset, most often related to head trauma	Usually single sudden event, fatality more likely with presence of coma.

TIA, Transient ischemic attack.

supplied by the involved vessel (Fig. 62.2B). Embolism is the second most common cause of stroke.[2] Most emboli originate in the endocardial (inside) layer of the heart when a plaque breaks off from the endocardium and enters the circulation. The embolus travels upward to the cerebral circulation and lodges where a vessel narrows or bifurcates (splits). Heart conditions, including atrial fibrillation, MI, infective endocarditis, valvular heart prostheses, patent foramen ovale, and atrial septal defects, cause most embolic ischemic strokes.[2] Less common causes of emboli include air and fat from long bone (e.g., femur) fractures. Embolic strokes can affect any age group. Rheumatic heart disease is a cause of embolic stroke in young to middle-aged adults. An embolus from an atherosclerotic plaque is more common in older adults.

The patient with an embolic stroke often has severe manifestations that occur suddenly. Warning signs are less common than with thrombotic stroke. The embolic stroke often occurs rapidly, giving little time to accommodate an obstructed blood vessel by developing collateral circulation. The patient is usually conscious. They may have a headache. The effects of the emboli are initially characterized by severe neurologic deficits, which can be temporary if the clot breaks up and allows blood to flow. Smaller emboli then continue to obstruct smaller vessels, which in turn involve smaller portions of the brain with fewer deficits noted.

The prognosis is related to the amount of brain tissue deprived of its blood supply. Recurrence of embolic stroke is common unless the underlying cause is aggressively treated.

Hemorrhagic Stroke

Hemorrhagic strokes result from bleeding into the brain tissue itself (intracerebral or intraparenchymal hemorrhage) or into the subarachnoid space or ventricles (SAH or intraventricular hemorrhage).

Intracerebral Hemorrhage

Intracerebral hemorrhage is bleeding within the brain caused by a rupture of a vessel (usually in the basal ganglia) (Fig. 62.2C). The prognosis of patients with intracerebral hemorrhage is poor. The 30-day mortality rate is 40% to 80%. Half of the deaths occur within the first 48 hours.[2]

Hypertension is the most common cause of intracerebral hemorrhage (Fig. 62.3). Other causes include vascular

Fig. 62.3 Massive hypertensive hemorrhage rupturing into a lateral ventricle of the brain. (From Kumar V, Abbas AK, Aster JC, et al.: *Robbins and Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.)

malformations, coagulation disorders, anticoagulant and thrombolytic drugs, trauma, brain tumors, and ruptured aneurysms. Hemorrhage often occurs during periods of activity. Most often, there is a sudden onset of symptoms, with progression over minutes to hours because of ongoing bleeding.

Manifestations include neurologic deficits, headache, nausea, vomiting, decreased LOC, and hypertension. The extent of the symptoms varies depending on the amount, location, and duration of the bleeding. A blood clot within the closed skull can result in a mass that causes pressure on brain tissue, displaces brain tissue, and decreases CBF, leading to ischemia and infarction.

Most intracerebral hemorrhages occur in the cerebral lobes, cerebellum, pons, thalamus, subcortical white matter, internal capsule, or a part of the basal ganglia called the putamen. At first, patients have a severe headache with nausea and vomiting. Manifestations of putaminal and internal capsule bleeding include weakness of 1 side (including the face, arm, and leg), slurred speech, and deviation of the eyes. Progression of symptoms related to a severe hemorrhage includes hemiplegia, fixed and dilated pupils, abnormal body posturing, and coma. Thalamic hemorrhage results in hemiplegia with more sensory than motor loss. Bleeding into the subthalamic areas of the brain leads to problems with vision and eye movement. Cerebellar hemorrhages are characterized by severe headache, vomiting, loss of ability to walk, dysphagia, dysarthria, and eye movement changes.

Hemorrhage in the pons is the most serious because basic life functions (e.g., respiration) are rapidly affected. Hemorrhage in the pons can be characterized by hemiplegia leading to complete paralysis, coma, abnormal body posturing, fixed pupils, hyperthermia, and death.

Subarachnoid Hemorrhage

Subarachnoid hemorrhage (SAH) occurs when there is intracranial bleeding into the cerebrospinal fluid (CSF)–filled space between the arachnoid and pia mater membranes on the surface of the brain. SAH is often caused by rupture of a cerebral **aneurysm** (congenital or acquired weakness and ballooning of vessels). Aneurysms may be saccular or berry aneurysms, ranging from a few millimeters to 20 to 30 mm in size, or fusiform atherosclerotic aneurysms. Most aneurysms are in the circle of Willis. Other causes of SAH include trauma and illicit drug (cocaine) use. The incidence of SAH increases with age. The rate is higher in women.

The patient may have warning signs and symptoms if the ballooning artery applies pressure to brain tissue. Minor warning symptoms may result from leaking of an aneurysm before major rupture. In general, cerebral aneurysms are viewed as a "silent killer" since people do not have warning signs or symptoms of an aneurysm until rupture has occurred.

CHECK YOUR PRACTICE

You are watching your husband's "for fun" soccer game. He leaves the game and is kneeling on the ground. When you try to assess what is going on, he says, "I've got a terrible headache. It just started." Knowing that he sometimes gets headaches when he is stressed, you ask him if he is feeling stressed. He almost screams back at you, "NO! This is the worst headache of my life!"

- What are 3 priority interventions?

Loss of consciousness may or may not occur. The patient's LOC may range from alert to comatose, depending on the severity of the bleed. Other manifestations include focal neurologic deficits (including cranial nerve deficits), nausea, vomiting, seizures, and stiff neck.

Complications of aneurysmal SAH include rebleeding before surgery or other therapy is started and cerebral vasospasm (narrowing of the blood vessels), which can result in cerebral infarction. Cerebral vasospasm is likely due to an interaction between the metabolites of blood and the vascular smooth muscle. This occurs when the subarachnoid blood clots break down or dissolve, releasing metabolites that can cause endothelial damage and vasoconstriction. The release of endothelin (a potent vasoconstrictor) may play a key role in inducing cerebral vasospasm after SAH. Patients with SAH who are at risk for vasospasm are often in the intensive care unit (ICU) (up to 14 days) until the threat of vasospasm is reduced. Peak time for vasospasm is 6 to 10 days after the initial bleed.

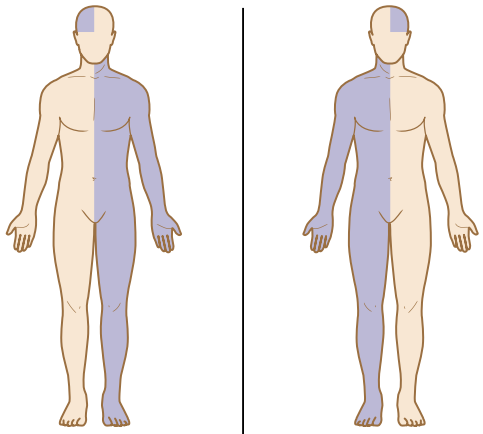
Despite improvements in surgical techniques and management, many patients with SAH die. Some die almost immediately when a rupture occurs. Others die from subsequent bleeding. Survivors can have significant deficits, including cognitive problems.

CLINICAL MANIFESTATIONS

Neurologic manifestations do not significantly differ between ischemic and hemorrhagic stroke. The reason for this is that neural tissue destruction is the basis for neurologic dysfunction caused by both types of stroke. The manifestations are related to the location of the stroke. Specific manifestations related to

TABLE 62.4 Stroke Manifestations Related to the Artery Involved

Artery	Manifestations
Anterior cerebral	Motor and/or sensory deficit (contralateral), sucking or rooting reflex, rigidity, gait problems, loss of proprioception and fine touch
Middle cerebral	*Dominant side:* Aphasia, motor and sensory deficit, hemianopsia *Nondominant side:* Neglect, motor and sensory deficit, hemianopsia
Posterior cerebral	Hemianopsia, visual hallucination, spontaneous pain, motor deficit
Vertebral	Cranial nerve deficits, diplopia, dizziness, nausea, vomiting, dysarthria, dysphagia, and/or coma



Right-brain damage
(stroke on right side of the brain)
- Paralyzed left side: hemiplegia
- Left-sided neglect
- Spatial-perceptual deficits
- Tends to deny or minimize problems
- Rapid performance, short attention span
- Impulsive, safety problems
- Impaired judgment
- Impaired time concepts

Left-brain damage
(stroke on left side of the brain)
- Paralyzed right side: hemiplegia
- Impaired speech/language aphasias
- Impaired right/left discrimination
- Slow performance, cautious
- Aware of deficits: depression, anxiety
- Impaired comprehension related to language, math

Fig. 62.4 Manifestations of right-brain and left-brain stroke.

the type of stroke were discussed in the previous section. The general manifestations of ischemic and hemorrhagic stroke are discussed together here.

A stroke can affect many body functions, including motor activity, bladder and bowel function, intellect, spatial perception, personality, affect, sensation, swallowing, and communication. The functions affected are directly related to the artery involved and area of the brain that it supplies (Table 62.4). Manifestations related to right- and left-brain damage differ somewhat. These are shown in Fig. 62.4.

Motor Function

Motor deficits are the most obvious effect of stroke. Motor deficits include impaired (1) mobility, (2) respiratory function, (3) swallowing and speech, (4) gag reflex, and (5) self-care abilities. Symptoms are caused by the destruction of motor neurons in the pyramidal pathway (nerve fibers from the brain that pass through the spinal cord to the motor cells). The characteristic motor deficits include loss of skilled voluntary movement *(akinesia),* impaired integration of movements, changes in muscle tone, and altered reflexes. The initial *hyporeflexia* (depressed reflexes) progresses to *hyperreflexia* (hyperactive reflexes) for most patients.

Motor deficits after a stroke follow certain specific patterns. Because the pyramidal pathway crosses at the level of the medulla, a lesion on 1 side of the brain affects motor function on the opposite side of the body (contralateral). The arms and legs of the affected side may be weakened or paralyzed to different degrees depending on which part of and to what extent the cerebral circulation was compromised. A stroke affecting the middle cerebral artery leads to greater weakness in the upper extremity than the lower extremity. The affected shoulder tends to rotate internally, and the hip rotates externally. The affected foot is plantar flexed and inverted. An initial period of flaccidity may last from days to several weeks. It is related to nerve damage. Muscle spasticity follows the flaccid stage. It is related to interruption of upper motor neuron influence.

Communication

The left hemisphere is dominant for language skills in right-handed persons and in most left-handed persons.[9] Language disorders involve expression and comprehension of written and spoken words. The patient may have **aphasia**. Types of aphasia include *receptive aphasia* (loss of comprehension), *expressive aphasia* (inability to produce language), or *global aphasia* (total inability to communicate). Aphasia occurs when a stroke damages the dominant hemisphere of the brain.

Dysphasia refers to impaired ability to communicate. However, in most settings, the terms *aphasia* and *dysphasia* are used interchangeably. Aphasia is the more common term used. Patterns of aphasia may differ since a stroke affects different portions of the brain. We describe aphasia as *nonfluent* (minimal speech activity with slow speech that requires obvious effort) or *fluent* (speech is present but has little meaningful communication) (Table 62.5). Most types of aphasia are mixed, with both impaired expression and understanding. A massive stroke may result in global aphasia.

Many stroke patients have **dysarthria**, a problem with the muscular control of speech. Impairment may involve pronunciation, articulation, and phonation. Dysarthria does not affect the meaning of communication or language comprehension. It does affect the mechanics of speech. Some patients have a combination of aphasia and dysarthria.

Affect

Patients who had a stroke may have a hard time controlling their emotions. Emotional responses may be exaggerated or unpredictable. Depression and feelings due to changes in body image and loss of function can make this worse.[10] Mobility and communication problems increase frustration.

CHECK YOUR PRACTICE

You are working in the outpatient stroke clinic, counseling the family of one of your favorite patients. He is a well-respected 65-year-old businessman who has returned home after a stroke. His family tells you that during meals, he becomes frustrated and begins to cry because of the difficulty getting food into his mouth and chewing. His family cannot understand why a previously very competent man is so emotional.

- What teaching will you provide the family?
- What measures can you take to support the family?

TABLE 62.5 Types of Aphasia

Type	Characteristics
Broca's	• Type of nonfluent aphasia • Damage to frontal lobe of brain • Often speak in short phrases that make sense but take great effort • Often omit small words (e.g., is, and, the) • May say, "Walk dog," meaning, "I will take the dog for a walk," or "Book 2 table," for "There are 2 books on the table" • Typically understands others' speech • Often aware of their difficulties and can become easily frustrated
Global	• Type of nonfluent aphasia • Results from damage to extensive portions of language areas of brain • Have severe communication difficulties • May be limited in ability to speak or understand language
Wernicke's	• Type of fluent aphasia • Damage occurs in left temporal lobe, although it can result from damage to right lobe • May speak in long sentences that have no meaning, add unnecessary words, and even create made-up words • May say, "You know that smoodle pinkered and that I want to get him round and take care of him like you want before" • Usually have great difficulty understanding speech • Often unaware of their mistakes • Often difficult to follow what person is trying to say
Other	• Results from damage to different language areas in brain • Some may have trouble repeating words and sentences, even though they can speak and understand the meaning of the word or sentence • May have trouble naming objects, even though they know what the object is and what its use is

Intellectual Function

A stroke may impair both memory and judgment. These impairments can occur with strokes affecting either side of the brain. A left-brain stroke is more likely to result in memory problems related to language. Patients with a left-brain stroke often are cautious in making judgments.

The patient with a right-brain stroke tends to be impulsive and move quickly. An example is that they try to rise quickly from a wheelchair without locking the wheels or raising the footrests. On the other hand, people with a left-brain stroke would move slowly and cautiously from the wheelchair. Patients with either type of stroke may find it hard to make generalizations, interfering with their ability to learn.

Spatial-Perceptual Problems

Those who had a stroke on the right side of the brain are more likely to have problems with spatial-perceptual orientation. However, this can also occur in people with left-brain stroke. Patients may or may not be aware of their spatial-perceptual problems. You need to assess for these problems as they will affect rehabilitation and recovery.

Spatial-perceptual problems fall within 4 categories:

- An incorrect perception of self and illness. In this situation, patients may deny their illnesses or not recognize their own body parts. This results from parietal lobe damage.
- Spatial neglect. This occurs when the patient neglects all input from the affected side (erroneous perception of self in space). This may be worsened by *homonymous hemianopsia,* in which blindness occurs in the same half of the visual fields of both eyes. The patient has trouble with spatial orientation, such as judging distances.
- *Agnosia.* This is the inability to recognize an object by sight, touch, or hearing.
- *Apraxia.* This is the inability to carry out learned, sequential movements on command.

Elimination

Most urinary and bowel elimination problems are temporary. When a stroke affects 1 hemisphere of the brain, the prognosis for normal bladder function is excellent. At least partial sensation for bladder filling remains, and voluntary urination is present. At first, the patient may have frequency, urgency, and incontinence. Although motor control of the bowel is usually not a problem, patients are often constipated. Constipation is associated with immobility, weak abdominal muscles, dehydration, and decreased response to the defecation reflex. Incontinence may occur if the patient is not able to say they need to eliminate or they have difficulty managing clothing. Scheduled toileting and clothes that are easily removed encourage independence.

DIAGNOSTIC STUDIES

When manifestations of a stroke occur, diagnostic studies (Tables 62.6 and 62.7) are done to (1) confirm that it is a stroke and not another type of brain lesion and (2) identify the likely cause of the stroke. Diagnostic study results also guide decisions about therapy. A key assessment is to determine the time of the onset of symptoms. This is important for all types of stroke, especially ischemic strokes, since time can affect treatment decisions.

When a person suspected of TIA or stroke arrives in the emergency department or mobile stroke unit, it is important for them to rapidly undergo either a noncontrast head CT or MRI. These tests can rapidly distinguish between ischemic and hemorrhagic stroke. They help determine the size and location of the stroke and treatment options. MRI is more effective in identifying ischemic stroke than CT scans. However, a CT scan is a rapid diagnostic tool to rule out hemorrhage. Serial scans

TABLE 62.6 Diagnostic Studies

Diagnosis of Stroke (Including Extent of Involvement)
- CT scan
- CT angiography (CTA)
- CT/MRI perfusion and diffusion imaging
- MRI
- Magnetic resonance angiography (MRA)

Cerebral Blood Flow
- Carotid angiography
- Carotid duplex scanning
- Cerebral angiography
- Digital subtraction angiography
- Transcranial doppler ultrasonography

Cardiac Assessment
- Cardiac markers (troponin, creatine kinase-MB)
- Chest x-ray
- Echocardiography (transthoracic, transesophageal)
- ECG

Additional Studies
- Coagulation studies: prothrombin time, activated partial thromboplastin time
- CBC (including platelets)
- Electrolyte panel with blood glucose
- Lipid profile
- Renal and hepatic studies

TABLE 62.7 Interprofessional Care

Acute Stroke

Diagnostic Assessment
- History and physical assessment
- Diagnostic studies (Table 62.6)

Management

Drug Therapy
- Platelet inhibitors (e.g., aspirin)
- Anticoagulation therapy for patients with atrial fibrillation

Surgical Therapy
- Carotid endarterectomy
- Stenting of carotid artery
- Transluminal angioplasty
- Surgical interventions for aneurysms at risk for bleeding

Acute Care
- Maintain airway
- Fluid therapy
- Treat cerebral edema
- Prevent secondary injury

Ischemic Stroke
- Tissue plasminogen activator (tPA) IV or intraarterial
- Endovascular therapy

Hemorrhagic Stroke
- Surgical decompression if indicated
- Clipping or coiling of aneurysm

Role of Interprofessional Team Members

Speech Therapy
- Assess swallowing reflex
- Evaluate patient for communication defects (e.g., aphasia)

Occupational Therapy
- Evaluate ability to perform self-care
- Teach to perform activities of daily living and adapting tasks

Physical Therapy
- Recommend functional position
- Assess function and, together with patient, plan a rehabilitation program

may be used to assess the effectiveness of treatment and to evaluate recovery.

CT angiography (CTA) provides visualization of cerebral blood vessels. It can be done after or at the same time as the noncontrast CT scan. CTA can give an estimate of perfusion and detect filling defects in the cerebral arteries. Magnetic resonance angiography (MRA) can detect vascular lesions and blockages, similar to CTA. CT/MRI perfusion and diffusion imaging may be done.

If the suspected cause of the stroke includes emboli from the heart, diagnostic cardiac tests should be done. Cardiac imaging is recommended because many strokes are caused by blood clots from the heart. Blood tests can help identify conditions contributing to stroke and guide treatment (Table 62.6).

Angiography can identify cervical and cerebrovascular occlusion, atherosclerotic plaques, and malformation of vessels. Cerebral angiography can find the source of SAH. Risks of angiography include dislodging an embolus, causing vasospasm, inducing further hemorrhage, and provoking an allergic reaction to contrast media.

Intraarterial digital subtraction angiography (DSA) involves injecting a contrast agent to visualize blood vessels in the neck and the large vessels of the circle of Willis. It reduces the dose of contrast material, uses smaller catheters, and shortens the length of the procedure compared with conventional angiography. It is considered safer than cerebral angiography because there is less vascular manipulation.

Transcranial doppler (TCD) ultrasonography is a noninvasive study that measures the velocity of blood flow in the major cerebral arteries. TCD is effective in detecting microemboli and vasospasm. It is ideal for the patient suspected of having an SAH. Carotid duplex scanning is used to detect the cause of the stroke and stratify patients for either medical management or carotid intervention if they have carotid stenosis.

An LP can determine if red blood cells are present in the CSF if we suspect SAH and the CT does not show hemorrhage. An LP is avoided if the patient is suspected of having an obstruction in the foramen magnum or other signs of increased ICP because of the danger of herniation of the brain downward. This could lead to pressure on cardiac and respiratory centers in the brainstem and potentially death.

BOX 62.2 PROMOTING POPULATION HEALTH

Stroke Prevention

- Reduce salt and sodium intake.
- Maintain a normal body weight.
- Follow a diet low in saturated fat and high in fruits and vegetables.
- Limit alcohol use to moderate levels.
- Maintain a systolic BP less than 140 mm Hg.
- Avoid cigarette smoking and tobacco products.
- Maintain a normal blood glucose level and control diabetes.
- Follow the prescribed treatment plan for diagnosed heart problems.
- Moderate exercise for 150 min/week or vigorous exercise for 75 min/week.

The LICOX system may be used as a diagnostic tool to evaluate the progression of stroke. LICOX measures brain oxygenation and temperature.

INTERPROFESSIONAL CARE

Preventive Therapy

Primary prevention is a priority for decreasing morbidity and mortality from stroke. The goals of stroke prevention include adopting a healthy lifestyle and managing modifiable risk factors (Box 62.2). Health promotion focuses on (1) healthy diet, (2) weight control, (3) regular exercise, (4) no smoking, (5) limiting alcohol use, and (6) BP management. Patients with known risk factors (e.g., diabetes, hypertension, obesity, high serum lipids, cardiac disease) need close management.

Preventive Drug Therapy

We use measures to prevent the development of a thrombus or embolus in patients with TIAs since they are at high risk for stroke. Antiplatelet drugs are a first-line treatment to prevent stroke in patients who had a TIA. Aspirin, at a dose of 81 mg/day, is the most often used antiplatelet agent. Other agents include ticlopidine, clopidogrel (Plavix), dipyridamole (Persantine), and combined dipyridamole and aspirin (Aggrenox).

DRUG ALERT

Ticlopidine and Clopidogrel (Plavix)

- Inform all HCPs and dentists that the drug is being taken before scheduling surgery or major dental procedures.
- Therapy may be stopped 10–14 days before surgery if the antiplatelet effect is not desired.

For patients with atrial fibrillation, oral anticoagulation can include warfarin (Coumadin) and the direct factor Xa inhibitors: rivaroxaban (Xarelto), dabigatran (Pradaxa), and apixaban (Eliquis). The primary advantage of direct factor Xa inhibitors compared to warfarin is that they do not need close monitoring or dosage adjustments. Statins (e.g., simvastatin, lovastatin) are effective in stroke prevention for those with high cholesterol levels who had a TIA.

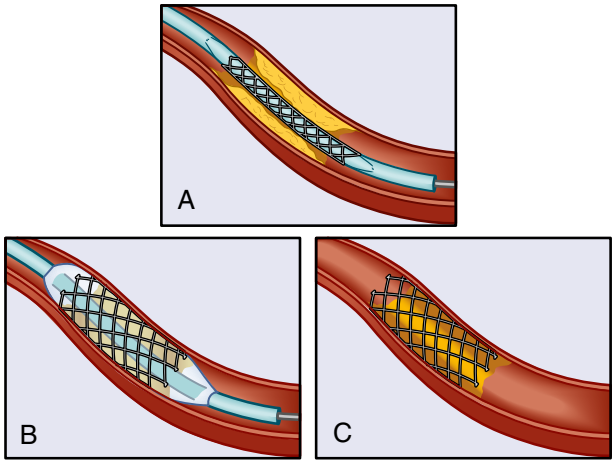

Fig. 62.5 Brain stent used to treat blockages in cerebral blood flow. (A) A balloon catheter is used to implant the stent into an artery of the brain. (B) The balloon catheter is moved to the blocked area of the artery and then inflated. The stent expands due to inflation of the balloon. (C) The balloon is deflated and withdrawn, leaving the stent permanently in place, holding the artery open, and improving the flow of blood.

Left Atrial Appendage Occlusion

The left atrial appendage (LAA) is a pouch that extends off the left atrium. We think the LAA is the source of many stroke-causing emboli in patients with atrial fibrillation. Removing or occluding the LAA decreases the risk of strokes. LAA occlusion can help prevent blood clot formation in patients with atrial fibrillation. It is an alternative for patients who cannot use oral anticoagulants, such as warfarin. After LAA occlusion, patients may be able to stop taking anticoagulants.

A special stapler can be used to remove the LAA. Or, the HCP can place sutures that manually occlude the LAA. There are also special LAA occlusion devices (e.g., AtriClip, Watchman). These devices are positioned around the LAA and then closed, like a clamp, shutting off the blood supply. This prevents blood from flowing into and out of the LAA.

Patent Foramen Ovale

Patients with a patent foramen ovale have a hole between the left and right atriums. Blood clots can pass through this opening and go to the brain, leading to ischemia. An occlusion device implanted in the opening can prevent clot dislodgment.[11]

Surgical/Endovascular Therapy for TIA and Stroke Prevention

Surgical interventions for patients with TIAs due to carotid disease include carotid endarterectomy (CEA), transluminal angioplasty, and stenting. In a *carotid endarterectomy*, the atheromatous lesion is removed from the carotid artery to improve blood flow.

Transluminal angioplasty involves inserting a balloon to open a stenosed artery in the brain and improve blood flow. The balloon is threaded up to the carotid artery through a catheter inserted in the femoral artery.

Stenting involves the intravascular placement of a stent to try to maintain patency of the artery (Fig. 62.5). The stent can be inserted during an angioplasty. Once in place, the system can be used with a tiny filter that opens like an umbrella. The

TABLE 62.8 60 Minute Door-to-Needle Time Interval Goals

Action Time	
Door to physician	≤10 min

filter catches and removes the debris that is stirred up during the stenting procedure before it floats to the brain, where it can trigger a stroke. Stenting is a less invasive strategy for revascularization in patients unable to withstand the CEA because of coexisting medical conditions.

Care after stenting or angioplasty includes neurovascular assessment and BP management. Monitor vital signs. Assess for complications, including stent occlusion and bleeding. Minimize the risk for bleeding at the insertion site by keeping the patient's leg straight for the prescribed time.

Acute Care for Ischemic Stroke

During initial evaluation, the single most important point in the patient's history is the time of onset of symptoms. Care goals during the acute phase are preserving life, preventing further brain damage, and reducing disability (Table 62.7).

For emergency care, patients should be transported to the closest certified stroke center. If one is not available, the patient should be sent to the closest place offering emergency stroke care.[12] Some communities have a mobile stroke unit that offers onsite emergency CT and point of care testing.[13] Meeting the AHA's Door-to-Needle or Door-to-Device time initiative promotes better patient outcomes (Table 62.8). [14] The stroke (STK) core measures (Table 62.9) are proven standards of care that reduce complications, also leading to better outcomes (Table 62.9).

Table 62.10 outlines the emergency management of the patient with a stroke. In the unresponsive person, acute care begins with assessing circulation, airway, and breathing. Patients may have difficulty keeping an open and clear airway because of a decreased LOC or decreased or absent gag and swallowing reflexes. Maintaining adequate oxygenation is important. O_2 administration, artificial airway insertion, intubation, and mechanical ventilation may be needed. Perform a baseline neurologic assessment. Monitor closely for signs of increasing neurologic deficit. Many patients worsen in the first 24 to 48 hours.

Elevated BP is common right after a stroke. It may be a protective response to maintain cerebral perfusion. However, it can be detrimental. In patients with an ischemic stroke who do not receive fibrinolytic therapy, the use of drugs to lower BP is recommended only if BP is markedly increased (SBP greater than 220 mm Hg or DBP greater than 120 mm Hg). In a patient who is going to have fibrinolytic therapy, the BP must be less than 185/110 mm Hg and then maintained at or below 180/105 mm Hg for at least 24 hours after fibrinolytic therapy. In an acute stroke, IV antihypertensives, such as labetalol and nicardipine, are preferred. Although low BP right after a stroke is uncommon, we correct hypotension and hypovolemia if present.

Fluid and electrolyte balance must be controlled carefully. The goal is to keep the patient adequately hydrated to promote perfusion and decrease further brain injury. Overhydration may compromise perfusion by increasing ICP and cerebral edema. Adequate fluid intake during acute care is a priority. Monitor urine output to make sure the patient does not become dehydrated.

If secretion of antidiuretic hormone (ADH) increases in response to the stroke, urine output decreases, and fluid is retained. Low serum sodium (hyponatremia) may occur. IV solutions with glucose and water are avoided because they are hypotonic and may further increase cerebral edema and ICP. Glycemic control should be maintained. In general, decisions about fluid and electrolyte replacement therapy are based on the extent of intracranial edema, manifestations of increased ICP, central venous pressure levels, electrolyte levels, and intake and output.

Increased ICP is more likely to occur with hemorrhagic strokes but can occur with ischemic strokes. Increased ICP from cerebral edema usually peaks in 72 hours and may cause brain herniation. Management of increased ICP includes practices that improve venous drainage. These include elevating the head of the bed, keeping the head and neck in alignment, and avoiding hip flexion. Other measures for reducing ICP include managing fever (goal temperature of 96.8°F to 98.6°F [36°C to 37°C]), drug therapy to prevent seizures, pain management, and preventing constipation. CSF drainage may be used in some patients to reduce ICP. The specific management of increased ICP is discussed in Chapter 61.

Drug Therapy for Ischemic Stroke

Fibrinolytic therapy should not be delayed. Recombinant tissue plasminogen activator (tPA) is used to produce localized fibrinolysis by binding to the fibrin in the thrombi. The fibrinolytic action of tPA occurs as the plasminogen is converted to plasmin, whose enzymatic action then digests fibrin and fibrinogen, thus breaking down the clot. Other fibrinolytic agents cannot be substituted for tPA. Fibrinolytic therapy is discussed in Chapter 37.

IV tPA can reestablish blood flow through a blocked artery and prevent cell death in patients with the acute onset of ischemic stroke. tPA must be given within 3 to 4½ hours of the onset of signs of ischemic stroke.[15] We must screen patients carefully

TABLE 62.10 EMERGENCY MANAGEMENT

Stroke

Etiology	Assessment Findings	Interventions
• Aneurysm • Arteriovenous malformation • Embolism • Hemorrhage • Sudden vascular compromise causing disruption of blood flow to brain • Thrombosis • Trauma	• Altered level of consciousness • Bladder or bowel incontinence • ↑ BP • Difficulty swallowing • Facial drooping on affected side • Heart rate ↑ or ↓ • Numbness, weakness, or paralysis of part of body • Respiratory distress • Seizures • Severe headache • Speech or visual changes • Unequal pupils • Vertigo	**Initial** • If unresponsive, assess circulation, airway, and breathing. • If responsive, monitor airway, breathing, and circulation. • Call stroke code or stroke team. • Remove dentures. • Perform pulse oximetry. • Maintain adequate oxygenation (SaO_2 >95%) with supplemental O_2, if needed. • Establish IV access with normal saline. • Maintain BP according to guidelines. • Remove clothing. • Obtain CT scan or MRI. • Perform baseline laboratory tests (including blood glucose) immediately and treat if hypoglycemic. • Position head in midline. • Elevate head of bed 30 degrees if no symptoms of shock or injury. • Institute seizure precautions. • Anticipate thrombolytic therapy for ischemic stroke. • Keep patient NPO until swallow reflex evaluated. **Ongoing Monitoring** • Monitor vital signs and neurologic status, including level of consciousness (NIH Stroke Scale), motor and sensory function, pupil size and reactivity, SaO_2, and cardiac rhythm. • Reassure patient and family.

before they receive tPA. Screening includes a noncontrast CT scan or MRI to rule out hemorrhagic stroke; blood tests for coagulation disorders; screening for recent history of gastrointestinal (GI) bleeding, stroke, or head trauma within the past 3 months; major surgery within 14 days; or recent active internal bleeding within 22 days.[15]

During tPA infusion, closely monitor the patient's vital signs and neurologic status to assess for improvement or for potential deterioration related to intracerebral hemorrhage. Control of BP (SBP less than 185 mm Hg) is critical during treatment and for 24 hours following.

Patients with an ischemic stroke may receive an intraarterial tPA infusion if mechanical thrombectomy is not an option. To be effective, intraarterial tPA must be given within 6 hours of the onset of stroke symptoms. With intraarterial tPA, the HCP inserts a thin, flexible catheter into an artery (usually the femoral artery) and guides the catheter (using angiogram) to the area of the clot. The tPA is given through the catheter and immediately targets the clot. Less tPA is needed when it is delivered directly to the clot, reducing the risk for intracranial hemorrhage.

Anticoagulant (e.g., heparin) use in the emergency phase after an ischemic stroke is not recommended because of the risk for intracranial hemorrhage. Aspirin at a higher dose may be started within 24 to 48 hours after the onset of an ischemic stroke. Complications of high dose aspirin include GI bleeding. Aspirin should be given cautiously if the patient has a history of peptic ulcer disease.

After the patient has stabilized and to prevent further clot formation, patients with strokes caused by thrombi and emboli may be treated with anticoagulants and platelet inhibitors. For patients with atrial fibrillation, oral anticoagulant options include warfarin and direct factor Xa inhibitors (e.g., rivaroxaban [Xarelto], dabigatran [Pradaxa], apixaban [Eliquis]). Platelet inhibitors include aspirin, ticlopidine, clopidogrel, and dipyridamole. The use of statins is effective for the patient after an ischemic stroke.

Endovascular Therapy for Ischemic Stroke

Stent retrievers are a way of opening blocked arteries in the brain by using a removable stent system.[16] During the procedure, a catheter is used to guide the small stent from the femoral or radial artery into the part of the artery where a blood clot has formed. The stent expands the interior walls of the artery and allows blood to get to the patient's brain immediately to prevent as much brain damage as possible. The clot seeps into the mesh of the stent. Then, after a few minutes, the stent and clot are removed together. Stent retrievers are becoming the most effective way of managing ischemic stroke.[16]

Acute Care for Hemorrhagic Stroke

Drug Therapy for Hemorrhagic Stroke

Anticoagulants and platelet inhibitors are contraindicated in patients with hemorrhagic strokes. Drug therapy for patients with hemorrhagic stroke involves managing hypertension. Oral and IV agents may be used to maintain BP within a normal to high-normal range (SBP less than 160 mm Hg). Seizure prophylaxis is patient-specific.[17]

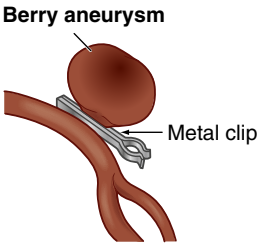

Fig. 62.6 Clipping of aneurysms.

Surgical Therapy for Hemorrhagic Stroke

Surgical interventions for hemorrhagic stroke include immediate evacuation of aneurysm-induced hematomas or cerebellar hematomas larger than 3 cm. Those who have an arteriovenous malformation (AVM) may have a hemorrhagic stroke if the AVM ruptures. The treatment of AVM is surgical resection and/or radiosurgery. Catheter embolization of affected vessels can block the blood supply to the AVM.

SAH is usually caused by a ruptured aneurysm. Patients may have multiple aneurysms. Treatment of an aneurysm often involves clipping or coiling the aneurysm to prevent rebleeding (Figs. 62.6 and 62.7). In clipping the aneurysm, the HCP places a metallic clip on the neck of the aneurysm to block blood flow and prevent rupture. The clip stays in place for life.

Interventional radiology procedures include coiling and flow diversion. With coiling, a hydrogel-coated platinum coil is inserted into the lumen of the aneurysm (Fig. 62.7). Guglielmi detachable coils (GDCs) give immediate protection against hemorrhage by reducing the blood pulsations within the aneurysm. Eventually, a thrombus forms within the aneurysm. Then the aneurysm becomes sealed off from the parent vessel by the formation of an endothelialized layer of connective tissue. Flow diverters placed in the parent blood vessel divert blood flow away from an aneurysm.

After clipping or coiling, hyperdynamic therapy (hemodilution-induced hypertension using vasoconstricting agents, such as phenylephrine or dopamine, and hypervolemia) may be started to increase the mean arterial pressure and cerebral perfusion. Volume expansion is achieved with crystalloid or colloid solutions.

With SAH, bleeding from a damaged vessel causes blood to accumulate between the brain and skull. The leaked blood can irritate, damage, or destroy the surrounding brain cells. When blood enters the subarachnoid space, it mixes with the CSF. This can block CSF circulation, thus increasing pressure on the brain. The open spaces in the brain (ventricles) may enlarge, causing hydrocephalus. This further increases ICP (due to the large accumulation of blood) and can result in further brain injury. Inserting a ventriculostomy for CSF drainage can dramatically improve these situations by reducing ICP.[18] Goals for managing ICP are the same for patients with SAH as they are for patients dealing with acute stroke. The management of ICP is discussed in Chapter 61.

Patients with SAH may receive the calcium channel blocker nimodipine to treat cerebral vasospasms and minimize cerebral damage. We think it dilates narrowed blood vessels around the area of the bleeding, so blood flows more easily. This minimizes cerebral damage

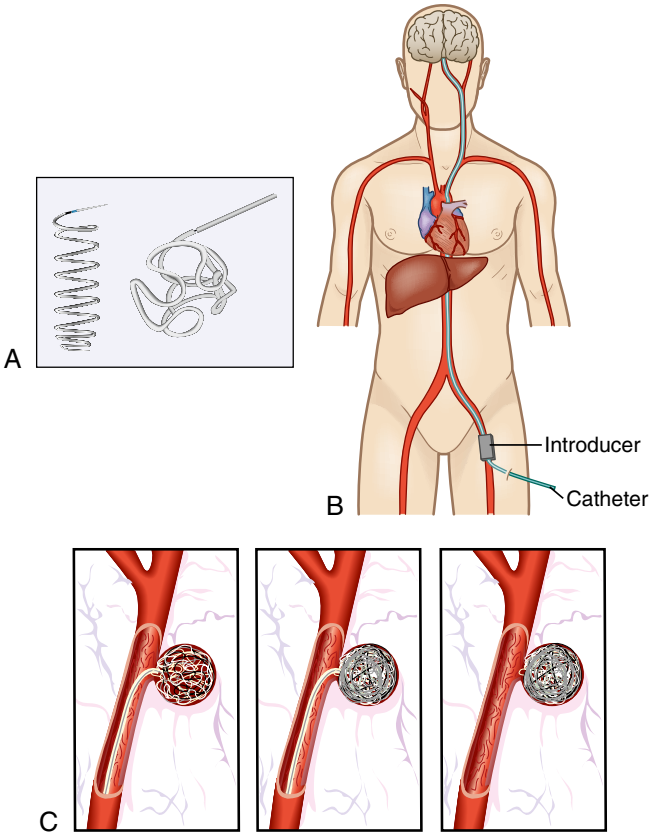

Fig. 62.7 Guglielmi detachable coil (GDC). (A) A coil is used to occlude an aneurysm. Coils are made of soft, spring-like platinum. The softness of the platinum allows the coil to assume the shape of irregularly shaped aneurysms while posing little threat of rupture of the aneurysm. (B) A catheter is inserted through an introducer (small tube) in an artery in the leg. The catheter is threaded up to the cerebral blood vessels. (C) Platinum coils attached to a thin wire are inserted into the catheter and then placed in the aneurysm until the aneurysm is filled with coils. Packing the aneurysm with coils prevents the blood from circulating through the aneurysm, reducing the risk for rupture.

DRUG ALERT

Nimodipine

- Assess BP and apical pulses before administration.
- If pulse is ≤60 beats/min or systolic BP is <90 mm Hg, hold the medication and contact the HCP.

Rehabilitation Care

After the stroke patient has stabilized for 12 to 24 hours, care goals shift from preserving life to lessening disability and reaching optimal function. Many of the interventions started in the acute phase are continued during this phase. The patient may be evaluated by a physiatrist (a physician who specializes in physical medicine and rehabilitation). Some aspects of rehabilitation begin in the acute care phase as soon as the patient is stable. Specific rehabilitation measures are discussed in the section on Ambulatory Care.

❖ NURSING MANAGEMENT: STROKE

◆ Assessment

Subjective and objective data that you should obtain from a person who has had a stroke are detailed in Table 62.11. The primary assessment focuses on cardiac and respiratory status and neurologic assessment. If the patient is stable, obtain a history as follows: (1) description of the current illness with attention to initial symptoms, especially symptom onset and duration, nature (intermittent or continuous), and changes; (2) history of having had similar symptoms previously; (3) current medications; (4) history of risk factors and other illnesses, such as hypertension; and (5) family history of stroke, aneurysm, or cardiovascular diseases. Obtain this information through interviewing the patient and caregivers.

Secondary assessment includes a comprehensive neurologic assessment. The primary assessment tool to evaluate and document neurologic status in acute stroke patients is the NIHSS, which measures stroke severity (Table 62.12).[19] The NIHSS is a predictor of both short- and long-term outcomes of stroke patients. It also serves as a data collection tool for planning patient care and exchanging information among HCPs. Other assessment data includes (1) LOC; (2) cognition; (3) motor abilities; (4) cranial nerve function; (5) sensation; (6) proprioception; (7) cerebellar function; and (8) deep tendon reflexes. Clear documentation of initial and ongoing neurologic assessment is essential to note changes in the patient's status.

◆ Clinical Problems

Clinical problems for the person with a stroke may include:

- Neurologic problems
- Increased intracranial pressure
- Impaired communication
- Difficulty coping
- Risk for aspiration
- Musculoskeletal problems
- Risk for injury

More information on clinical problems and interventions are presented in eNursing Care Plan 62.1 (available on the website for this chapter).

◆ Planning

Establish the goals of nursing care together with the patient, caregiver, and family. Typical goals are that the patient will (1) maintain a stable or improved LOC, (2) attain maximum physical functioning, (3) attain maximum self-care abilities and skills, (4) maintain stable body functions (e.g., bladder control), (5) maximize communication abilities, (6) maintain adequate nutrition, (7) avoid complications, and (8) maintain effective personal and family coping.

◆ Implementation

◆ Health Promotion

You have a key role in promoting a healthy lifestyle. Teaching should focus on stroke prevention, especially for persons with known risk factors. Most strokes are caused by modifiable risk factors. Measures to reduce risk factors for stroke are similar to those for coronary artery disease (see Chapter 37).

Uncontrolled or undiagnosed hypertension is the primary cause of stroke. Therefore, you need to be involved in BP screening and ensuring that patients adhere to their antihypertensive

TABLE 62.11 NURSING ASSESSMENT

Stroke

Subjective Data

Important Health Information

Health history: Hypertension, previous stroke, TIA, aneurysm, cardiac disease (including recent myocardial infarction, dysrhythmias, heart failure, valvular heart disease, infective endocarditis), hyperlipidemia, polycythemia, blood clotting disorders, diabetes, gout

Family history: Neurologic disorders, aneurysms, stroke, TIA, diabetes, hypertension, coronary artery disease

Medications: Oral contraceptives; use of and adherence with antihypertensive and anticoagulant therapy; illicit substance use

Functional Health Patterns

Health perception–health management: Alcohol use, smoking, drug use

Nutritional-metabolic: Anorexia, nausea, vomiting. Dysphagia, altered sense of taste and smell

Elimination: Change in bowel and bladder patterns

Activity-exercise: Loss of movement and sensation. Syncope, weakness on one side, generalized weakness, easy fatigability

Cognitive-perceptual: Numbness, tingling of one side of the body, loss of memory. Change in speech, language, problem-solving ability. Pain, headache (possibly sudden and severe) (hemorrhage). Visual changes. Denial of illness

Objective Data

Cardiovascular

↑ BP, ↑ HR, carotid bruit

General

Emotional lability, lethargy, apathy or combativeness, fever

Gastrointestinal

Loss of gag reflex, bowel incontinence, decreased or absent bowel sounds, constipation

Neurologic

Contralateral motor and sensory deficits, including weakness, paresis, paralysis, anesthesia. Unequal pupils, hand grasps. Akinesia, aphasia (expressive, receptive, global), dysarthria (slurred speech), agnosia, apraxia, visual deficits, perceptual or spatial problems, altered level of consciousness (drowsiness to deep coma), and Babinski sign, ↓ followed by ↑ deep tendon reflexes, flaccidity followed by spasticity, amnesia, ataxia, personality change, nuchal rigidity, seizures

Respiratory

Loss of cough reflex, labored or irregular respirations, tachypnea, wheezes (aspiration), airway occlusion (tongue), apnea, coughing when eating, or delayed coughing

Urinary

Frequency, urgency, incontinence

Possible Diagnostic Findings

Positive CT, CT angiography, MRI, magnetic resonance angiography, or other neuroimaging scans showing size, location, and type of lesion. Positive Doppler ultrasonography and angiography showing stenosis

TABLE 62.12 National Institutes of Health Stroke Scale

Description

The NIH Stroke Scale (NIHSS) is a 15-item neurologic examination used to evaluate the effect of an acute stroke. Total scores on the NIHSS range from 0 to 42, with higher values reflecting more severity.

Procedure for Use

A trained observer rates the patient's ability to answer questions and perform activities. Ratings for each item are scored, and there is an allowance for untestable (UN) items. If an item is left untested, a detailed explanation must be clearly written on the form. Training can be completed free at www.nihstrokescale.org.

Item	Scale Definition
Level of consciousness	0 = Alert 1 = Not alert, but arousable by minor stimulation 2 = Not alert, requires repeated stimulation to get attention 3 = Responds only with reflex motor or autonomic effects or unresponsive, flaccid, areflexic
Level of consciousness questions	0 = Answers both questions correctly 1 = Answers 1 question correctly 2 = Answers neither question correctly
Level of consciousness commands	0 = Performs both tasks correctly 1 = Performs 1 task correctly 2 = Performs neither task correctly
Best gaze	0 = Normal 1 = Partial gaze palsy 2 = Forced deviation, or total gaze paresis
Visual	0 = No visual loss 1 = Partial hemianopsia 2 = Complete hemianopsia 3 = Bilateral hemianopsia or blind
Facial palsy	0 = Normal symmetric movement 1 = Minor paralysis 2 = Partial paralysis 3 = Complete paralysis of 1 or both sides
Motor and drift (for each extremity)	0 = No drift 1 = Drift 2 = Some effort against gravity 3 = No effort against gravity, limb falls 4 = No movement UN = Amputation
Limb ataxia	0 = Absent 1 = Present in 1 limb 2 = Present in 2 limbs
Sensory	0 = Normal 1 = Mild to moderate sensory loss 2 = Severe to total sensory loss
Best language	0 = No aphasia, normal 1 = Mild to moderate aphasia 2 = Severe aphasia 3 = Mute, no usable speech or auditory comprehension
Dysarthria	0 = Normal 1 = Mild to moderate 2 = Severe UN = Intubated or other physical barrier
Extinction or inattention	0 = No abnormality 1 = Inattention or extinction to bilateral stimulation 2 = Does not recognize own hand
Distal motor function	0 = Normal (no flexion after 5 sec) 1 = At least some extension but not fully extended 2 = No voluntary extension after 5 sec

Source: National Institutes of Health: NIH Stroke Scale. Retrieved from https://www.stroke.nih.gov/resources/scale.htm.

therapy. If a person has diabetes, it is important that it is well controlled. If a person has atrial fibrillation, anticoagulant therapy may reduce the risk for stroke. Because smoking is a major risk factor for stroke, help patients to stop smoking (see Chapter 11).

Another important aspect of health promotion is teaching patients and families about early symptoms of stroke or TIA. Table 62.1 presents information on when to seek health care for these symptoms.

◆ Acute Care

Respiratory system. During the acute phase after a stroke, management of the respiratory system is a nursing priority. Stroke patients are vulnerable to respiratory problems. Advancing age and immobility increase the risk for atelectasis and pneumonia.

Interventions to support adequate respiratory function are tailored to meet the patient's specific needs (Table 62.13). Some stroke patients, especially those with brainstem or hemorrhagic stroke, may need endotracheal intubation and mechanical ventilation. An oropharyngeal airway in a comatose patient may prevent the tongue from falling back and obstructing the airway and provide access for suctioning. Alternatively, a nasopharyngeal airway may be used to provide airway protection and access. When an artificial airway is needed for a prolonged time, a tracheostomy may be done.

Frequently assess airway patency and function. Provide O_2 therapy as ordered. Suction the patient as needed and encourage deep breathing. In patients who are on mechanical ventilation, oral care at least every 2 hours reduces the risk of ventilator-assisted pneumonia.

Position the patient to prevent aspiration. Risk for aspiration pneumonia is high because of impaired consciousness or dysphagia. Dysphagia after stroke is common. Airway obstruction can occur because of problems with chewing and swallowing, food pocketing (food remaining in the buccal cavity of the

TABLE 62.13 NURSING MANAGEMENT

Caring for the Patient With an Acute Stroke

- Assess manifestations of stroke and determine when they started.
- Screen patient for contraindications for tissue plasminogen activator (tPA) therapy.
- Infuse tPA for patients with ischemic stroke who meet the criteria for tPA administration.
- Assess respiratory status and start needed actions, such as O_2, oropharyngeal or nasopharyngeal airways, suctioning.
- Position patient to prevent aspiration and atelectasis.
- Assess neurologic status, including intracranial pressure (ICP), if needed.
- Monitor cardiovascular status, including hemodynamic monitoring, if needed.
- Calculate intake and output, noting imbalances.
- Regulate IV infusions and adjust fluid intake to patient needs.
- Assess patient's ability to swallow in conjunction with the speech therapist.
- Give scheduled anticoagulant and antiplatelet drugs.
- Implement measures to prevent venous thromboembolism and skin breakdown.
- Delegate to AP:
  - Obtain vital signs and report these to RN.
  - Measure and record urine output.
  - Help with positioning and turning patient at least every 2 h.
  - Perform passive and active range-of-motion exercises.

mouth), and the tongue falling back. Enteral nutrition (EN) places the patient at risk for aspiration pneumonia. Screen all patients for their ability to swallow. Keep them NPO until dysphagia is ruled out.

Patients who have an unclipped or uncoiled aneurysm may have rebleeding and further increased ICP with coughing or suctioning. Care is aimed at reducing these interventions while maintaining a patent airway.

Neurologic system. Perform ongoing neurologic assessments, including the NIHSS, mental status, pupillary response, and extremity movement and strength. A decreasing LOC may indicate increasing ICP. Monitor ICP and cerebral perfusion pressure if the patient is in ICU. Record your assessment promptly to communicate the patient's neurologic status to the stroke team.

Cardiovascular system. Nursing goals for the cardiovascular system are aimed at maintaining homeostasis. Many patients with stroke have decreased cardiac reserves from cardiac disease. Fluid retention, overhydration, dehydration, or BP changes may further compromise cardiac efficiency. Central venous pressure, pulmonary artery pressure, or hemodynamic monitoring may be used to assess fluid balance and cardiac function in the ICU.

Monitor vital signs and maintain ECG monitoring. Hypertension sometimes occurs after a stroke as the body tries to increase CBF. It is important to assess for orthostatic hypotension before ambulating the patient for the first time. Neurologic changes can occur with a sudden decrease in BP.

Calculate intake and output, noting imbalances. Regulate IV infusions and adjust fluid intake to meet the patient's needs. Monitor lung sounds for crackles and wheezes, which may indicate pulmonary congestion.

The patient is at risk for venous thromboembolism (VTE), especially in the weak or paralyzed lower extremity. VTE is related to immobility, loss of venous tone, and decreased muscle pumping activity in the leg. The most effective prevention is to keep the patient moving. Teach the patient active range-of-motion (ROM) exercises if the patient has voluntary movement in the affected extremity. For the patient with hemiplegia, perform passive ROM exercises several times a day. Other measures to prevent VTE include positioning to minimize the effects of dependent edema and using intermittent pneumatic compression devices. VTE prophylaxis may include low-molecular-weight heparin (e.g., enoxaparin [Lovenox]). Your assessment includes observing for swelling of the lower extremities, noting unusual warmth of the leg, and asking the patient about pain in the calf.

Musculoskeletal system. The nursing goal for the musculoskeletal system is to maintain optimal function by preventing joint contractures and muscular atrophy. In the acute phase, ROM exercises and positioning are important nursing interventions. Passive ROM exercise is begun on the first day of hospitalization. Muscle atrophy from lack of innervation and activity can develop after a stroke, so exercise is an important intervention for rehabilitation and recovery.

The paralyzed or weak side needs special attention when the patient is positioned. Position each joint higher than the joint proximal to it to prevent dependent edema. Specific deformities on the weak or paralyzed side that may be present include internal rotation of the shoulder; flexion contractures of the hand, wrist, and elbow; external rotation of the hip; and plantar flexion of the foot. Subluxation of the shoulder on the affected side is common. Careful positioning and moving of the affected arm may prevent the development of a painful shoulder condition. Immobilization of the affected upper extremity may precipitate a painful shoulder-hand syndrome.

Interventions to promote musculoskeletal function include (1) trochanter roll at the hip to prevent external rotation; (2) hand cones (not rolled washcloths) to prevent hand contractures; (3) arm supports with slings and lap boards to prevent shoulder displacement; and (4) avoidance of pulling the patient by the arm to avoid shoulder displacement; and (5) posterior leg splints or high-top tennis shoes to prevent footdrop.

Using a footboard for patients with spasticity is controversial. Rather than preventing plantar flexion (footdrop), the sensory stimulation of a footboard against the bottom of the foot increases plantar flexion. Likewise, experts disagree on whether hand splints decrease spasticity. The decision about using footboards or hand splints is made on an individual patient basis.

Integumentary system. The skin of the patient with stroke is susceptible to breakdown related to loss of sensation, decreased circulation, and immobility. Advanced age, poor nutrition, dehydration, edema, and incontinence compound the risk.

Measures to prevent skin breakdown include (1) pressure relief by position changes, special mattresses, or wheelchair cushions; (2) good skin hygiene; (3) emollients applied to dry skin; and (4) early mobility. An example of a position change schedule is side-back-side, with a maximum duration of 2 hours for any position. Position the patient on the weak or paralyzed

side for only 30 minutes. Controlling pressure is key in both preventing and treating skin breakdown. Use pillows under lower extremities to reduce pressure on the heels. See more information on preventing pressure injuries in Chapter 12.

Gastrointestinal system. The most common bowel problem after stroke is constipation. Fluid and fiber intake goals are determined with the stroke team based on the patient's nutrition and fluid status. Patients may be prophylactically placed on stool softeners and/or fiber (psyllium [Metamucil]). Laxatives, suppositories, or additional stool softeners may be ordered if the patient does not respond to increased fluid and fiber. Enemas are used only if suppositories and digital stimulation are ineffective because they cause vagal stimulation and increase ICP. Physical activity promotes bowel function. If a patient has liquid stools, check for stool impaction.

Bowel retraining may be needed and continued into the rehabilitation phase. A bowel management program consists of placing the patient on the bedpan or bedside commode or taking the patient to the bathroom at a regular time daily to reestablish bowel regularity. A good time for a bowel movement is 30 minutes after breakfast because eating stimulates the gastrocolic reflex and peristalsis. The timing may need adjusted as bowel habits vary.

Urinary system. In the acute stage of stroke, the primary urinary problem is poor bladder control, resulting in incontinence. Take steps to promote normal bladder function and avoid the use of indwelling catheters. If an indwelling catheter is used initially, remove it as soon as the patient is medically and neurologically stable. Long-term use of an indwelling catheter is associated with urinary tract infections and delayed bladder retraining.

Avoid bladder overdistention. An intermittent catheterization program may be used for patients with urinary retention to lower the risk of urinary infections. An alternative to intermittent catheterizations for a male patient is an external catheter. External catheters do not address problems with urine retention.

Often the patient has functional incontinence, which is associated with communication, mobility, and dressing problems. A bladder retraining program consists of (1) adequate fluid intake, with most of it given between 7:00 AM and 7:00 PM; (2) scheduled toileting every 2 hours using bedpan, commode, or bathroom while encouraging the usual position for urinating (standing for men, sitting for women); (3) observing for signs of restlessness, which may indicate the need for urination; and (4) assessing for bladder distention by palpation. Encourage patients to wear pants without drawstrings, buttons, or zippers. These can be hard to manage if motor or sensory deficits exist.

Assessing postvoid residual volume is often done using bladder ultrasound. The ultrasound measures how much urine is in the bladder after voiding. If urine stays in the bladder, incomplete emptying is a problem and may cause urinary tract infections. A coordinated program by the entire nursing staff is needed to achieve urinary continence.

Nutrition. The patient's nutrition needs require quick assessment and treatment. The patient may initially receive IV infusions to maintain fluid and electrolyte balance. Patients with severe impairment may need EN or parenteral nutrition. Patients should have their nutrition needs addressed in the first 24 hours of admission because nutrition is important for recovery and healing.[20]

Many patients have dysphagia after a stroke. Keep patients NPO until a speech therapist performs a swallowing evaluation. This should be done in the first 24 hours after the stroke.[20] You or another health care team member may perform the screen if a speech therapist cannot perform the formal evaluation.

Before starting feeding, assess the gag reflex. If the gag reflex is absent, defer the feeding and begin exercises to stimulate swallowing. The speech therapist or occupational therapist is usually responsible for designing this program. However, you may be involved in helping to develop the program in some clinical settings.

! SAFETY ALERT

Oral Feeding After Stroke

- Dysphagia is common after stroke.
- Keep the patient on NPO status until a speech therapist does a swallowing evaluation.

To assess swallowing ability, elevate the head of the bed to an upright position (unless contraindicated). Give the patient a small amount of crushed ice or ice water to swallow. If the gag reflex is present and the patient can swallow safely, you may proceed with feeding.

The speech therapist may recommend various foods. Foods should be easy to swallow and provide enough texture, temperature (warm or cold), and flavor to stimulate a swallow reflex. Crushed ice can be used as a stimulant. Pureed foods are not usually the best choice because they are often bland or too smooth. Thin liquids are often hard to swallow and may promote coughing. We can thicken thin liquids with a commercially available thickening agent. Avoid milk products because they tend to increase the viscosity of mucus and increase salivation.

Mouth care before feeding helps stimulate sensory awareness and salivation and can help swallowing. Keep the patient in the high-Fowler's position, preferably in a chair, for the feeding and 30 minutes afterward. While feeding, keep the head flexed forward. Place food in the unaffected side of the mouth. Teach the patient to swallow and then swallow again. Follow feedings with good oral hygiene because food may collect in the affected side of the mouth.

A dietitian can help determine the daily caloric intake based on the patient's size, weight, and activity level. If the patient is unable to take in an adequate oral diet and dysphagia persists, a percutaneous endoscopic gastrostomy (PEG) tube may be used for EN (Box 62.3). EN is described in Chapter 44.

The inability to feed one's self can be frustrating and may result in malnutrition and dehydration. Interventions to promote self-feeding include using the unaffected upper extremity to eat; employing assistive devices, such as rocker knives, plate guards, and nonslip pads for dishes; and removing unnecessary items from the tray or table, which can reduce spills. Provide a

BOX 62.3 EVIDENCE-BASED PRACTICE

Enteral Nutrition and Stroke Rehabilitation

In your role as a clinical nurse on a stroke rehabilitation unit, you often care for patients who need enteral nutrition (EN) to meet their nutrient needs. In caring for 87-year-old E.R., a female who had a stroke, you realize you often interrupt scheduled feedings to accommodate physical therapy or off-unit testing.

Making Clinical Decisions

Synthesis of Best Available Evidence

EN is critical for patients with impaired swallowing. Without EN, the patient, after a stroke, is at risk of decline. Because of interruptions, however, most patients receive only about 60% of their nutrient requirements through EN.

Clinician Expertise

As a member of the EBP Committee, you identify interrupted enteral feedings as a clinical problem. You express concern at the committee meeting that patients may not be meeting their nutrient needs based on current EN ordering practices. You suggest that this could affect their length of stay and potential for achieving optimal health. Committee members agree. After reviewing the literature, the group decides to recommend volume-based tube feeding (VBTF) as a way to adjust feedings throughout the day to meet each patient's nutrition goals. Committee members note VBTF has been mainly used in acute care settings but suggest this is an opportunity to optimize nutrition support for patients after stroke.

Patient Preferences and Values

You reconnect E.R.'s enteral feeding after her return from physical therapy. She says, "I thought I was finished with that. It seems like I'm always connected to some tube, yet I never have any energy."

Implications for Nursing Practice

1. How could VTBF better address patients' caloric needs?
2. What outcomes may be affected if patients have adequate caloric intake?

Reference for Evidence

Bonomo A, Blume DL, Davis K, Kim HJ: Implementing volume-based feeding to optimize delivery of enteral nutrition, *Crit Care Nurse* 41:16, 2021.

calm environment (e.g., turn off the television) to decrease sensory overload and distraction. Introduce these interventions in the acute care setting so that maximum rehabilitation can occur once the patient is discharged. We evaluate the effectiveness of the diet program in terms of weight, adequate hydration, and patient satisfaction.

Communication. During the acute stage of stroke, your role in meeting the patient's psychologic needs is primarily supportive. Speech, comprehension, and language deficits are the most difficult problems for the patient and caregiver. Assess the patient for the ability to speak and understand. The patient's response to simple questions can guide you in structuring explanations and instructions. If the patient cannot understand words, use gestures to support verbal cues. Collaborate with the speech therapist to assess and develop a plan of care to enhance communication.

Interventions that support communication include (1) communicating often and meaningfully; (2) allowing time for the patient to comprehend and answer; (3) using simple, short sentences; (4) using visual cues; (5) structuring conversation so that it allows simple answers by the patient; and (6) praising the patient honestly for improvements with speech.

TABLE 62.14 Communicating With a Patient With Aphasia

The following are guidelines for communicating with a patient with aphasia:

1. Decrease environmental stimuli that may be distracting and disrupting to communication efforts.
2. Treat the patient as an adult.
3. Speak with normal volume and tone.
4. Present a single thought or idea at a time.
5. Keep questions simple or ask questions that can be answered with "yes" or "no."
6. Let the person speak. Do not interrupt. Allow time for the person to complete thoughts.
7. Make use of gestures as an alternative form of communication. Encourage this by saying, "Show me . . . ." or "Point to what you want."
8. Do not pretend to understand the person if you do not. Calmly say you do not understand. Encourage the use of nonverbal communication or ask the person to write out what they want.
9. Give the patient time to process information and generate a response before repeating a question or statement.
10. Allow body contact (e.g., clasp of a hand, touching) as much as possible. Realize that touching may be the only way the patient can express feelings.
11. Organize the patient's day by preparing and following a schedule (the more familiar the routine, the easier it will be).
12. Do not push communication if the person is tired or upset. Aphasia worsens with fatigue and anxiety.
13. Teach communication techniques to caregivers and family members.

An alert patient is usually anxious because of what has happened and problems with communication or the inability to communicate. Verbal stimuli can easily overwhelm the patient with aphasia. Give the patient extra time to understand and respond to communication. Guidelines for communicating with a patient who has aphasia are outlined in Table 62.14. A picture board may be helpful for communicating with the stroke patient. The speech therapist often does further evaluation and treatment of language and communication deficits once the patient has stabilized. It is important to teach the caregiver and family these communication strategies.

Sensory-perceptual problems. Patients who had a stroke often have perceptual deficits. Patients with a stroke on the right side of the brain usually have difficulty judging position, distance, and rate of movement. These patients are often impulsive and impatient. They tend to deny problems related to strokes. They may not correlate spatial-perceptual problems with the inability to perform activities, such as guiding a wheelchair through the doorway. They best understand directions given verbally. Break down the task into simple steps for ease of understanding. The patient with a right-brain stroke and left hemiplegia is at higher risk for injury because of mobility problems. Environmental control (e.g., removing clutter, using good lighting) aids in concentration and safer mobility. Provide nonslip socks at all times. One-sided neglect is common for people with right-brain stroke. You may need to help or remind the patient to dress the weak or paralyzed side or shave the forgotten side of the face.

Patients with a left-brain stroke (right hemiplegia) often are slower in organizing and performing tasks. They tend to have impaired spatial discrimination. These patients usually admit to

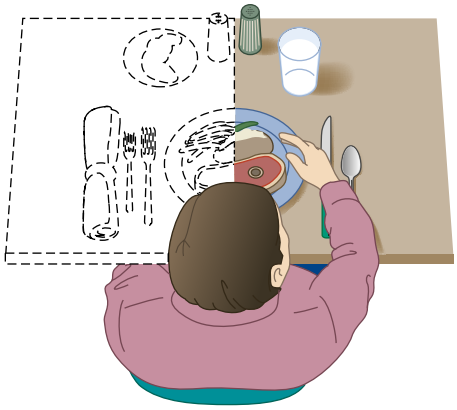

Fig. 62.8 Spatial and perceptual deficits in stroke. Perception of a patient with homonymous hemianopsia shows that food on the left side is not seen and thus is ignored. (Modified from Hoeman SP: *Rehabilitation nursing,* ed 2, St Louis, 1995, Mosby.)

deficits and have a fearful, anxious response to a stroke. Their behaviors are slow and cautious. Nonverbal cues and instructions are helpful for patients who had a left-brain stroke.

Homonymous hemianopsia (blindness in the same half of each visual field) is common after a stroke. Persistent disregard of objects in part of the visual field should alert you to this possibility. At first, help the patient to compensate by arranging the environment within the patient's perceptual field, such as arranging the food tray so that all foods are on one side to accommodate for the field of vision (Fig. 62.8). Later, the patient learns to compensate for the visual defect by consciously attending to or by scanning the neglected side. Weak or paralyzed extremities are carefully checked for adequacy of dressing, hygiene, and trauma.

It is often hard to distinguish between a visual field cut and a neglect syndrome. Both problems may occur with strokes affecting either the right or the left side of the brain. A person may have both homonymous hemianopsia and a neglect syndrome, which increases the inattention to the weak or paralyzed side. Neglect syndrome results in decreased safety awareness and places the patient at high risk for injury. Immediately after the stroke, anticipate safety hazards and provide protection from injury. Safety measures include closely observing the patient, elevating side rails, lowering the height of the bed, and using video monitors. Avoid using restraints and soft vests because these may agitate the patient.

Other visual problems may include *diplopia* (double vision), loss of the corneal reflex, and *ptosis* (drooping eyelid), especially if the stroke is in the vertebrobasilar distribution. Diplopia is often treated with an eye patch. If the corneal reflex is absent, the patient is at risk for corneal abrasion. Prevent corneal abrasions with artificial tears or gel to keep the eyes moist and an eye shield (especially at night). We usually do not treat ptosis unless it inhibits vision.

Coping. A stroke is usually a sudden, very stressful event. Stroke is often a family disease, affecting the family emotionally, socially, and financially and changing roles and responsibilities within the family. The stroke patient and family may perceive the stroke as a threat to life and their accustomed lifestyle. Reactions to this threat vary considerably. They may involve fear, apprehension, denial of the severity of the stroke, depression, anger, and sorrow. During the acute phase of caring for the stroke patient and caregiver, interventions that promote coping involve teaching and providing emotional support.

Give clear, understandable explanations about what has happened and diagnostic and therapeutic procedures. Reinforce as needed. Decision making and upholding the patient's wishes during this challenging time are important. Advance directives should be honored. Update the family daily and hold family meetings about feeding tube placement or tracheostomy.

Give the caregiver and family a careful, detailed explanation of what has happened to the patient. However, if the family is anxious and upset during the acute phase, you may have to repeat explanations later. Because family members usually have not had time to prepare for the illness, they may need help in arranging care for family members or pets and for transportation and finances. A social services referral is often helpful.

It is challenging to keep the patient with aphasia adequately informed. Use demeanor and touch to convey support. When communicating with a patient who has a communication deficit, speak in a normal volume and tone. Keep questions simple. Present one thought or idea at a time. To decrease frustration, let the patient speak without interruption and make use of gestures. Use writing and communication boards.

Ambulatory Care

Care transitions. The patient is usually discharged from the acute care setting to home, an intermediate- or long-term care facility, or a rehabilitation facility. Ideally, discharge planning with the patient and caregiver starts early in the hospitalization and promotes a smooth transition between care settings. The stroke team provides guidance for the appropriate care needed after discharge. Factors that are considered include the patient's medical needs and independence in performing ADLs, caregiver's ability to provide care, and community setting. If the patient needs a short- or long-term health care facility, the team can make appropriate referrals that allow time to select and arrange for care.

If the patient is returning home, the team can make referrals for needed equipment and services. You can prepare the patient and caregiver through teaching. Evaluate the transition plan for any barriers. Follow-up care is carefully planned to allow continued nursing care; physical, occupational, and speech therapy; and medical care. Identify community resources to provide recreational activities, group support, spiritual assistance, respite care, adult day care, and home assistance based on the patient's needs.

Rehabilitation. *Rehabilitation* is the process of maximizing the patient's capabilities and resources to promote optimal functioning related to physical, mental, and social well-being. Many interventions started in the acute phase of care continue throughout rehabilitation. The goals of rehabilitation are to prevent deformity and maintain and improve function. Ongoing rehabilitation is essential to maximize the patient's abilities. Most patients recover in the first 6 months after a stroke, with a maximum benefit 1 year after a stroke.[1]

Rehabilitation requires an interprofessional team approach so that the patient and caregiver can benefit from the team's combined, expert care. The team must communicate and coordinate care to achieve the patient's goals. As a nurse, you can facilitate this process and are often the key to successful rehabilitation efforts. The rehabilitation team is composed of many other members. These include physicians; psychiatrists or psychologists; physical, occupational, speech, vocational, recreational, and respiratory therapists; registered dietitians; social workers; pharmacists; and chaplains.

Physical therapy focuses on mobility, progressive ambulation, transfer techniques, and equipment needed for mobility. Occupational therapy emphasizes retraining for skills of daily living, including eating, dressing, hygiene, and cooking. Occupational therapists are skilled in cognitive and perceptual evaluation and training. Speech therapy focuses on speech, communication, cognition, and eating abilities.

The rehabilitation nurse assesses the patient, caregiver, and family with attention to the patient's (1) rehabilitation potential, (2) physical status, (3) complications caused by the stroke or other chronic conditions, (4) cognitive status, (5) family resources and support, and (6) expectations related to the rehabilitation program.

Musculoskeletal function. The initial assessment consists of determining the stage of recovery of muscle function. If the muscles are still flaccid several weeks after the stroke, the prognosis for regaining function is poor, and care focuses on preventing further loss.

Most patients begin to show signs of spasticity with exaggerated reflexes within 48 hours after the stroke. Spasticity at this phase denotes progress toward recovery. As improvement continues, small voluntary movements of the hip or shoulder may be accompanied by involuntary movements in the rest of the extremity. The last stage of recovery occurs when the patient has voluntary control of isolated muscle groups.

Interventions advance in a manner of progressive activity. Balance training is the first step. It begins with the patient sitting up in bed or dangling the legs over the edge of the bed. Assess tolerance by noting dizziness or syncope caused by vasomotor instability. Loss of postural stability is common after stroke. When the non-dominant hemisphere is involved, walking apraxia and loss of postural control are usually apparent. The patient may be unable to sit upright and tends to fall sideways. Provide support with pillows or cushions.

Assess whether patients autocorrect their posture when sitting on the edge of the bed. If the patient can straighten their posture instead of leaning to the weaker side, the patient may be ready for the next step of transferring from bed to chair. Place the chair beside the bed so that the patient can lead with the stronger arm and leg. The patient sits on the side of the bed, stands, places the strong hand on the far wheelchair arm, and sits down. You may either supervise the transfer or provide minimal aid by guiding the patient's strong hand to the wheelchair arm, standing in front of the patient while blocking the patient's knees with your knees to prevent knee buckling, and guiding the patient into a sitting position.

In some rehabilitation units, the Bobath method is used as an approach to mobility. The Bobath method helps the patient gain control over spasticity by inhibiting abnormal reflex patterns. Therapists and nurses use the Bobath approach to encourage normal muscle tone, normal movement, and bilateral function of the body. An example is to have the patient transfer into the wheelchair using the weak or paralyzed side and the stronger side to facilitate more bilateral functioning.

Another approach is *constraint-induced movement therapy* (CIMT) (Fig. 62.9). CIMT encourages the patient to use the weakened extremity by restricting movement of the normal extremity. This approach can be challenging for patients. It is used only under the supervision of physical or occupational therapy. Movement training, skill acquisition, stretching, and exercise are other therapies used.[21]

Supportive or assistive equipment, such as canes, walkers, and leg braces, may be needed on a short- or long-term basis for mobility. The physical therapist usually selects the right supportive device(s) to meet individual needs and instructs the patient about use. Include physical therapy activities into the patient's daily routine for added practice and repetition of rehabilitation efforts (Fig. 62.10).

Stroke survivorship and coping. The patient may have many losses, including sensory, intellectual, communicative, functional, role behavior, emotional, social, and vocational losses. The patient, caregiver, and family often go through the process of grief and mourning associated with the losses. Some patients develop long-term depression, with symptoms including anxiety, weight loss, fatigue, poor appetite, and sleep problems. The time and energy needed to perform previously simple tasks can result in anger and frustration.

The magnitude of disability and changes in total function can leave patients wondering if they can ever return to their "old self." Loss of independence may be a major concern. The ability to perform ADLs may require many adaptive changes because of physical, emotional, perceptual, and cognitive deficits. There may be limited family members, including adult children, living nearby to provide help. Patients may become fearful and depressed because they think they may have another stroke or die. The fear can become immobilizing and interfere with effective rehabilitation.

The patient, caregiver, and family need help coping with the losses from the stroke. Provide assistance by (1) supporting communication between the patient and family; (2) discussing lifestyle changes resulting from stroke deficits; (3) discussing changing roles and responsibilities within the family; (4) being an active listener to allow the expression of fear, frustration, and anxiety; (5) including the family and patient in short- and long-term goal planning and patient care; (6) supporting family conferences; and (7) identifying support groups and referrals as needed. Stroke support groups in rehabilitation facilities and the community are helpful in terms of mutual sharing, education, coping skills, and understanding.

Changes may occur in the patient-partner relationship. The dependency resulting from a stroke may threaten the relationship. The partner may be older or have chronic health problems that affect their ability to care for the stroke survivor. The patient may not want anyone other than the partner to provide care, thus putting a significant burden on the partner. There may be

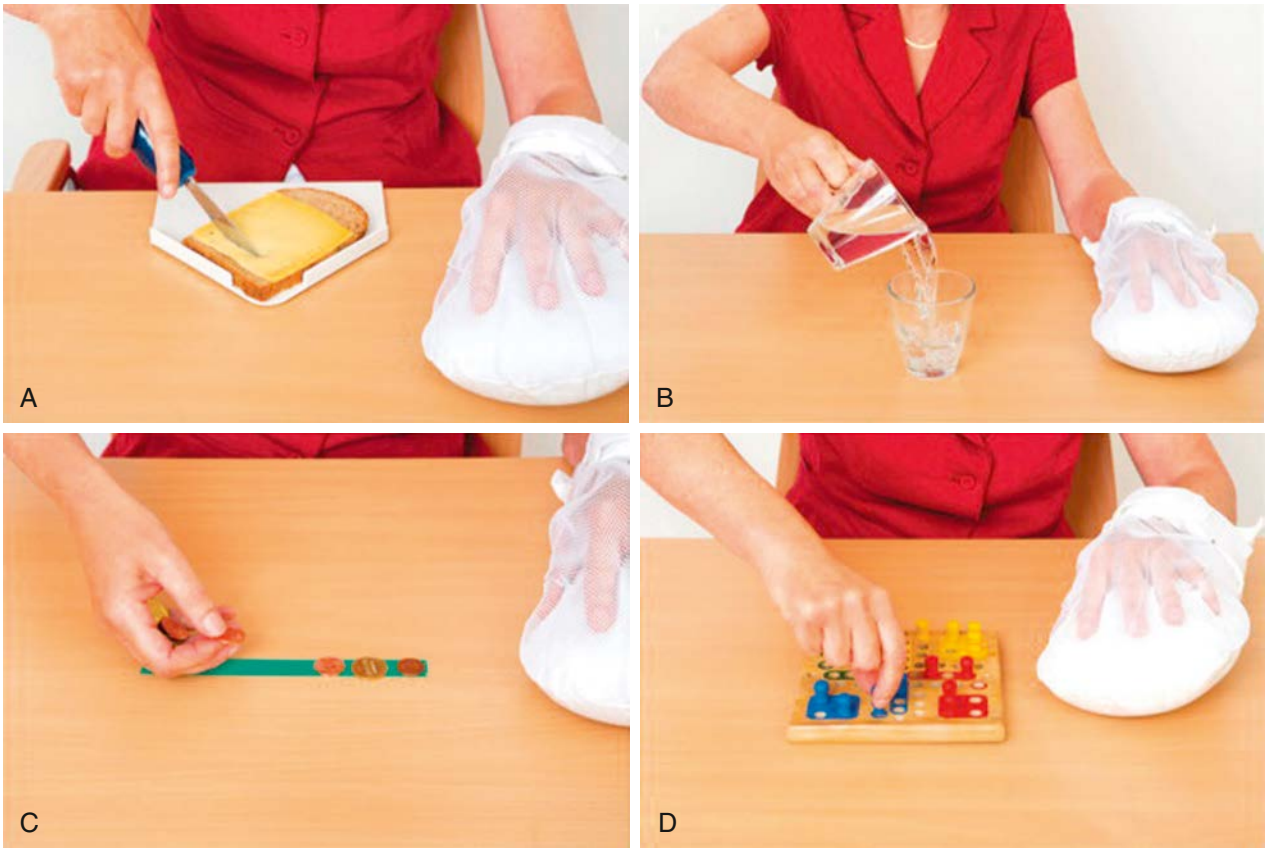

Fig. 62.9 Constraint-induced movement therapy after stroke. (From Kwakkel G, Veerbeek JM, van Wegen EE, et al.: Constraint-induced movement therapy after stroke, *Lancet Neurol* 14:224, 2015. Reprinted with permission from Elsevier.)

Fig. 62.10 A patient who had a stroke works with a physical therapist to improve arm strength. (© Thinkstock 78783452.)

limited family members, including adult children, living nearby to provide help.

Patients who had a stroke often have emotional responses that are not appropriate or typical for the situation. They may appear apathetic, depressed, fearful, anxious, weepy, frustrated, and angry. Some patients, especially those with a stroke on the left side of the brain (right hemiplegia), have exaggerated mood swings. The patient may be unable to control emotions and suddenly burst into tears or laughter. This behavior is out of context and often unrelated to the patient's underlying emotional state. Interventions for atypical emotional response are to (1) distract the patient who suddenly becomes emotional, (2) explain to the patient and family that emotional outbursts may occur after a stroke, (3) maintain a calm environment, and (4) avoid shaming or scolding the patient during emotional outbursts.

Maladjusted dependence with inadequate coping occurs when the patient does not maintain optimal functioning for self-care, family responsibilities, decision making, or socialization. This situation can cause resentment from both the patient and family with a negative cycle of interpersonal dependency and control. Family therapy is often helpful. Caregivers and family members must cope with 3 aspects of the patient's behavior: (1) recognition of behavioral changes resulting from neurologic deficits that are not changeable, (2) responses to multiple losses by both the patient and family, and (3) behaviors that may have been reinforced during the early stages of stroke as a continued dependency.

Sexual function. A patient who had a stroke may be concerned about the loss of sexual function. Many patients are comfortable talking about their anxieties and fears about sexual function if you are comfortable and open to the topic. You can start a discussion about the topic with the patient and spouse or significant other. Common concerns include impotence and the chance of another stroke occurring during sex. Interventions include teaching about (1) optional positioning of partners, (2) timing for peak energy periods, and (3) patient and partner counseling.

Community integration. Traditionally, successful community integration after stroke is hard for the patient because of persistent problems with cognition, coping, physical deficits, and emotional changes that interfere with functioning. Older adults who had a stroke often have more severe deficits and multiple health problems. Failure to continue rehabilitation at home may result in deterioration and further complications.

Community resources can be an asset to patients and their families. The National Stroke Association provides information, resources, referral services, and quarterly newsletters on stroke. The ASA has information about stroke, hypertension, diet, exercise, and assistive devices. They also sponsor self-help groups in many areas. Easter Seals supplies wheelchairs and other assistive devices for stroke patients. Local groups can offer more daily help with meals and transportation.

Case Study

Stroke

(© iStockphoto/Thinkstock.)

Patient Profile

J.K. is a 57-year-old woman who was referred to the neurosurgery service for management of a temporal-parietal glioblastoma (see the Case Study in Chapter 60). She was diagnosed after presenting with persistent headaches, a seizure in her HCP's office, and left-side upper visual field loss and neglect. Her MRI/MRA showed a temporal-parietal glioblastoma that extends into the occipital lobes. She was scheduled for surgery to debulk the tumor. J.K. lives alone and holds a management position. She was concerned about her ability to return to work after her surgery.

J.K. returned from surgery to the neurosurgery unit drowsy but following commands. Her pupils were equal and responded to light. During the night, J.K. developed left-sided weakness of both arm and leg. She is now having difficulty answering questions.

Subjective Data

- Left arm and leg are weak and feel numb
- Trying to answer questions but looks confused and cannot follow commands

Objective Data

- BP 150/90 mm Hg
- Right gaze preference
- Left homonymous hemianopsia
- Left arm weakness (3/5) greater than leg weakness (4/5)
- Decreased sensation on both left arm and leg
- Has speech but not clear. Difficulty with word finding and following commands
- CT scan shows a hemorrhagic stroke into the site of the tumor bed, and temporal-parietal and anterior occipital areas extending into the thalamus

Discussion Questions

1. ***Recognize***: How did J.K.'s diagnosis of glioblastoma put her at risk for a stroke?
2. ***Analyze:*** What potential complications is J.K. at highest risk for developing?
3. ***Plan:*** How would you involve other interprofessional team members in J.K.'s care?
4. ***Prioritize:*** Based on the assessment data provided, what are the priority clinical problems?
5. ***Prioritize:*** What are the priority nursing interventions for J.K.?
6. ***Act***: What nursing interventions can you delegate to AP?
7. ***Act:*** What strategies can you implement to improve communication for J.K.?
8. ***Act:*** How can you address J.K.'s concerns about her finances and self-care?
9. ***Safety:*** How can you ensure safety for J.K. in light of her homonymous hemianopsia and left-sided neglect?
10. Develop a conceptual care map for J.K.

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Which patient has the *highest* risk for having a stroke?
   - **a.** A 45-year-old Native American with obesity
   - **b.** A 65-year-old Black man with hypertension
   - **c.** A 35-year-old Asian American woman who smokes
   - **d.** A 32-year-old White woman taking oral contraceptives
2. The factor related to cerebral blood flow that *most* often determines the extent of cerebral damage from a stroke is the
   - **a.** O_2 content of the blood.
   - **b.** amount of cardiac output.
   - **c.** level of CO_2 in the blood.
   - **d.** degree of collateral circulation.
3. Information provided by the patient that would help distinguish a hemorrhagic stroke from a thrombotic stroke includes
   - **a.** sensory changes.
   - **b.** a history of hypertension.
   - **c.** presence of motor weakness.
   - **d.** sudden onset of severe headache.
4. A patient after a stroke has difficulty finding words and weakness in his right arm. What area of the brain is *most* likely involved?
   - **a.** Brainstem
   - **b.** Vertebral artery
   - **c.** Left middle cerebral artery
   - **d.** Right middle cerebral artery
5. Which test would provide the best initial diagnostic information for a patient who presents to the emergency department with a potential stroke?
   - **a.** Noncontrast head CT
   - **b.** Cerebral angiography
   - **c.** Transcranial doppler ultrasonography
   - **d.** Intraarterial digital subtraction angiography
6. A patient having TIAs is scheduled for a carotid endarterectomy. The nurse explains that the purpose of this procedure is to
   - **a.** decrease cerebral edema.
   - **b.** reduce the brain damage that occurs during a stroke in evolution.

c. prevent a stroke by removing atherosclerotic plaques blocking cerebral blood flow.
d. provide a circulatory bypass around thrombotic plaques obstructing cranial circulation.

7. For a patient who is suspected of having a stroke, the *most* important piece of information that the nurse would obtain is
a. time of the patient's last meal.
b. time at which stroke symptoms first appeared.
c. patient's hypertension history and management.
d. family history of stroke and other cardiovascular diseases.

8. Bladder training in a male patient who has urinary incontinence after a stroke includes
a. limiting fluid intake.
b. helping the patient to stand to void.
c. keeping a urinal in place at all times.
d. catheterizing the patient every 4 hours.

9. A patient who recently had a stroke is home after one month of rehabilitation. The home care nurse is concerned when the patient says *(select all that apply)*
a. "I just don't want to do anything anymore."
b. "My daughter visits twice a day and helps me."
c. "I just can't sleep at night. I wake up every hour."
d. "I understand that my atrial fibrillation caused my stroke."
e. "I have no problem going up the stairs. Why is everyone so worried?"

1. b; 2. d; 3. d; 4. c; 5. a; 6. c; 7. b; 8. b; 9. a, c, e.

LEARNING OUTCOMES

1. Compare the etiology, clinical manifestations, and interprofessional and nursing management for types of primary headaches.
2. Describe the clinical manifestations, diagnostic studies, and interprofessional and nursing management of seizure disorder and restless legs syndrome.
3. Discern the clinical manifestations and nursing and interprofessional management of multiple sclerosis, Parkinson disease, myasthenia gravis, amyotrophic lateral sclerosis, and Huntington disease.
4. Explain the potential impact of chronic neurologic disease on well-being.
5. Outline the major goals of nursing care for the patient with a chronic, progressive neurologic disease.

KEY TERMS

absence seizure
amyotrophic lateral sclerosis (ALS)
aura
cluster headache
focal-onset seizures
generalized-onset seizures
Huntington disease (HD)
migraine headache
multiple sclerosis (MS)
myasthenia gravis (MG)
myasthenic crisis
Parkinson disease (PD)
restless legs syndrome (RLS)
seizure
seizure disorder
status epilepticus
tension-type headache (TTH)
tonic-clonic seizure

This chapter discusses headaches, chronic neurologic disorders, and degenerative neurologic disorders. Chronic neurologic disorders include seizure disorder and restless legs syndrome (RLS). *Degenerative nerve diseases* lead to nerve damage that worsens as the diseases progress. These neurologic problems have no cure. Treatment aims to reduce symptoms and help the patient maintain optimal function. Many have a genetic basis.

Degenerative nerve diseases include multiple sclerosis (MS), Parkinson disease (PD), myasthenia gravis (MG), amyotrophic lateral sclerosis (ALS), and Huntington disease (HD). They affect many activities, including vision, balance, movement, speech, swallowing, and heart and lung function. Patients with these diseases have similar concerns and problems. They must deal with the disease and its impact on quality of life. Many patients have concerns about safety, mobility, self-care, and coping. Patients and their caregivers often need psychosocial support, especially as the disease progresses and disability worsens.

HEADACHES

Headache is one of the most common types of pain. Most people have functional headaches, such as migraine or tension-type headaches. Others have organic headaches caused by intracranial or extracranial disease.

Pain-sensitive structures in the head include venous sinuses, dura, cranial blood vessels, and some nerves. There are 3 divisions of the trigeminal nerve (cranial nerve [CN] V), facial nerve (CN VII), glossopharyngeal nerve (CN IX), vagus nerve (CN X), and the first 3 cervical nerves. Pain occurs when these structures experience pull, displacement, inflammation, or swelling. Because these nerves have both motor and sensory functions, increased pain intensity and symptoms can occur when a person moves.

We classify headaches as primary or secondary. This is based on the International Headache Society (IHS) guidelines outlining characteristics of headaches.[1] *Primary headaches* include tension-type, migraine, and cluster headaches (Table 63.1). They are not caused by a disease or another medical problem. *Secondary headaches* are caused by another disease or problem, such as sinus infection, neck injury, or brain tumor.

A patient may have more than 1 type of headache. The history and neurologic assessment are key to deciding the type of headache. The assessment is often normal. Unexplained abnormal findings require further diagnostic studies.

TENSION-TYPE HEADACHE

Tension-type headache (TTH), or *stress headache,* is the most common type of headache. It is characterized by its bilateral location and pressing or tightening quality. TTH is usually of

TABLE 63.1 Interprofessional Care

Comparison of Headaches

Tension-Type Headaches	Migraine Headache	Cluster Headache
Location		
Bilateral, bandlike pressure at base of skull	Unilateral in 60%, may switch sides; often anterior location	Unilateral, radiating up or down from 1 eye
Quality		
Constant, squeezing, tightness	Throbbing, synchronous with pulse	Severe, bone crushing
Frequency		
Cycles for many years	Periodic, cycles of several months and years	May have months or years between attacks. Attacks occur in clusters over a period of 2–12 weeks
Duration		
30 min–7 days	4–72 hr	5 min–3 hr
Time and Mode of Onset		
Not related to time	May be preceded by prodromal symptoms or aura Onset after awakening Improves with sleep	Nocturnal, often awakens person from sleep
Associated Symptoms		
Palpable neck and shoulder muscle tension Stiff neck Tenderness	Aura: visual, sensory, aphasic Irritability, sweating Nausea, vomiting Photophobia Phonophobia Prodromal symptoms: sensory, motor, or psychic phenomena	Facial flushing or pallor Unilateral lacrimation, ptosis, rhinitis
Treatment: Abortive and Symptomatic Drugs		
Nonopioid analgesics: aspirin, acetaminophen, NSAIDs Analgesic combinations • butalbital/acetaminophen/caffeine • butalbital/aspirin/caffeine (Fiorinal) Muscle relaxants	α-Adrenergic blockers • ergotamine • dihydroergotamine NSAIDs Serotonin receptor agonists • almotriptan • eletriptan (Relpax) • frovatriptan (Frova) • naratriptan (Amerge) • rizatriptan (Maxalt) • sumatriptan (Imitrex) • zolmitriptan (Zomig) Combination • acetaminophen/caffeine/aspirin • sumatriptan/naproxen (Treximet) CGRP antagonists • Lasmiditan (Reyvow)	α-Adrenergic blockers Serotonin receptor agonists • almotriptan • eletriptan • frovatriptan • naratriptan • rizatriptan • sumatriptan • zolmitriptan High-flow 100% O_2

mild or moderate intensity. It can last from minutes to days. TTHs are divided by frequency into episodic or chronic. Chronic TTH occurs more than 15 days per month. It can lead to decreased quality of life and severe disability.[1]

Etiology and Pathophysiology

We do not know the cause of TTH. It may have a neurobiologic basis similar to migraine headaches. Triggers may include stress, anxiety, or depression. They may develop after exposure to caffeine or smoking. Many patients have tight cervical muscles and general pain in the back, hip, and knees. For some, episodic headaches evolve into chronic headaches. Headaches may occur intermittently for weeks, months, or even years.

Clinical Manifestations

Patients often have a bilateral frontal-occipital headache (Fig. 63.1). They describe the pain as a constant, dull pressure or bandlike. There may be increased cervical and neck muscle tone with neck pain. The patient may have sensitivity to light *(photophobia)* or sound *(phonophobia)*. There is no nausea or vomiting. Activity does not make the pain worse. There are no *prodromal symptoms* (warning symptoms of impending headache). Many patients have a combination of migraine headache and TTH, with features of both occurring together.

Diagnostic Studies

The history may be the most useful tool for diagnosing TTH (Table 63.2). If TTH is present during physical assessment, we may see increased resistance to passive movement of the head and head and neck tenderness. Electromyography (EMG) may show sustained contraction of neck, scalp, or facial muscles. However, the patient may not have increased muscle tension

BOX 63.1 BIOLOGIC SEX CONSIDERATIONS

Headaches

Men
- Cluster headaches are 3 to 7 times more common.
- Have more exercise-induced headaches.

Women
- Migraine headaches are 3 times more common.
- Have more tension-type headache.

with an EMG, even during a headache. Imaging is done when symptoms raise concern about a possible pathologic cause.

MIGRAINE HEADACHE

Migraine headache is a recurring headache characterized by unilateral throbbing pain. Migraines are most common between the ages of 25 and 55. One in 4 US households have someone with migraines. Migraines account for up to 5 million emergency room visits a year.[2] The IHS divides migraines into 2 categories: migraine without aura and migraine with aura. Migraine without aura is more common.[1]

Etiology and Pathophysiology

We do not know the exact cause of migraines. They likely result from complex interactions between trigeminal neuron, vascular, genetic, hormonal, and environment factors causing vasodilation and inflammation in the brain.[3] Current theory suggests a complex series of neurovascular events starts the headache. People who have migraines have a state of neuron hyperexcitability in the cerebral cortex, especially in the occipital cortex. Genetics may play a role. 50% of people with migraine have first-degree relatives with the disorder.[3]

Migraines are related to many disorders. These include seizure disorder, ischemic stroke, asthma, depression, anxiety, hypertension, and irritable bowel syndrome.[4] In many cases, migraines have no known precipitating events.[5] Other risk factors include age, female gender, obesity, low education level, and stressful life events (Box 63.1).

For some patients, specific factors may trigger a headache. Triggers include hormone fluctuations, environment factors like bright lights or loud noises, barometric pressure changes, skipping meals, odors, alcohol, depression, lack of sleep, and stress. Common food triggers include caffeine, monosodium glutamate, and high tyramine foods (red wine, aged cheese).[5]

Clinical Manifestations

Prodromal symptoms and an aura may precede the headache phase by several hours or days. Prodromal symptoms occur before the onset of aura or headache. Common prodromal symptoms include a change in activity level, depression, fatigue, pallor, yawning, or difficulty concentrating.[6] Aura occurs in about 25% of patients. An **aura** is a group of neurologic symptoms that occur before a headache begins but may continue into the headache. The symptoms of an aura are completely reversible. There are 3 main types of auras: visual, sensory, and aphasic. Visual symptoms, such as flashes of bright lights, blind spots, distortions, or zigzag lines, are the most common type of aura. Sensory auras may start as tingling or numbness in the fingers or in the mouth, voices that do not exist, or unusual odors. Aphasic aura presents as speech problems.[7]

A migraine may last 4 to 72 hours. Patients often describe the pain as steady, pounding, or throbbing. It is synchronous with the pulse and worsens with movement. The pain is usually unilateral (Fig. 63.1). During the headache, patients may try to avoid noise, light, odors, people, and stress.

! SAFETY ALERT
- A severe headache accompanied by a stiff neck, vomiting, confusion, weakness, double vision, a rash, or difficulty arousing requires emergent evaluation.
- These signs may indicate life-threatening illness.

Diagnostic Studies

The diagnosis is usually based on the history. Neurologic and other diagnostic examinations are often normal (Table 63.2). No specific laboratory or radiologic test can diagnose migraine headache. Neuroimaging techniques (e.g., head CT scan, MRI) are not part of the routine evaluation unless the neurologic assessment is abnormal. If atypical features are present, further testing is done.

CLUSTER HEADACHE

Cluster headache is the most severe form of primary headache. It is classified as a *trigeminal autonomic cephalalgia* (TAC). Cluster headache effects the trigeminal nerve (CN V) and has associated autonomic symptoms (e.g., tears, stuffy nose). Age at onset is often 20 to 50 years, but they can start at any age. They more often affect persons who smoke and men (Box 63.1).[8]

Etiology and Pathophysiology

We do not know the cause nor how cluster headache occurs. Imaging studies show activation of the hypothalamus and trigeminal vascular complex at the onset.[8] There may be a genetic influence. Many attacks occur at night, waking the person 1 to hours after falling asleep. Alcohol, caffeine, and tyramine foods can be diet triggers. Pain often starts within 1 hour of a drink. Strong odors (e.g., gasoline, paint fumes) or getting overheated are other triggers.[9] Cluster headaches may occur at high altitudes when less O_2 is available in the atmosphere.

Clinical Manifestations

Patients have severe, intense pain lasting from 15 minutes to 3 hours. The pain is sharp and stabbing, described as excruciating. It is usually around the eye, radiating to the temple, forehead, cheek, nose, teeth, or jaw along the CN V pathway (Fig. 63.1). Patients have characteristic autonomic features include swelling around the eye, lacrimation (tearing), facial flushing or pallor, nasal congestion or running, and miosis (pupil constriction). During the headache, the patient may be agitated and restless, unable to sit still or relax.[9]

Repeated headaches occur in clusters, recurring regularly. A cluster typically lasts 4 to 12 weeks. Then, the patient goes into remission for months to years. Headaches usually occur at the same time in the day and as often as 8 times a day. Because cluster periods often occur seasonally, headaches may be mistaken for allergy symptoms. About 20% of patients have chronic headaches without pain-free intervals.[9]

Diagnostic Studies

The diagnosis is based on the history.[9] Asking patients to keep a headache diary can be useful. CT scan, MRI, or magnetic resonance angiography (MRA) may rule out an aneurysm, tumor, or infection. A lumbar puncture (LP) may rule out other disorders with similar symptoms (Table 63.2).

OTHER TYPES OF HEADACHES

Other types of headaches can occur. They may be related to external and internal changes (cold, cough, hormone disruption, seasonal). A headache may be from external head trauma or the first symptom of a more serious illness. Headache can occur with subarachnoid hemorrhage, brain tumors, intracranial masses, vascular abnormalities, trigeminal neuralgia, systemic illness (e.g., infection), and eye, nose, or teeth problems. Because of the varied causes of headache, assessment is important. Assess personality, life adjustment, environment, and living situation with the physical assessment.

INTERPROFESSIONAL CARE: HEADACHES

If no systemic disease is the cause, the type of headache guides the therapy. Tables 63.1 and 63.3 show therapies for preventing and managing headaches.

Cognitive-behavioral therapy, sleep modification therapy, and relaxation therapy used alone, or in conjunction with drug therapy, may help some patients (see Chapter 7). Biofeedback involves using physiologic monitoring equipment that gives the patient information about muscle tension and peripheral blood flow. The patient is trained to relax the muscles and raise the finger temperature. Positive reinforcement occurs when the patient makes these changes. Acupuncture, acupressure, and hypnosis are options for some patients.

Drug Therapy

Tension-Type Headache

Drug therapy for TTH usually involves aspirin, acetaminophen, or nonsteroidal antiinflammatory drugs (NSAIDs) used alone or in combination with caffeine, a sedative, or a muscle relaxant. These analgesics may be only partly effective, even with use of the maximum dose. Stronger analgesics provide no added benefit. Tricyclic antidepressants, some antiseizure medications, or muscle relaxants may be used as preventative therapy.

Many of these drugs have serious side effects. Caution the patient about the long-term use of aspirin or aspirin-containing drugs because they can cause gastrointestinal (GI) bleeding and bleeding problems in some patients. Drugs containing acetaminophen can cause kidney damage with chronic use and liver damage when taken in large doses or with alcohol. Psychoactive medications and antiseizure medications may be sedating and interfere with daily activities.

Migraine Headache

The aim of drug treatment in an acute migraine is stopping or decreasing the symptoms. Many people with mild or moderate migraine headache can get relief with NSAIDs, aspirin, or caffeine-containing analgesics. For moderate to severe headache pain, triptans are the first line of therapy (Table 63.1).[2]

Triptans (e.g., sumatriptan) affect selected serotonin receptors. They reduce neurogenic inflammation of cerebral blood vessels and cause vasoconstriction. Some patients respond better to certain triptans than to others. Triptans are most effective when taken at the start of a migraine headache or during the aura. Sumatriptan is available in several dosage forms and delivery systems (oral, subcutaneous, nasal spray, transdermal). It is also the only ultrafast-acting triptan. A combination of oral sumatriptan and naproxen sodium (Treximet) is more effective for symptom relief than either drug alone. Because triptans cause vasoconstriction, they are contraindicated for people with heart disease (e.g., angina, myocardial infarction, hypertension) or stroke.[2]

When triptans are contraindicated or ineffective, we can give other drugs (Table 63.1). Vasoconstrictors used to treat acute migraine include dihydroergotamine (Dhe 45) and other ergot-based agents. Patients with cardiovascular disease or those taking other vasoconstrictors should use these drugs cautiously.[2] The serotonin (5-HT) receptor agonist lasmiditan (Reyvow) increases serotonin and reduces inflammation and pain during a migraine.[8]

DRUG ALERT

Sumatriptan (Imitrex)

- Should not be used by patients with a history of:
  - Ischemic cardiac, cerebrovascular, or peripheral vascular problems.
  - Uncontrolled hypertension (may increase BP).
- Excess dosage may cause tremor and decrease respirations.

Preventive treatment is important in managing migraine headache. The decision to start preventive treatment is made based on frequency, severity, and disability related to headaches. Patients with migraine may take preventative drugs if they must take triptans more than 3 days a week for migraine symptoms. Several different classes of drugs are used.

Antiseizure drugs (e.g., topiramate, divalproex, valproate) may be taken daily for migraine prevention. Common side effects include hypoglycemia and cognitive changes. They take 2 to 3 months to reach full effectiveness. Antiseizure drugs should never be abruptly stopped because seizures may develop. We must provide thorough teaching to promote safe use. Extended-release forms promote adherence, with fewer cognitive effects.[3]

Commonly prescribed β-adrenergic blockers include propranolol (Inderal), metoprolol (Lopressor), and atenolol (Tenormin). They should be used cautiously in patients with

asthma and diabetes. Tricyclic antidepressants like amitriptyline are another option.

Botulinum toxin A (Botox) may be an effective prophylactic treatment for adults who have chronic migraines at least 15 days each month or migraines that do not respond to other medications. Botox is given by multiple injections around the head and neck into the pain fibers involved in headaches. Maximum benefit may not be seen for up to 6 months. During this time, the patient should continue their regular medications. Injections are usually given every 3 months. The most common reactions are neck pain and headache. A slight risk exists for the toxin to migrate to other areas of the face and neck, causing swallowing and breathing difficulties. Teach the patient to seek immediate medical attention if this occurs.

CGRP antagonists block the effect of CGRP. CGRP is a small protein involved with pain transmission. It is highly prevalent in the sensory nerves that supply the head and neck. Levels increase during a migraine attack. Injectable agents include erenumab (Aimovig), fremanezumab (Ajovy), and galcanezumab (Emgality).[8] Ubrogepant (Ubrelvy) is given orally.

Other prophylactic treatments for migraine include supraorbital transcutaneous electrical stimulation, vagal nerve stimulation (VNS), and single pulse transcranial magnetic stimulation. These treatments use energy stimulation to prevent headache.[10] Herbal treatments that may be helpful in migraine prophylaxis include riboflavin, coenzyme Q10, magnesium, melatonin, and feverfew.[11]

Cluster Headache

Triptans (e.g., sumatriptan, zolmitriptan) are the standard of treatment for occasional cluster headache. Nasal administration or subcutaneous injection is appropriate. As discussed earlier, they are contraindicated for some patients. Options for patients with refractory cluster headaches include invasive nerve blocks, deep brain stimulation (DBS), vagal or trigeminal stimulators, and ablative neurosurgical procedures (e.g., percutaneous radiofrequency).[3]

High-flow 100% O_2 by non-rebreather mask is well-tolerated, safe, and effective as an alternative treatment. O_2 delivered at a rate of 7 to 12 L/min for 20 minutes may relieve headache by causing vasoconstriction and reducing inflammation in the brain. Treatment can be repeated after a 5-minute rest.

Those with chronic cluster headache often seek preventive treatment. High-dose verapamil is the first-choice drug to prevent cluster headache. The patient needs careful monitoring during treatment. An electrocardiogram (ECG) should be done with every dose increase and every 6 months.

Other Headaches

Patients with frequent headaches may overuse drugs used for headache treatment. *Medication overuse headache* (MOH) is the term used to describe a new type of headache or marked worsening of a preexisting headache condition. Drugs known to cause this problem are acetaminophen, aspirin, NSAIDs (e.g., ibuprofen), triptans, barbiturates, and ergotamine.[1,2,8] MOH often occurs daily and is present on wakening. Patients may have nausea, restlessness, weakness, lack of energy, decreased memory, difficulty concentrating, depression, and irritability. Treatment involves stopping the offending drug and using alternative agents, such as amitriptyline.

TABLE 63.3 NURSING ASSESSMENT

Headaches

Subjective Data

Important Health Information

Health history: Seizures, cancer, recent fall or other trauma, cranial infection, stroke. Asthma or allergies. Relationship of headache to overwork, stress, menstruation, exercise, food, sexual activity, travel, bright lights, or noxious environmental stimuli

Medications: Hydralazine, bromides, nitroglycerin, ergotamine (withdrawal), NSAIDs (in high daily doses), estrogen preparations, oral contraceptives, OTC medications

Surgical interventions or other treatments: Craniotomy, sinus surgery, facial surgery

Functional Health Pattern

Health perception–health management: Positive family history. Malaise

Nutritional-metabolic: Ingesting alcohol, caffeine, cheese, chocolate, monosodium glutamate, aspartame, lunch meats (nitrites in cured meats), sausage, hot dogs, onions, avocados. Anorexia, nausea, vomiting (migraine premonitory symptom); unilateral lacrimation (cluster)

Activity-exercise: Vertigo, fatigue, weakness, paralysis, fainting

Sleep-rest: Insomnia

Cognitive-perceptual

- *Tension type:* Bilateral, bandlike, dull and persistent, base-of-skull headache, neck tenderness
- *Migraine:* Aura. Unilateral, severe, throbbing headache (possible switching of side). Vision changes, photophobia, phonophobia, dizziness, tingling or burning sensations
- *Cluster:* Unilateral and severe, nocturnal headache. Nasal stuffiness

Self-perception–self-concept: Depression

Coping–stress tolerance: Stress, anxiety, irritability, withdrawal

Objective Data

General

Anxiety, apprehension

Musculoskeletal

Resistance of head and neck movement, nuchal rigidity (meningeal, tension type), palpable neck and shoulder muscle tension (tension type)

Neurologic

Restlessness (cluster), hemiparesis (migraine)

Skin

Migraine: Generalized edema (premonitory symptom) pallor, diaphoresis

Cluster: Forehead diaphoresis, pallor, unilateral facial flushing with cheek/eye edema, conjunctivitis

Possible Diagnostic Findings

Evidence of disease, deformity, or infection on brain imaging (CT, MRI, MRA), cerebral angiogram, LP, EEG, EMG

❖ NURSING MANAGEMENT: HEADACHES

◆ Assessment

Table 63.3 outlines subjective and objective data to obtain from a patient with headaches. The history is key and focused on

specific details of the headaches. Include location and type of pain, onset, frequency, duration, relation to events (emotional, psychologic, physical), and time of day of the occurrence. A thorough history may suggest headache is due to other problems or drug therapies.

Ask the patient to keep a diary of headaches with specific details. This can help identify the type of headache and precipitating events. Avoiding diet triggers is helpful for most patients with cluster and migraine headache. If there is a history of primary headache, ask if the character, intensity, or location of the headache has changed. The answer may be an important clue about the cause of the headache.

Clinical Problems

Clinical Problems for the patient with headaches may include:

- Pain
- Deficient knowledge

Additional information on clinical problems and interventions is presented in eNursing Care Plan 63.1 for the patient with headaches (available on the website for this chapter).

Planning

The overall goals are that the patient with headaches will (1) have reduced or no pain, (2) understand triggering events and treatments, (3) use positive coping strategies to deal with pain, and (4) have increased quality of life and decreased disability.

Implementation

Patients benefit from engaging in stress reduction techniques.[9] An inability to cope with daily stresses can cause headaches. Effective treatment may involve helping the patient examine the daily routine, recognize stressful situations, and develop effective coping strategies. Help the patient identify precipitating factors and develop ways to avoid or minimize them. Encourage daily exercise, relaxation periods, and socialization as ways to decrease headaches. Suggest meditation, yoga, biofeedback, and other ways to reduce stress and address headache pain. Encourage a consistent daily routine with adequate sleep and regular well-balanced meals.[12]

Table 63.4 shows a teaching guide for the patient with headaches. Teach the patient about drugs prescribed for preventive and symptomatic treatment. Encourage the patient with migraines to seek a quiet, dimly lit environment. Massage and cool or hot packs or cool packs to the neck and head can help.

Provide diet teaching if headaches are triggered by food. Encourage the patient to eliminate foods that may provoke headaches. Active challenge testing (designed specifically to provoke symptoms) with suspect foods may help determine specific causative agents.

Evaluation

Expected outcomes are that the patient with headaches will:

- Report satisfaction with pain management
- Use measures appropriately to manage pain
- Report an increase in quality of life

TABLE 63.4 PATIENT & CAREGIVER TEACHING

Headaches

Include the following instructions when teaching the patient with headaches and the patient's caregiver:

1. Keep a diary or calendar of headaches and possible precipitating events.
2. Avoid possible headache triggers:
   - Drugs, such as ergot-containing preparations (ergotamine tartrate) and monoamine oxidase inhibitors
   - Fatigue
   - Foods
     - Alcohol (especially red wine)
     - Amines (cheese, chocolate)
     - Aspartame
     - Caffeine
     - Fermented or marinated foods, vinegar
     - Ice cream
     - Monosodium glutamate
     - Nitrites (meats, such as hot dogs)
     - Onions
     - Oranges
     - Tomatoes
   - Nicotine
3. Learn the purpose, action, dosage, and side effects of drugs taken.
4. Self-administer sumatriptan nasally or subcutaneously, if prescribed.
5. Use stress management techniques (see Chapter 7).
6. Take part in regular exercise.
7. Avoid smoking and exposure to environmental triggers, such as strong perfumes.
8. Contact HCP if any of the following occur:
   - Symptoms become more severe, last longer than usual, or are resistant to medication
   - Nausea and vomiting (if severe or not typical), change in vision, or fever occurs with the headache
   - Problems occur with any drugs

CHRONIC NEUROLOGIC DISORDERS

Seizure Disorder

A **seizure** is a sudden abnormal, excessive, electrical discharge of neurons in the brain. During a seizure, multiple neurons fire at a rate much faster than normal, causing involuntary movements, sensory phenomena, emotional expression, and unusual behaviors.[13] Seizures may accompany a variety of disorders or occur without any apparent cause.

Seizure disorder, or *epilepsy*, is a group of neurologic diseases marked by recurring seizures. If a person has 2 or more seizures more than 24 hours apart without an underlying problem that caused the seizure, they may have seizure disorder. Seizures from systemic and metabolic problems are not seizure disorder if they stop when the underlying problem is corrected.

It is the 4th most common neurologic disorder. About 3.4 million or 1.2% of Americans have seizure disorder. 1 in 26 people will develop seizure disorder during their lifetime.[14] It effects men and women of all ages, races, and ethnic backgrounds.[15]

Etiology and Pathophysiology

For most persons, the cause of seizure disorder is unknown. These cases are known as *idiopathic generalized epilepsy*

(IGE). Known causes include stroke, brain tumors, cerebral infection, traumatic brain injury, hypoxic birth injury, neurodevelopmental disorders (e.g., autism spectrum disorders), or neurodegenerative disease (e.g., Alzheimer).[15] Other common causes include low or very high glucose levels, abnormal serum electrolytes (sodium, magnesium, calcium), eclampsia with pregnancy, lack of sleep, and alcohol withdrawal. Children may have seizures with high fever. Medical problems that may cause seizures include hypertension, sepsis, and heart, lung, liver, or kidney diseases. Immune factors may influence seizure disorder. Patients with autoimmune disease, like systemic lupus erythematosus (SLE) and MS, have inflammatory changes in the brain increasing seizure risk. Research into the role of neural antibodies and seizures is ongoing.

Seizure disorder is characterized by a group of abnormal neurons that seem to fire without a clear cause. This may happen due to the release of excitatory neurotransmitters or by an absence of neuroinhibitory activity. Both allow abnormal excitement of neurons, leading to excessive discharge of electrical activity. Any stimulus that causes the neuron's cell membrane to depolarize can cause this firing which spreads by physiologic pathways. Localizing the *seizure focus* (the place where the seizure originates) is critical to the success of any surgical treatment.

Genetic Link

One or more genetic abnormalities affect up to 70% of people with seizure disorder.[13] Seizure disorder can develop from the interaction between genetics and the environment. Some genetic diseases cause brain malformations that lead to a seizure disorder. Gene mutations that cause a low seizure threshold, a change in nutrient metabolism, or neural migration in brain development can lead to seizure disorder. Patients with chromosomal disorders (e.g., Down syndrome) often have seizure disorder.[13]

Clinical Manifestations

Specific manifestations of seizure are determined by the site of the electrical disturbance. The International League Against Epilepsy has developed a classification system for seizures. This system divides seizures into 3 major classes based on where the seizure activity begins: *generalized onset, focal onset*, and unknown onset.[16] 60% of patients have focal seizures (Table 63.5). Seizures within each classification as *motor* or *nonmotor* and by level of awareness. These descriptors address what occurs during the seizure. It may not be easy to figure out what type of seizure a patient is having. Seizures may begin with a single focus but may spread and become generalized throughout the brain.

Depending on the type, a seizure may occur in 4 phases: (1) *prodromal phase,* with sensations or behavior changes that precede a seizure by hours or days; (2) *aural phase,* with a sensory warning that is similar each time a seizure occurs and is part of the seizure; (3) *ictal phase,* from 1st symptoms to the end of seizure activity; and (4) *postictal phase,* the recovery period after the seizure. Not all patients have every phase.

TABLE 63.5 Classification of Seizures

Generalized Onset Seizure
(Involves both hemispheres of brain)
- Motor seizure
  - Atonic
  - Clonic
  - Epileptic spasms
  - Myoclonic
  - Myoclonic-atonic
  - Myoclonic-tonic-clonic
  - Tonic
  - Tonic-clonic
- Nonmotor (Absence) seizure
  - Typical
  - Atypical
  - Myoclonic
  - Eyelid myoclonia

Focal-Onset Seizure
(Limited to 1 hemisphere of brain)
- Aware (no impairment of awareness/consciousness)
- Impaired awareness (impairment of awareness/consciousness)
- Motor onset
  - Automatisms
  - Atonic
  - Clonic
  - Epileptic spasms
  - Hyperkinetic
  - Myoclonic
  - Tonic
- Nonmotor onset
  - Autonomic
  - Behavior arrest
  - Cognitive
  - Emotional
  - Sensory

Unknown Onset Seizure
(Due to inadequate information or inability to assign to other categories above)

Adapted from Fisher RS, Cross JH, D'Souza C, et al.: Instruction manual for the ILAE 2017 operational classification of seizure types, *Epilepsia* 58:4, 2017.

Generalized-Onset Seizures

Generalized-onset seizures start over wide areas of both sides of the brain. They are characterized by bilateral, synchronous neural discharges. In most cases, the patient has impaired consciousness for a few seconds to several minutes. Generalized seizures are either motor or nonmotor. Motor movements are bilateral.

Tonic-clonic seizure. **Tonic-clonic seizure** (formerly called grand mal) is the most common generalized-onset motor seizure. During a tonic-clonic seizure, the patient loses consciousness and, if upright, falls to the ground. The body stiffens (tonic phase) for 10 to 20 seconds and then the extremities jerk (clonic phase). This may last 30 to 40 seconds up to several minutes. Cyanosis, excessive salivation, tongue or cheek biting, and incontinence may occur during the seizure.

In the postictal phase, the patient usually has muscle soreness, feels tired, and may sleep for several hours. Some patients do not feel normal for several hours or days after a seizure. The patient has no memory of the seizure.

Other generalized-onset motor seizures. Other types of generalized-onset motor seizures include tonic and clonic. A tonic seizure involves a sudden onset of increased tone in the extensor muscles, contributing to sudden stiff movements. Tonic seizures most often occur in sleep and affect both sides of the body. Patients will fall if they are standing when the seizure occurs. Tonic seizures usually last less than 20 seconds. The patient usually stays aware. Clonic seizures begin with loss of awareness and sudden loss of muscle tone, followed by rhythmic limb jerking that may or may not be symmetric.

A generalized *atonic seizure* (or *drop attack*) involves a brief, sudden loss of tone. It may affect just the head and neck or result in the person falling to the ground. Seizures typically last a few seconds. There is a brief loss of consciousness and a brief post ictal confusion. Patients with atonic seizure are at great risk for head injury. They often need protective helmets.

Generalized-onset nonmotor (absence) seizures. **Absence seizure** most often occurs in children. They rarely occur beyond adolescence. This type of seizure occurs more often in girls. It usually begins between ages 4 and 8. They may stop altogether as the child matures or evolve into another type of seizure. A *typical absence seizure* is marked by a sudden onset brief staring spell that resembles daydreaming and sudden recovery. It often goes unnoticed because it lasts less than 10 to 20 seconds. Usually, the patient is unresponsive when spoken to during the seizure.[3]

In *atypical absence seizure,* the staring spell is accompanied by other signs and symptoms, such as eye blinking or jerking movements of the lips and repetitive finger movements (automatisms). This type of seizure often lasts as much as 30 seconds, with a gradual beginning and end. If the patient has existing cognitive problems, it may be hard to tell seizure activity from usual behavior. Atypical absence seizures usually continue into adulthood.

Focal-Onset Seizures

Focal-onset seizures (formerly called *partial* or *partial focal seizures*) are the other major class of seizures (Table 63.5). Focal seizures begin in 1 hemisphere of the brain in a localized region of the cortex. They cause sensory, motor, cognitive, or emotional manifestations based on the function of the involved area of the brain. For example, if the discharging focus is in the medial aspect of the postcentral gyrus, the patient may have paresthesia in the leg on the side opposite the focus. This can help discern the type of seizure.

Focal seizures are motor or nonmotor. Motor activities include atonic (loss of tone, relaxed muscles), tonic (sustained stiffening), clonic (rhythmic jerking), or myoclonic (very rapid, irregular, brief jerking).[8] Some people show strange behavior, such as lip smacking, picking at clothes, or other repetitive, purposeless actions (automatisms). With a focal nonmotor seizure, the patient can have emotional manifestations or autonomic symptoms.[13]

A patient with focal-onset seizure may be described as aware or impaired awareness. In *focal awareness seizures*, patients are conscious and alert, but have unusual feelings or sensations. They may have sudden and unexplainable feelings of joy, anger, sadness, or nausea. They may hear, smell, taste, see, or feel things that are not real. Some have localized twitching.

In a *focal impaired awareness seizure*, patients have a loss of consciousness or a change in awareness producing a dream-like state. Their eyes are open. They make movements that may seem purposeful, but they cannot interact with others. During a seizure, some people may do things that can be dangerous or embarrassing, such as walking into traffic or removing their clothes. They may continue an activity started before the seizure, such as counting coins or choosing items from a grocery shelf. After the seizure they do not remember the activity performed during the seizure. Seizures usually last 1 to 2 minutes. Patients may be tired or confused after the seizure and not return to normal activity for hours. The degree of awareness can be unspecified.

Psychogenic Nonepileptic Seizures

Psychogenic nonepileptic seizures (PNES) imitate seizures but are triggered by emotional events not neuronal activity. Because of the close resemblance, we may misdiagnose PNES as seizure disorder. Proper diagnosis usually requires video-EEG monitoring during the attack.[13] A history of emotional or physical abuse or a specific traumatic event often emerges. Treatment includes cognitive behavioral therapy and serotonin reuptake inhibitors.[13]

Complications

Physical

People with seizure disorder have a higher mortality rate than the general population. Severe injury, or death, can result from trauma suffered during a seizure. Patients who lose consciousness during a seizure are at greatest risk. Other deaths are due to accidents during seizures, death from an underlying disease, sudden unexpected death in epilepsy (SUDEP), or status epilepticus.

Status epilepticus (SE) is a state of continuous seizure activity. We define SE as any seizure lasting longer than 5 minutes or occurring so close together the patient cannot recover between them.[17] The patient does not return to consciousness between seizures. The longer a seizure lasts, the less likely it is to stop without drug therapy.

SE is a neurologic emergency. It can occur with any type of seizure. The highest incidence occurs in children and older adults. In adults it is most common with stroke, metabolic problems, or low therapeutic levels of seizure medications. Most patients who have SE do not have a history of seizure disorder.[13]

During repeated seizures, the brain uses more energy than the body can supply. As neurons become exhausted and cease to function, permanent brain damage may result. *Convulsive status epilepticus* (CSE) is the most common form. It occurs with prolonged or repeated tonic-clonic or other motor seizures. The goal of therapy is to rapidly end clinical and electrical seizure activity before neuronal damage occurs. Without effective,

prompt treatment, CSE can lead to respiratory insufficiency, hypoxemia, dysrhythmias, hyperthermia, and systemic acidosis. The prognosis is related to the cause, length of the seizures, patient's age, and time to treatment.[13]

We use the term *nonconvulsive status epilepticus* to describe long or repeated focal impaired awareness seizures. Symptoms may be subtle, making it hard to tell recovery from seizure symptoms.

Refractory status epilepticus (RSE) is continuous seizure activity despite administration of first- and second-line therapy. RSE has a high risk for mortality and neurologic damage. This highlights the need for rapid escalation of treatment for CSE to avoid progression. *Super refractory SE* is a refractory condition that continues or recurs 24 hours or more after starting anesthesia treatment. It also includes cases in which seizure activity returns after withdrawal of anesthesia drugs or persists after 7 days of continuous general anesthesia.

Subclinical seizures are a form of SE in which a sedated patient seizes but there are no external signs because of sedative use. For example, a patient under sedation for ventilatory support in the intensive care unit (ICU) could have a seizure without physical movements and we miss the seizure occurrence.

SUDEP affects about 1.6 in 1000 persons with uncontrolled seizures each year.[18] Most cases occur during or right after a seizure. It is most often from tonic-clonic seizures. SUDEP is more common at night, in those taking multiple antiseizure drugs, and in patients with poorly managed seizure activity. We think that people who acquire seizure disorder at a young age or who drink alcohol are higher at risk. We do not know the exact cause. Ictal and postictal apnea and hypoxia are believed to play a role.[18] Specific teaching about medication adherence and disease awareness is critical for at-risk people.

Psychosocial

Perhaps the most common complication of seizure disorder is the effect on a patient's lifestyle. Patients may have psychosocial problems related to having chronic seizures. An increased incidence of depression occurs in people who have seizures that are difficult to control.

A diagnosis of seizure disorder carries a social stigma. Patients may be victims of discrimination in employment and educational opportunities. Transportation may be difficult if state law does not allow the person to drive. Screen patients often for depression. Encourage them to pursue available treatment options.

Diagnostic Studies

The most useful diagnostic tool is an accurate, comprehensive description of seizures and the patient's health history (Table 63.6). If a patient is diagnosed with seizure disorder, the seizure type must be correctly identified to determine the correct treatment.

The EEG is useful if it shows abnormalities. Abnormal findings help determine the type of seizure and pinpoint the seizure focus. An EEG should be done within 24 hours of a suspected seizure. Only a small number of patients with seizure disorder have abnormal EEG findings the first time they have an EEG.

TABLE 63.6 Interprofessional Care

Seizure Disorder

Diagnostic Assessment

History and Physical Assessment

- Health history
  - Birth and developmental
  - Significant illnesses and injuries
  - Family history
- Febrile seizures
- Comprehensive neurologic assessment
- Seizure history
- Precipitating factors
- Antecedent events
- Seizure description (aura, onset, duration, frequency, postictal state)

Diagnostic Studies

- CBC, metabolic panel
- Urinalysis
- LP for CSF analysis
- CT, MRI, MRA, MRS, PET scan
- EEG

Management

- Antiseizure drugs (Table 63.8)
- Surgery
- Vagal nerve stimulation
- Deep brain stimulation
- Responsive neurostimulation
- Counseling
- Physical therapy

Repeated EEGs, continuous EEG monitoring, or video-EEG may be needed to detect abnormalities. Many patients with seizure disorder have normal EEG results between seizures. Magnetoencephalography (MEG) may be done with the EEG. MEG has greater sensitivity in detecting small magnetic fields of neuron activity.

A complete blood count (CBC), serum chemistries, liver and kidney function tests, and urinalysis assess for metabolic problems. A CT scan or MRI should be done in any new-onset seizure to rule out a structural lesion. If an MRI shows a spot or lesion but EEG results differ, MEG can see if the brain waves are coming from the lesion. Other imaging tests (e.g., PET, SPECT) or angiography may be done in some situations.

Interprofessional Care

Most seizures do not require emergency medical care because they are self-limiting and rarely cause injury (Table 63.6). However, if SE or injury occurs, or if the event is a first-time seizure, medical care should be sought immediately. Table 63.7 outlines emergency care of the patient with a tonic-clonic seizure.

Drug Therapy

The main treatment for seizure disorder is antiseizure drugs (Table 63.8). Because a cure is not possible, the goal of therapy is to prevent seizures with minimal drug side effects. Most drugs

TABLE 63.7 EMERGENCY MANAGEMENT

Tonic-Clonic Seizures

Etiology

Drug-Related
- Ingestion, inhalation
- Overdose
- Withdrawal of alcohol, opioids, antiseizure drugs

Head Trauma
- Cerebral contusion
- Epidural hematoma
- Intracranial hematoma
- Subdural hematoma
- Traumatic birth injury

Idiopathic

Infection
- Encephalitis
- Meningitis
- Sepsis

Intracranial Events
- Brain tumor
- Hypertensive crisis
- Increased ICP due to clogged shunt
- Stroke
- Subarachnoid hemorrhage

Medical Problems
- Heart, liver, lung, or kidney disease
- SLE

Metabolic Problems
- Fluid and electrolyte imbalance
- Hypoglycemia

Other
- Cardiac arrest
- High fever
- Psychiatric problems

Assessment Findings

Aural Phase
- Bowel and bladder incontinence
- Diaphoresis
- Loss of consciousness
- Pallor, flushing, or cyanosis
- Peculiar sensations that precede seizure
- Tachycardia
- Warm skin

Tonic Phase
- Continuous muscle contractions

Hypertonic Phase
- Extreme muscular rigidity lasting 5–15 sec

Clonic Phase
- Rigidity and relaxation alternating in rapid succession

Postictal Phase
- Altered level of consciousness, lethargy
- Confusion and headache
- Repeated tonic-clonic seizures for several min

Interventions

Initial
- Ensure patent airway.
- Protect patient from injury during seizure. Do not restrain. Pad side rails.
- Remove sharp objects and glasses.
- Never force anything between patient's clenched teeth.
- Remove or loosen tight clothing.
- Establish IV access.
- Stay with patient until seizure has passed.
- Anticipate giving phenytoin, benzodiazepines (e.g., diazepam, midazolam, lorazepam) to try to stop seizures.
- Suction as needed.
- Assist ventilations if patient does not breathe spontaneously after seizure.
- Anticipate need for intubation.

Ongoing Monitoring
- Monitor vital signs, level of consciousness, O_2 saturation, Glasgow Coma Scale results, pupil size and reactivity.
- Reassure and orient patient after seizure.
- Give IV dextrose for hypoglycemia.
- Maintain NPO till awake with gag reflex.

stabilize nerve cell membranes and prevent spread of the epileptic discharge. Therapy should begin with a single drug based on the patient's age, weight, and type, frequency, and cause of seizure. Dosage should be increased until seizures are under control or toxic side effects occur. Antiseizure drugs successfully control seizures for about 70% of patients. The other 30% do not respond to antiseizure drugs. They have *medically refractory epilepsy* (drug resistant epilepsy).

If seizure control is not achieved with a single drug, we can change the dose or timing of administration or add a second drug. About one-third of patients need combination therapy for control. Patients should discuss their treatment with the HCP. Our goal is to provide the best control with the least amount of medication. Each drug has a therapeutic range. Above that range, most patients have toxic side effects, and below that range, most continue to have seizures. Therapeutic drug ranges are guides for therapy. If seizures are well controlled with a subtherapeutic level, the dose does not have to be increased. Likewise, if a drug level is above the therapeutic range and the patient has good seizure control without toxic side effects, the dose does not have to be decreased. Drug levels are monitored if seizures continue to occur, frequency increases, or drug adherence is questioned. Because they have a large therapeutic range, many newer drugs do not require drug-level monitoring.

The main drugs to treat tonic-clonic and focal-onset seizures are phenytoin, carbamazepine (Tegretol), and divalproex (Depakote). The drugs used most often to treat generalized onset nonmotor and myoclonic seizures include ethosuximide (Zarontin), divalproex, and clonazepam (Klonopin). Treatments for focal seizures are carbamazepine, lamotrigine (Lamictal), or levetiracetam (Keppra). Pregabalin (Lyrica) is an added treatment for focal aware or impaired awareness seizures not successfully controlled with 1 medication. Table 63.8 lists other drugs used for seizure treatment. Some drugs are effective for multiple seizure types.

TABLE 63.8 Drug Therapy

Select Antiseizure Agents

Drug	Route	Side Effects	Considerations
GABA Analogs			
gabapentin (Neurontin)	PO	Ataxia Dizziness Drowsiness Vision changes Weight gain	Monitor weight. Avoid pregnancy. Use safety measures if CNS effects occur. Avoid alcohol.
pregabalin (Lyrica)	PO	Dizziness Drowsiness Edema Vision problems Weight gain	Avoid pregnancy. Use safety measures if CNS effects occur. Avoid alcohol. Monitor weight.
vigabatrin (Sabril)	PO	Dizziness Drowsiness Impaired memory Vision changes	Stop if vision changes occur. Avoid pregnancy. Use safety measures if CNS effects occur. Avoid alcohol.
Hydantoins			
phenytoin (Dilantin) fosphenytoin (Cerebyx, Sesquient)	IV, PO IM, IV	Ataxia Drowsiness GI distress Gingival hyperplasia Liver toxicity Nystagmus Rash	Avoid alcohol, direct sunlight. Monitor drug levels. Monitor site when giving IV. Monitor CBC and liver function tests. May change urine color to pink or red-brown. Maintain good oral hygiene.
Iminostilbenes			
carbamazepine (Tegretol) oxcarbazepine (Trileptal)	PO PO	Bleeding Dizziness Gait changes GI distress Headache Rash Vision problems	Take with meals; avoid grapefruit juice. Avoid direct sunlight. Monitor drug levels, CBC, and liver function tests. Avoid pregnancy. Use safety measures if CNS effects occur. Avoid alcohol.
Miscellaneous			
brivaracetam (Briviact)	IV, PO	Dizziness GI distress Suicidal thoughts	Avoid alcohol. Monitor for depression.
cenobamate (Xcopri)	PO	Dizziness Drowsiness Suicidal thoughts Vision problems	Use safety measures if CNS effects occur. Monitor for depression. Avoid alcohol.
clonazepam (Klonopin)	PO	Confusion Dizziness Drowsiness	Do not stop suddenly. Use safety measures if CNS effects occur. Can develop tolerance. Monitor liver function tests.
divalproex (Depakote)	PO	Bleeding Drowsiness GI distress Liver toxicity Suicidal thoughts Vision changes Weight gain	Use safety measures if CNS effects occur. Monitor for depression. Monitor CBC, liver function tests. Monitor weight.
eslicarbazepine (Aptiom)	PO	Depression Drowsiness GI distress Rash Speech problems Vision changes	Monitor for depression. Avoid alcohol. Use safety measures if CNS effects occur. Avoid pregnancy. Monitor liver function tests.

Continued

TABLE 63.8 Drug Therapy—cont'd

Select Antiseizure Agents

Drug	Route	Side Effects	Considerations
ethosuximide (Zarontin)	PO	Drowsiness GI distress Liver toxicity Rash	Monitor liver function tests. Use safety measures if CNS effects occur. Avoid alcohol. Avoid pregnancy. Stop if rash occurs.
felbamate (Felbatol)	PO	Decreased appetite with weight loss Liver toxicity Vision changes	Monitor CBC, liver function tests. Monitor weight.
lacosamide (Vimpat)	IV, PO	Dizziness Drowsiness Dysrhythmias GI distress	Use safety measures if CNS effects occur. Avoid alcohol. Avoid pregnancy.
lamotrigine (Lamictal)	PO	Dizziness Drowsiness GI distress Rash Vision changes	Use safety measures if CNS effects occur. Monitor liver function tests. Stop if rash occurs.
levetiracetam (Keppra)	PO	Dizziness GI distress Suicidal thoughts	Avoid alcohol. Monitor for depression.
perampanel (Fycompa)	PO	Anxiety Dizziness GI distress Suicidal thoughts	Give at bedtime. Monitor for depression. Avoid alcohol. Use safety measures if CNS effects occur. Avoid pregnancy.
tiagabine (Gabitril)	PO	Agitation Dizziness GI distress Rash Suicidal thoughts	Monitor for depression. Avoid in pregnancy. Avoid alcohol. Use safety measures if CNS effects occur.
topiramate (Topamax)	PO	Ataxia Drowsiness GI distress Vision changes	Stop if vision changes occur. Use safety measures if CNS effects occur. Avoid alcohol. Avoid pregnancy.
valproic acid (Depakene)	PO	Bleeding Drowsiness GI distress Weight gain	Avoid use in pregnancy. Take with food; avoid carbonated beverages. Monitor bleeding times, CBC, drug levels, liver function tests. Use safety measures if CNS effects occur.
zonisamide (Zonegran)	PO	Confusion Drowsiness Gait changes GI distress Kidney stones	Use safety measures if CNS effects occur. Encourage fluids.

Treatment of SE requires a rapid-acting antiseizure drug. The drugs most often used are benzodiazepines. Options include midazolam IM autoinjector (Seizalam) and buccal or intranasal midazolam (Nayzilam).[17] If a patient has an IV, then IV lorazepam is preferred. Because these are short-acting drugs, we follow their administration with long-acting drugs, such as fosphenytoin. Ongoing administration of IV antiseizure and anesthetic drugs is needed if the seizures are not stopping.[13]

Because many antiseizure drugs (e.g., phenytoin, phenobarbital, ethosuximide, lamotrigine, topiramate) have a long half-life, they can be given once or twice a day. This increases the patient's adherence because the drug does not have to be taken at work or school.

DRUG ALERT

Antiseizure Drugs

- Abrupt withdrawal after long-term use may cause seizures.
- If weaning is to occur, the patient must be seizure free for a prolonged period (e.g., 2–5 years) and have a normal neurologic assessment and EEG.

Side effects of antiseizure drugs involve the CNS. They include vision changes, drowsiness, ataxia, and mental slowness. Neurologic assessment for dose-related toxicity involves testing for nystagmus and evaluating hand and gait coordination, cognitive function, and general alertness.

Gerontologic Considerations: Drug Therapy for Seizure Disorder

Many older adults have a first single seizure, then do not have another seizure. To be considered for antiseizure drug therapy, older adults should have recurrent seizures, an obvious structural predisposition for seizures, or onset of seizure disorder presenting as SE. Older adults are more responsive to antiseizure drugs than younger adults, but they also are more likely to have side effects at lower serum drug levels.

Because the liver metabolizes phenytoin, it should not be used in older patients with liver problems. The potential effects on cognitive function and bone demineralization make carbamazepine less desirable for older adults. Many newer antiseizure drugs offer greater treatment benefit to older adults. Compared with older drugs, gabapentin, lamotrigine, oxcarbazepine (Trileptal), and levetiracetam may be safer, with fewer effects on cognitive function and fewer drug interactions.

Surgical Therapy

People with a defined site of seizure origin (epileptogenic zone) can benefit from surgical resection of that focal area, laser ablation, or radiosurgery over continued use of antiseizure drugs. For severe cases, hemispherectomy can be done. Most HCPs recommend staying on seizure control medication for 2 years after surgery.[13] About 65% of patients are seizure free after surgery, depending on surgery type.[8]

Not all patients benefit from surgery. Extensive preoperative evaluation is important. This includes continuous EEG monitoring and other tests to ensure precise localization of the focal point. Surgical treatment destroys or removes brain tissue, so it is best for seizures that do not arise from critical areas.

Other Therapies

VNS, a form of neuromodulation, is used as an adjunct to drugs when an accessible focal point cannot be identified for surgical removal. The exact mechanism of action is unknown. It may increase blood flow to specific brain areas or raise levels of neurotransmitters. In VNS, a surgically implanted electrode in the neck is programmed to deliver electrical impulses to the CN X at specific intervals or when the pulse elevates. Elevated pulse often occurs with seizures. The patient can also activate the electrode with a magnet if they sense a seizure is imminent. Adverse effects include coughing, hoarseness, dyspnea, and tingling in the neck. Batteries need replaced every 3 to 10 years. Benefits of VNS increase with time.[13] Contraindications include a history of dysrhythmias or sleep apnea.

Responsive neurostimulation (NeuroPace RNS System) is like a pacemaker. It continually monitors the EEG to detect abnormalities, then responds to seizure activity by delivering electrical stimulation to a precise location. The device is placed under the skin, outside the skull, with connections to electrodes over the area of seizure focus. The HCP uses a programmable wand to collect information about seizure activity. This can be used to assess treatment efficacy. This modality is an option for persons who are not surgical candidates or have multiple areas of seizure focus.

DBS consists of electrodes placed by a neurosurgeon in the brain at defined areas. They are connected to a neurostimulator (like a pacemaker) that delivers electrical stimulation at preset cycles, not in response to seizure activity. The device can collect information from the brain that can be used in treatment decisions. Effectiveness improves over time. Other neurostimulators include repetitive transcranial magnetic stimulation.[13]

A ketogenic diet is a special high-fat, low-carbohydrate diet that helps control seizures in some people. A person on this diet makes ketones that pass into the brain, where they replace glucose as an energy source. Meals are carefully planned to restrict the amount of protein and carbohydrate. Patients who take anticoagulants need close monitoring for bleeding. Most people must continue their use of antiseizure medication but may take smaller doses or fewer medications. Seizures may worsen if the diet is stopped abruptly. Long-term effects of the diet are not clear.

NURSING MANAGEMENT: SEIZURE DISORDER

Assessment

Subjective and objective data to obtain from a patient with seizure disorder are outlined in Table 63.9. Obtain data related to a specific seizure episode from a witness.

Clinical Problems

Clinical Problems for the patient with seizure disorder may include:

- Impaired respiratory function
- Difficulty coping
- Risk for injury

Additional information on clinical problems and interventions for the patient with seizure disorder is presented in eNursing Care Plan 63.2 (available on the website for this chapter).

Planning

The overall goals are that the patient with seizure disorder will (1) be free from injury during a seizure, (2) have optimal function while taking antiseizure drugs, and (3) have satisfactory psychosocial function.

Implementation

Health Promotion

Following general safety measures (e.g., wearing helmets to reduce risk for head injury) can prevent some seizure disorders. Improved perinatal care has reduced fetal trauma and hypoxia and thus brain damage leading to seizure disorder.

Help the patient identify events or situations that cause seizures. Provide suggestions for handling them better. The patient should practice good general health habits. Teach them to avoid excess alcohol use, fatigue, and loss of sleep. Help the patient

TABLE 63.9 NURSING ASSESSMENT

Seizure Disorder

Subjective Data

Important Health Information

Health history: Seizures, birth defects or injuries, anoxic episodes. CNS trauma, tumors, or infections. Stroke, metabolic disorders, alcohol use, exposure to metals or carbon monoxide, hepatic or renal failure, fever, pregnancy, SLE

Medications: Adherence to antiseizure medication plan. Barbiturate or alcohol withdrawal. Use or overdose of cocaine, amphetamines, lidocaine, theophylline, penicillin, lithium, phenothiazines, tricyclic antidepressants, benzodiazepines

Functional Health Patterns

Health perception–health management: Family history

Cognitive-perceptual: Headaches, aura, mood, or behavioral changes before seizure. Mentation changes, abdominal pain, muscle pain (postictal).

Self-perception–self-concept: Anxiety, depression. Loss of self-esteem, social isolation

Sexuality-reproductive: Decreased sexual drive, erectile dysfunction. Increased sexual drive (postictal)

Objective Data

Cardiovascular

Hypertension, tachycardia or bradycardia (ictal)

General

Precipitating factors, including severe metabolic acidosis or alkalosis, hyperkalemia, hypoglycemia, dehydration, water intoxication

GI

Bowel incontinence, excessive salivation

Musculoskeletal

Weakness, paralysis, ataxia (postictal)

Neurologic

Generalized Onset

Tonic-clonic: Loss of consciousness, muscle tightening, then jerking. Dilated pupils. Hyperventilation, then apnea. Postictal somnolence

Absence: Altered consciousness (5–30 s), minor facial motor activity

Focal Onset

Aware: Aura. Focal sensory, motor, cognitive, or emotional phenomena (focal motor)

Impaired awareness: Altered consciousness with inappropriate behaviors, automatisms, amnesia of event

Respiratory

Abnormal respiratory rate, rhythm, or depth. Apnea (ictal). Absent or abnormal breath sounds, possible airway occlusion

Skin

Bitten tongue, soft tissue damage, cyanosis, diaphoresis (postictal)

Urinary

Incontinence

Possible Diagnostic Findings

Positive toxicology screen or blood alcohol level. Altered serum electrolytes, acidosis or alkalosis, very low blood glucose, ↑ blood urea nitrogen or serum creatinine, abnormal liver function tests, ammonia; abnormal CT scan or MRI of head, abnormal findings from LP. Abnormal discharges on EEG

handle stress constructively. Maintaining healthy weight and engaging in regular exercise can help manage seizures and other health problems.

Acute Care

Nursing care for a hospitalized patient with seizure disorder or a patient who has had seizures due to other factors involves observation and treatment of the seizure, patient and caregiver teaching, and psychosocial intervention. Provide acute care for the seizure and maintain patient safety (Table 63.10).

CHECK YOUR PRACTICE

You are making your morning rounds and go to check a patient who was admitted the night before with increased seizure activity. When you go to the room, the roommate is yelling, "Help, help!" You find the patient is on the floor jerking and stiffening and not responding to you.

- What should you do?

When a seizure occurs, carefully observe and record details of the event. The diagnosis and subsequent treatment often rest on the seizure description. What events preceded the seizure? When did the seizure occur? How long did each phase (aural [if any], ictal, postictal) last? What occurred during each phase?

Note patient description of aura (if any); the exact onset of the seizure; the course and nature of the seizure activity (awareness, motor movements, automatisms); body parts involved, their sequence of involvement, and autonomic signs, such as dilated pupils, excessive salivation, altered breathing, cyanosis, flushing, diaphoresis, or incontinence. Assessment of the postictal period should include a detailed description of the level of consciousness, vital signs, pupil size and position of the eyes, memory loss, muscle soreness, speech disorders (aphasia, dysarthria), weakness or paralysis, sleep period, and the duration of each sign or symptom.

SAFETY ALERT

Seizure

During a seizure, you should:

- Maintain a patent airway for the patient.
- Protect the patient's head, turn the patient to the side, loosen constrictive clothing, ease patient to the floor (if seated).
- Do not restrain the patient.
- Do not place any objects in the patient's mouth.

After the seizure, the patient may need repositioning to open and maintain the airway, suctioning, and O_2. A seizure can be frightening for the patient and others who witnessed it. Assess

TABLE 63.10 NURSING MANAGEMENT

Care of the Patient With Seizure Disorder

- Initiate safety precautions for the patient at risk for seizures.
- Assess and record details of seizure events, including events preceding the seizure; length of each phase of the seizure; course and nature of seizure activity; and level of consciousness, vital signs, and activity during the postictal period.
- Assess airway patency, and position patient to maintain airway during and after seizures.
- Give IV antiseizure medications to the patient with SE.
- Give oral antiseizure medications as scheduled.
- Make appropriate referrals to community agencies to help the patient with the financial impact of seizure disorder, work training, employment, and living arrangements.
- Provide patient and caregiver teaching (Table 63.11).
- In the ambulatory and home care setting, evaluate patient self-management of medications and lifestyle.
- Supervise AP:
  - Place suction equipment, bag-valve-mask, and O_2 at the patient's bedside.
  - Remove potentially harmful objects from the bedside and pad side rails.
  - Immediately report any seizure activity to the RN.
  - Provide no food or fluid until awake
  - Obtain vital signs during the postictal period.

Collaborate With Other Team Members

Respiratory Therapist

- Assess airway patency and suction as needed.
- Assist ventilations if patient does not breathe spontaneously after seizure.
- Assist with intubation if needed.

Social Worker

- Help patient identify and obtain needed resources.
- Offer counseling to develop positive coping skills.

TABLE 63.11 PATIENT & CAREGIVER TEACHING

Seizure Disorder

Include the following information in the teaching plan for the patient with seizure disorder:

1. Take antiseizure medications as prescribed. Report all drug side effects to the HCP.
2. When needed, blood is drawn to ensure therapeutic drug levels. Schedule regular visits with the HCP to discuss treatment options.
3. Do not add any supplements without HCP approval.
4. Use nondrug techniques, such as relaxation therapy and diet modification, to try to reduce the number of seizures.
5. Be aware of community and online resources for education and help with tracking and explaining seizure activity.
6. Wear a medical alert bracelet or necklace and carry an identification card.
7. Avoid excess alcohol use, fatigue, and loss of sleep.
8. Eat regular meals and snacks in between if feeling shaky, faint, or hungry.
9. Be knowledgeable as a woman of childbearing age about antiseizure medications and contraceptive use.

Caregivers should receive the following information:

Focal-Onset Seizures

1. Stay calm. Guide patient to safety to prevent injury but do not restrain.
2. Observe for asymmetry of activity and focus on specific actions, such as lip smacking and abnormal movements.
3. Assess patient's level of consciousness and ability to converse and respond appropriately.
4. Note the time the seizure started and stopped. Take note of the time of return to baseline.
5. Provide respect and explanation of occurrence.

Generalized-Onset Tonic-Clonic Seizures

1. When seizure occurs outside the hospital setting, activate EMS if (1) the duration is greater than 5 min; (2) events recur without the patient recovering to baseline; (3) the patient is unable to establish a normal breathing pattern, is injured or pregnant; or (4) you do not know if this is a first-time seizure event.
2. Maintain patient safety. Lower the patient to the floor or bed, remove glasses if worn, and loosen restrictive clothing.
3. Do not place anything in the patient's mouth. Patient's teeth/dentures may be damaged. Caregiver may be bitten.
4. Position patient on side (if possible) to improve the patient's ability to drain oral secretions.
5. Note the time the seizure started and stopped. Take note of the time of return to baseline.
6. Assess for any injury and lingering motor weakness.

their level of understanding and provide information about how and why the event occurred. This is an excellent chance for you to discuss any misconceptions about seizures.

◆ Ambulatory Care

Preventing recurring seizures is the major treatment goal. You have a vital role in teaching the patient and caregiver (Table 63.11). Maintaining a seizure diary can be helpful in ongoing management. Encourage the patient to keep regular appointments with the HCP.

Medication nonadherence can be a problem. Take measures to increase adherence to the prescribed drug plan. Help the patient understand that for treatment to be effective, drugs must be taken regularly and consistently. Review details of the drug plan and what to do if a dose is missed. Usually, the dose is made up if the omission is remembered within 24 hours. Caution the patient not to adjust drug dosages without HCP guidance because this can increase seizure frequency and cause SE.

You need to know about drug side effects so you can teach patients and start proper treatment. Review side effects the patient needs to report. For example, common side effects of phenytoin are gingival hyperplasia (excess growth of gingival tissue) and hirsutism, especially in young adults. Good dental hygiene, including regular tooth brushing and flossing, can decrease gingival hyperplasia. If gingival hyperplasia is extensive, gingivectomy may be done and phenytoin replaced with another drug.

Teach caregivers the emergency management of tonic-clonic seizures (Table 63.7). Remind them they do not need to call an ambulance or send a person to the hospital after a single seizure unless the seizure is prolonged (longer than 5 minutes), another seizure immediately follows, injury has occurred, or it is unknown if this was a first-time seizure.

Patients may have concerns or fears related to recurrent seizures, incontinence, or loss of self-control. Support patients

through teaching and by helping them use effective coping mechanisms. Perhaps the greatest challenge is adjusting to any limitations imposed by the illness. Discrimination in employment is a serious problem facing the person with seizure disorder. For issues relating to job discrimination, refer patients to the state department of vocational rehabilitation or the U.S. Equal Employment Opportunity Commission (EEOC).

Help the patient find community resources. Local support groups may be identified through the Epilepsy Foundation (EF). This volunteer agency offers varied services to patients with a seizure disorder (www.epilepsy.com). Refer the patient who is an eligible veteran to a Department of Veterans Affairs medical center that provides comprehensive care. Refer the patient who needs counseling to a community mental health center.

Social workers and government programs can help with financial implications and living arrangements. State agencies specializing in vocational rehabilitation services can provide vocational assessment, counseling, and funding for training. They can help with job placement for patients whose seizures are not well controlled. Financial assistance for transportation and medical costs may be available.

Driving laws for patients who have had a seizure vary from state to state. They may require up to a year seizure free before reissuing a driver's license. The EF provides current information on driving laws for each state.

Medical alert bracelets, necklaces, and identification cards are available through the EF, local pharmacies, or companies specializing in identification devices (e.g., Medic Alert). Using medical identification is optional.

Encourage the patient to learn more about seizures through self-education. Many organizations and agencies that offer services to patients with seizure disorder offer teaching aids and support.

◆ Evaluation

Expected outcomes are that the patient with seizure disorder will:

- Have a breathing pattern adequate to meet O_2 needs
- Have no seizure-related injury
- Perform optimal-self management

RESTLESS LEGS SYNDROME

Etiology and Pathophysiology

Restless legs syndrome (RLS) *(Willis-Ekbom disease)* is a movement disorder with unpleasant sensory (paresthesia) and motor abnormalities of 1 or both legs. It is a relatively common sleep problem. Around 3% to 8% of the U.S. population has RLS.[19] RLS is more common in older adults and in women. RLS is lifelong and has no cure. Symptoms may disappear for a while, but they eventually reappear.[20]

There are 2 types of RLS: primary (idiopathic) and secondary. Most people have primary RLS. Secondary RLS can occur with metabolic problems from iron deficiency, renal disease and hemodialysis, or neuropathy as in MS. Many pregnant women develop RLS. Symptoms may be worsened by sleep deprivation, sleep apnea, stress, sedentary lifestyle, obesity, alcohol, nicotine, caffeine use, diabetes, peripheral neuropathy, and some medications (antihistamines, antiemetics, lithium, and some antipsychotics).[19,20] RLS has a genetic link. Those with primary RLS, especially those with an onset before 40 report family links.[21]

We do not know the exact cause of primary RLS. It may be a problem in the brain's basal ganglia circuits that use the neurotransmitter dopamine (DA). DA helps with smooth and purposeful movements. Disruption in these pathways can cause involuntary movement. We think DA levels fall throughout the day, and this causes muscle spasm and involuntary movement.[21]

Clinical Manifestations

The severity of RLS sensory symptoms ranges from infrequent minor discomfort (numbness, tingling, "pins and needles") to severe pain. A small number have severe symptoms that affect their quality of life and need drug therapy. Sensory symptoms often appear first. Patients describe a tingling, itching, "creepy-crawling," or throbbing feeling in their calf muscle, accompanied by an irresistible urge to move.[20] Symptoms most often begin when the patient is inactive or lying still. It is most common at night. Some patients have pain after sitting long periods. Patients can have pain in the arms too.[19]

Pain at night can disrupt sleep. Physical activity, such as walking, stretching, rocking, or kicking, often relieves the pain. In severe cases, patients sleep only a few hours at night. This causes daytime fatigue and disrupts the daily routine. Motor problems include voluntary restlessness and periodic, involuntary movements. Fatigue worsens symptoms. RLS worsens over time. Symptoms become more frequent and last longer.

Diagnostic Studies

RLS is diagnosed largely based on the history or the report of the bed partner about nighttime activities. The HCP may ask the patient to keep a sleep diary to aid in diagnosis and treatment. Diagnosis of RLS can be made when the patient meets 5 specific criteria: (1) overwhelming urge to move the legs, often accompanied by uncomfortable or unpleasant sensations in the legs; (2) urge to move the legs worsens during rest or inactivity; (3) urge to move the legs is partially or totally relieved by movement, as long as the activity continues; (4) urge to move the legs becomes worse in the evening or night; and (5) these features are not due to another problem.[22]

The patient may have polysomnography studies during sleep to discern RLS from other problems that can disturb sleep. Periodic leg movements are not exclusive to RLS. Blood tests, such as a CBC, serum ferritin, and renal function tests, may help exclude secondary causes of RLS. A patient with diabetes may have paresthesia caused by peripheral neuropathy.

Interprofessional Care

The goal of care is to reduce patient discomfort and distress and improve sleep quality. When RLS is due to renal failure or iron deficiency, treating these problems may decrease symptoms. Lifestyle changes may help persons with mild to moderate RLS. For example, decreasing the use of caffeine, alcohol, or tobacco; maintaining regular sleep habits; exercising; relaxation

techniques; and massaging and stretching the legs may be helpful. The patient should avoid antihistamine-containing medications (e.g., diphenhydramine).

If nondrug measures fail, drug therapy is an option. No specific medication effectively manages RLS for all patients. The main drugs used to treat RLS increase the amount of DA in the brain. DA agonists (e.g., ropinirole [Requip], pramipexole [Mirapex], rotigotine [Neupro]) can treat pain and provide more restful sleep. These drugs can cause impulse disorders (gambling, shopping).[20]

The antiseizure drugs gabapentin, enacarbil (Horizant), or pregabalin are first-line drugs for RLS. They may decrease the sensory sensations and nerve pain. The patient with iron deficiency anemia may need to start iron supplements. Other supplements that may help RLS include magnesium, zinc, and vitamin D.[20]

Other drugs may relieve some symptoms of RLS. Very low doses of opioids (e.g., oxycodone) may help patients with severe symptoms who do not respond to other drug therapies. Since the main side effect of opioids is constipation, the patient may need a stool softener or laxative. Clonidine and propranolol help some patients. Short-acting benzodiazepines (e.g., clonazepam, lorazepam) may help patients obtain more restful sleep. They should only be used if no other treatments work.[20]

Medical devices approved for use with RLS include a foot wrap that applies pressure to the foot and lower leg and a vibration and counter stimulation device (Relaxis) that competes with and decreases RLS sensations. Some HCPs recommend pneumatic compression devices.[20]

DEGENERATIVE NEUROLOGIC DISORDERS

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is a chronic, unpredictable, progressive, degenerative disorder of the CNS. It is characterized by disseminated demyelination of nerve fibers of the brain and spinal cord. MS can affect people of any age. The onset of MS is usually between ages 20 and 40 years. MS affects every patient differently. Some will have little permanent effect while others have progressive illness leading to severe disability.[23] People diagnosed at 50 years of age or older often have more progressive disease. MS affects women 2 to 3 times more often.

Almost a million people are living with MS in the United States. MS becomes more prevalent further away from the equator. MS effects people of all ethnic groups but is most prevalent in people of Northern European ancestry.[24] There is some evidence that maintaining adequate levels of vitamin D reduces the risk of MS.

Etiology and Pathophysiology

We do not know the cause of MS. It is unlikely due to a single cause, but a combination of genetic and environment factors. The primary problem is an autoimmune process driven by activated T cells. 15% of MS patients have a blood relative with the disease. We have found over 230 genetic variables that play a small part in MS risk.[13]

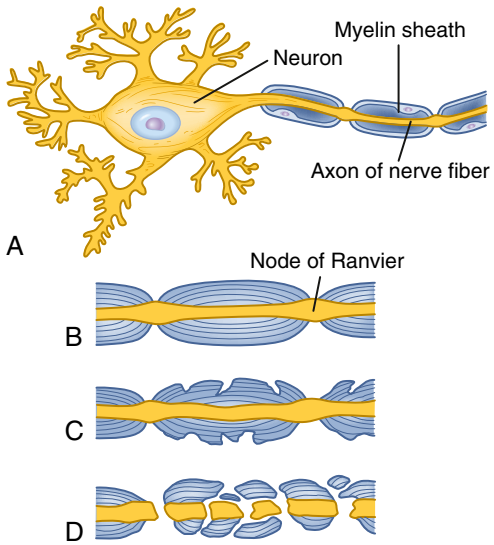

Fig. 63.2 Pathogenesis of multiple sclerosis. (A) Normal nerve cell with myelin sheath. (B) Normal axon. (C) Myelin breakdown. (D) Myelin totally disrupted; axon not functioning.

MS may develop in a genetically susceptible person after an environmental exposure, such as a viral infection. Some viral proteins are structurally similar to myelin. We believe viruses or other antigens activate T Cells, although we have not found a causative virus. The T cells cross the blood-brain barrier and begin the inflammatory process. T cells mistake the myelin protein for the viral antigen. Successive antigen-antibody reactions within the CNS activates the inflammatory response and lead to further demyelination and destruction.

MS is marked by 3 processes: chronic inflammation, demyelination, and gliosis in the CNS. The immune system attack on the myelin proteins causes damage to the myelin sheath (Fig. 63.2A–C). Transmission of nerve impulses still occurs, but it is slowed. The patient may have impaired function (e.g., weakness, numbness). Inflammation ceases and full recovery or partial recovery can occur. Symptoms all or partially disappear. At that point, the patient has a remission.

As inflammation continues or recurs, nearby oligodendrocytes are affected. Myelin loses the ability to regenerate. Eventually damage occurs to the underlying axon. This disrupts nerve impulse transmission. Nerve function is lost permanently (Fig. 63.2D). White, grey, and axonal matter are all eventually effected. As inflammation subsides, glial scar tissue replaces damaged tissue. This leads to the formation of hard, rigid plaques (Fig. 63.3). These plaques are found throughout the white matter of the CNS.[8] In late disease cerebral cortex atrophy occurs.

MS reduces life expectancy by about 7 years.[13] Often, death does not come from MS exacerbations. It is usually caused by infection or complications of immobility (e.g., pneumonia).

Clinical Manifestations

The onset of MS is often slow and gradual. Vague symptoms occur periodically over months or years. Because they do not prompt the patient to seek medical attention, MS may not be diagnosed until long after the first symptom. For some patients,

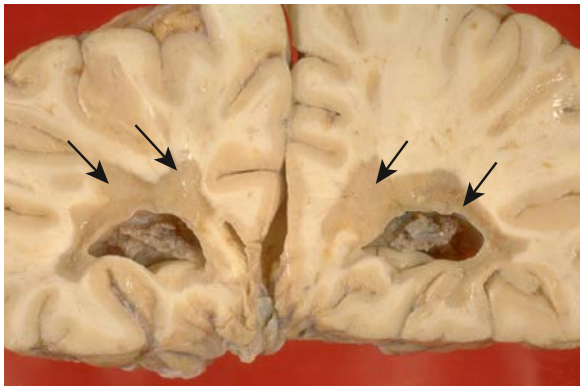

Fig. 63.3 Plaque lesions *(arrows)* from multiple sclerosis. (From Vanderah TW: *Nolte's the human brain in photographs and diagrams*, ed 5, St. Louis, 2020, Elsevier.)

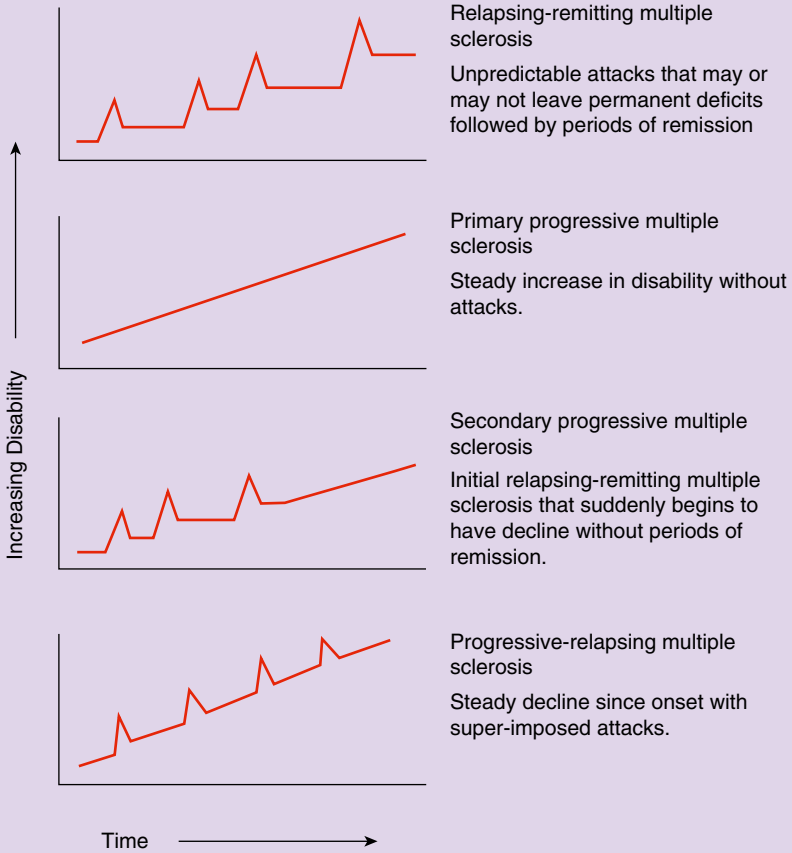
MS is marked by rapid, progressive deterioration. Others have remissions and exacerbations. With repeated exacerbations, the overall trend is progressive deterioration in neurologic function.

Because changes from MS have a spotty distribution in the CNS, symptoms vary based on the area of CNS involvement. Some patients have severe symptoms early in the disease. Some may have minimal symptoms for several years. The classification scheme of MS, with 4 primary patterns, is based on the clinical course (Table 63.12).

Vision changes like blurred or double vision, red-green color distortion, or blindness in 1 eye may be the first sign (Fig. 63.4). Many patients describe extremity muscle weakness and problems with coordination and balance. Those symptoms may affect walking or standing. MS can cause partial or complete paralysis in the worst cases. Most have numbness and tingling.

TABLE 63.12 Patterns of Multiple Sclerosis

Category	Characteristics
Relapsing-remitting	• Clearly defined attacks of worsening neurologic function *(relapses)* with partial or complete recovery *(remission).* • 85% of people first diagnosed with this type.
Primary-progressive	• Steadily worsening neurologic function from the beginning with minor improvements but no distinct relapses or remissions. • 10% of people first diagnosed with this type.
Secondary-progressive	• A relapsing-remitting initial course, followed by progression with or without occasional relapses, minor remissions, and plateaus. • New treatments may slow progression. • Most people initially diagnosed with relapsing-remitting MS eventually transition to this type.
Progressive-relapsing	• Progressive disease from onset, with clear acute relapses, with or without full recovery. Periods between relapses are characterized by continuing progression. • 5% of people with MS.



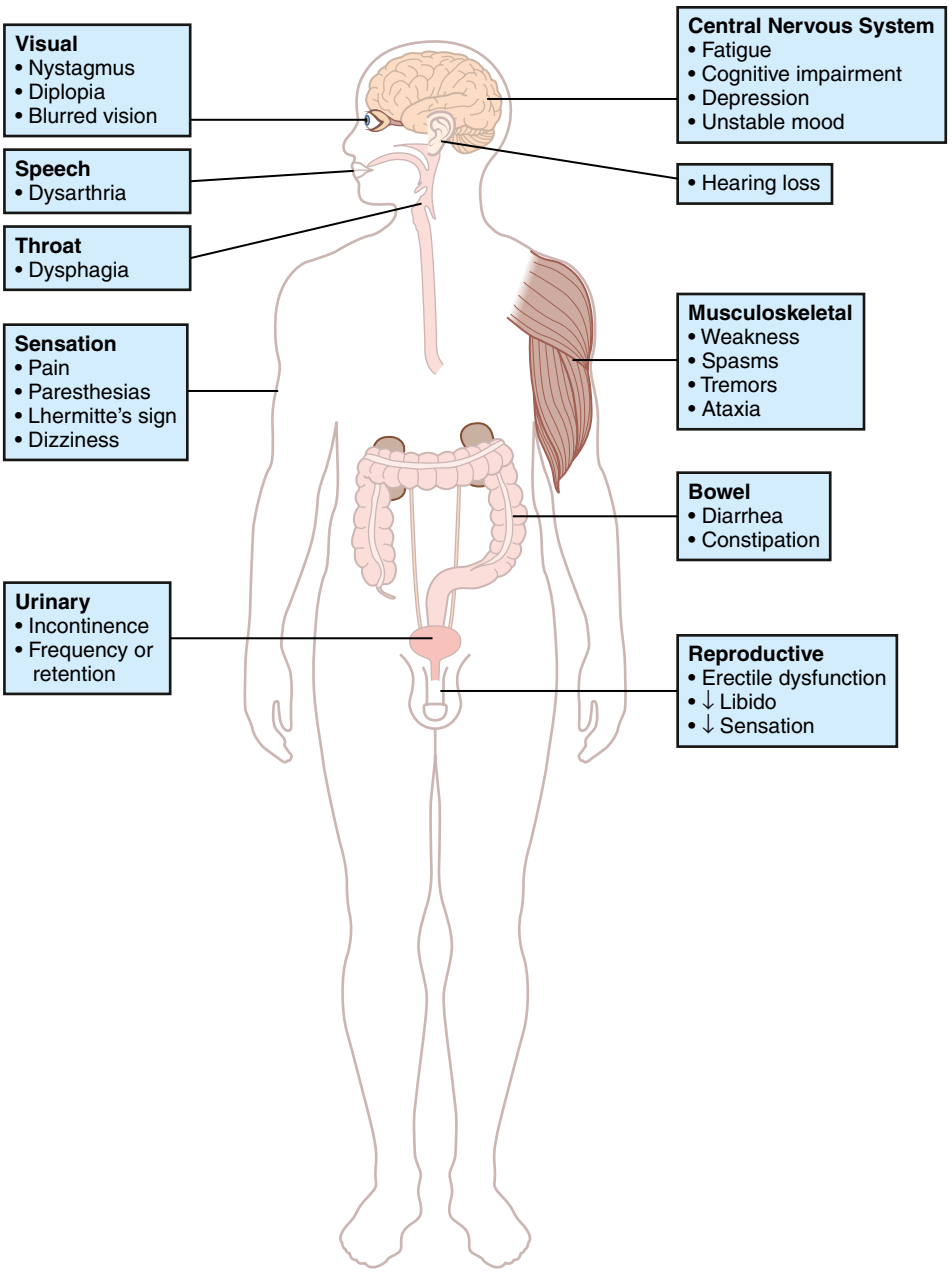


Fig. 63.4 Manifestations of multiple sclerosis.

Lhermitte's sign is a temporary sensory symptom described as an electric shock going down the spine or into the limbs with neck flexion. Some patients report pain, especially around the low thoracic and abdominal regions. Labeled the "MS hug," this is from muscle spasm in intercostal and abdominal muscles. Other frequent problems include speech problems, hearing loss, tremors, and dizziness. Possible cerebellar signs include nystagmus, ataxia, dysarthria, and dysphagia. Many patients have severe, even disabling fatigue. Heat, humidity, deconditioning, and medication side effects worsen fatigue.

A rigid plaque in areas of the CNS that control elimination can alter bowel and bladder function. Bowel problems usually involve constipation. Urinary problems vary. A common problem is *spastic* (uninhibited) bladder. The bladder has a small capacity for urine, and its contractions are unchecked. The result is urinary urgency and frequency, often with dribbling or incontinence.

A *flaccid* (hypotonic) bladder occurs with a lesion in the reflex arc controlling bladder function. The patient often has urinary retention because there is no sensation or desire to void, no pressure, and no pain. A combination of spastic and flaccid bladder can occur. Urinary problems can be diagnosed with urodynamic studies.

Sexual problems occur in many people. Physiologic erectile dysfunction may result from spinal cord involvement in men. Women may have decreased libido, difficulty with orgasm, painful intercourse, and decreased vaginal lubrication. Decreased sensation can prevent a normal sexual response. The emotional effects of chronic illness and the loss of self-esteem contribute to loss of sexual response. Some women with MS have remission

TABLE 63.13 Interprofessional Care

Multiple Sclerosis

Diagnostic Assessment

- History and physical assessment
- CSF analysis
- CT scan
- MRI, MRS (magnetic resonance spectroscopy)
- Evoked potential testing
- Somatosensory evoked potential (SSEP)
- Auditory evoked potential (AEP)
- Visual evoked potential (VEP)

Management

- Drug therapy
  - Disease modifying drugs (Table 63.14)
  - Corticosteroids
  - Symptom specific drugs
- Surgical therapy
- Thalamotomy (unmanageable tremor)
- Neurectomy, rhizotomy, cordotomy (unmanageable spasticity)
- Physical therapy
- Occupational therapy

or an improvement in symptoms during pregnancy. Hormonal changes with pregnancy appear to affect the immune system.

About half of people with MS have problems with 1 or more domains of cognitive function. Most involve problems with multitasking, concentration, short-term memory, speed of processing, and word finding. General intellect stays unchanged. There may be emotional changes, such as anger, depression, or euphoria.

Diagnostic Studies

No one specific diagnostic test for MS exists. The history and manifestations are important. An MRI with contrast of the brain and spinal cord may show plaques, inflammation, atrophy, and tissue destruction. CSF analysis may show an increase in immunoglobulin G and the presence of oligoclonal banding. These items indicate inflammation in the spinal fluid. Evoked potential responses are often delayed because of decreased nerve conduction from the eye and ear to the brain.[13]

Diagnostic criteria for MS specify that the patient must have (1) evidence of at least 2 inflammatory demyelinating lesions in at least 2 different locations within the CNS, (2) 2 or more attacks occurring at different times (usually 1 month or more apart), and (3) all other diagnoses ruled out. If evidence exists for only 1 lesion or only 1 clinical attack has occurred, the HCP will monitor the patient for another attack or confirm the presence of oligoclonal banding in the CSF.[13]

Interprofessional Care

No cure currently exists for MS. Care is aimed at treating the disease process and providing symptomatic relief (Table 63.13). No cases of MS are alike. We tailor therapy to the disease pattern and symptoms of each patient.

Drug Therapy

Table 63.14 shows common drugs used to treat MS. Disease-modifying drugs (DMDs) suppress the immune system in order to modify disease progression and prevent relapses. DMDs are more effective when started early in the course of MS. Delays in treatment are linked to poor outcomes.

DMDs include interferons, monoclonal antibodies, and synthetic agents. Treatment often begins with use of immunomodulator drugs. These drugs include interferon β-1a (Rebif, Plegridy, Avonex), interferon β-1b (Betaseron, Extavia), and glatiramer acetate (Copaxone, Glatopa).

DRUG ALERT

β-Interferon

- Assess for depression and suicidal thoughts.
- Teach patient to wear sunscreen and protective clothing when exposed to sun.
- Tell the patient that flu-like symptoms are common after starting therapy.

Teriflunomide (Aubagio) is an immunomodulatory agent with antiinflammatory properties. It can cause life-threatening liver toxicity. Fingolimod (Gilenya), ponesimod (Ponvory), and siponimod (Mayzent) reduce disease activity by preventing lymphocytes from reaching the CNS and causing damage. Cladribine (Mavenclad) is a cytotoxic agent taken orally in 2 cycles a year. Cancer risk increases with cladribine. Dimethyl fumarate (Tecfidera) helps the body defend itself against the inflammation and oxidative stress caused by MS. Dimethyl fumarate and fingolimod can cause a fatal viral brain infection, progressive multifocal leukoencephalopathy (PML).[25]

For more active forms of MS, IV monoclonal antibodies may suppress immunologic activity. These include natalizumab (Tysabri), alemtuzumab (Lemtrada), and ocrelizumab (Ocrevus). Due to the risk for PML and other side effects, these are only given to patients who had an inadequate response to other treatments. Ocrelizumab is approved for relapsing remitting and progressive forms of MS. It slows disease progression and improves symptoms. Ocrelizumab increases the risk for infection and breast cancer.[25]

IV corticosteroids (e.g., prednisone) can be used to treat acute MS exacerbations. They reduce edema and acute inflammation at the site of demyelination. They speed recovery, but do not affect the residual neurologic impairment from the exacerbation.[23] Therapeutic plasma exchange (plasmapheresis) and IV immunoglobulin G may be considered for a short time when treatment with corticosteroids alone does not achieve symptom improvement.

Many other drugs are used to treat the various MS symptoms. These may include drugs for spasticity, fatigue, tremor, vertigo or dizziness, depression, pain, bowel and bladder problems, sexual problems, and cognitive changes. For example, amantadine, modafinil (Provigil), and fluoxetine (Prozac) are used to treat fatigue. Anticholinergics (oxybutynin, propantheline) can treat bladder spasms. Tricyclic antidepressants and antiseizure drugs help with chronic pain. Dalfampridine

TABLE 63.14 Drug Therapy

Disease-Modifying Drugs for Multiple Sclerosis

Drug	Considerations
Injectable	
β-1a interferon (Rebif, Plegridy, Avonex)	• Teach self-injection techniques. • Rotate injection sites. • Report side effects. • Treat flu-like symptoms with an NSAID or acetaminophen. • Monitor for depression.
β-1b interferon (Betaseron, Extavia)	
glatiramer acetate (Copaxone, Glatopa)	• Teach self-injection techniques. • Monitor liver function tests.
ofatumumab (Kesimpta)	• Teach self-injection techniques. • Avoid pregnancy • Monitor liver function tests.
Oral Agents	
cladribine (Mavenclad)	• Avoid pregnancy. • No contact with large crowds and people who have an infection. • Follow cancer screening guidelines. • Monitor liver tests.
dimethyl fumarate (Tecfidera)	• Report side effects
fingolimod (Gilenya)	• Report side effects. • Monitor BP and heart rate regularly. • Avoid pregnancy.
monomethyl fumarate (Bafiertam)	• Report side effects. • Avoid pregnancy.
ponesimod (Ponvory)	• Report side effects. • Avoid pregnancy.
siponimod (Mayzent)	• Report side effects. • Monitor blood pressure and heart rate regularly. • Avoid pregnancy.
teriflunomide (Aubagio)	• Report side effects. • Avoid pregnancy. • No contact with large crowds and people who have an infection. • Monitor liver function tests.
IV infusions	
alemtuzumab (Lemtrada)	• Report side effects.
natalizumab (Tysabri)	• Avoid pregnancy.
ocrelizumab (Ocrevus)	• Monitor for infusion-related reactions. • Follow cancer screening guidelines.

(Ampyra) may improve walking speed.[23] It is a selective potassium channel blocker that improves nerve conduction in damaged nerve segments. Use may cause seizures, especially at higher doses. Bethanechol is a common treatment for urinary retention.

Other Therapies

Spasticity is a major problem for patients with MS. Severe muscle spasticity can be treated with stretching, physical therapy, baclofen, intrathecal pumps, or onabotulinumtoxin A (Botox).[23] Other options include surgery (e.g., neurectomy, rhizotomy, cordotomy) or dorsal-column electrical stimulation. Tremors that become unmanageable with drugs can be treated with thalamotomy or DBS.

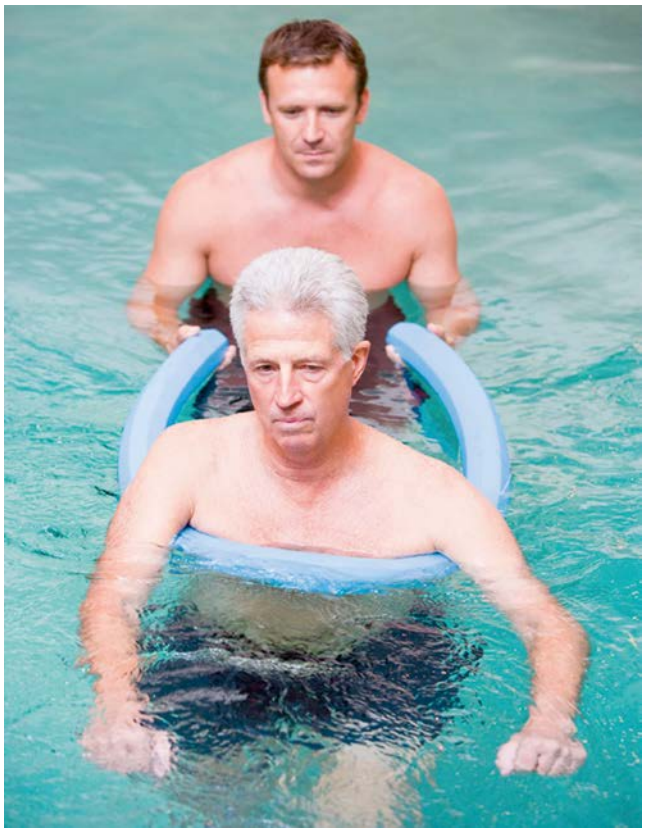

Fig. 63.5 Water therapy provides exercise and recreation for the patient with a chronic neurologic disease. (© Photos.com/AbleStock.com/Thinkstock.)

Neurologic problems sometimes improve with physical therapy. Exercise improves daily function for patients not having an exacerbation. Exercise decreases spasticity, increases coordination, and retrains unaffected muscles to act for impaired ones. Water exercise is especially beneficial (Fig. 63.5). Water, which gives buoyancy to the body, allows the patient to have more control and perform activities that would otherwise be impossible.

❖ NURSING MANAGEMENT: MULTIPLE SCLEROSIS

◆ Assessment

Subjective and objective data that you should obtain from a patient with MS are outlined in Table 63.15.

◆ Clinical Problems

Clinical problems for the patient with MS may include:

- Musculoskeletal problems
- Fatigue
- Difficulty coping
- Impaired urinary elimination

Additional information on clinical problems and interventions for the patient with MS is presented in the eNursing Care Plan 63.3 (available on the website for this chapter).

TABLE 63.15 NURSING ASSESSMENT

Multiple Sclerosis

Subjective Data

Important Health Information

Health history: Recent or past viral infections or vaccinations, other recent infections, residence in cold or temperate climates, physical or emotional stress, pregnancy, exposure to extremes of heat and cold

Medications: Adherence to treatment plan (corticosteroids, immunomodulators, immunosuppressants, cholinergics, anticholinergics, antispasmodics)

Functional Health Patterns

Health perception–health management: Positive family history; malaise

Nutritional-metabolic: Weight loss; difficulty in chewing, dysphagia

Elimination: Urinary frequency, urgency, dribbling or incontinence, retention; constipation

Activity-exercise: Generalized muscle weakness, muscle fatigue; tingling and numbness; ataxia (clumsiness)

Cognitive-perceptual: Eye, back, leg, joint pain; painful muscle spasms; vertigo; blurred or lost vision; diplopia; tinnitus

Sexuality-reproductive: Impotence, decreased libido

Coping–stress tolerance: Anger, depression, euphoria, social isolation

Objective Data

General

Apathy, inattentiveness

Musculoskeletal

Muscle weakness, paresis, paralysis, spasms, foot dragging, dysarthria

Neurologic

Nystagmus, ataxia, tremor, spasticity, hyperreflexia, decreased hearing

Skin

Pressure injury

Possible Diagnostic Findings

↓ T suppressor cells, demyelinating lesions on MRI or MRS scans, ↑ IgG or oligoclonal banding in CSF, delayed evoked potential responses

Planning

The overall goals are that the patient with MS will (1) maximize neuromuscular function, (2) maintain independence in activities of daily living (ADL) for as long as possible, (3) manage fatigue, (4) optimize psychosocial well-being, (5) adjust to the illness, and (6) reduce factors that trigger exacerbations.

Implementation

The patient with MS should be aware of triggers that may cause worsening of the disease. These include infection, trauma, live virus immunizations, childbirth, stress, and change in climate. Each person responds differently to triggers. Help the patient identify triggers and develop ways to avoid them or decrease their effects. Becoming overheated worsens symptoms of MS. If the patient lives in a warm climate, cooling vests may help maintain function. Avoiding the midday heat will help manage symptoms in the summer.

During the diagnostic phase, reassure the patient that tests are done to rule out other neurologic disorders, even if a tentative diagnosis of MS has been made. Help the patient to deal with anxiety caused by the diagnosis of a disabling illness. The patient with newly diagnosed MS may need support with the grieving process.

During an acute exacerbation, the patient may be immobile and confined to bed. The focus of nursing care at this phase is to prevent complications of immobility. These include respiratory complications, UTIs, and pressure injuries. Visual symptoms may make driving, reading, performing self-care, and even watching television difficult. Preparation for unexpected exacerbations can make coping with the physical changes easier.

Bladder control is a concerning and potentially embarrassing problem. Drug therapy may help some patients. You may need to teach self-catheterization. Constipation is common. Stress a diet high in fiber and maintaining activity.

Discuss ways to reduce illness. This includes avoiding fatigue, extremes of heat and cold, and exposure to infection. Encourage early treatment of infection when it occurs. Teach the patient to seek a good balance of exercise and rest. They should minimize caffeine intake and eat a healthy diet. The patient should know the treatment plan, drug side effects, how to identify and manage side effects, and drug interactions. Teach the patient to notify the HCP at the first signs of exacerbation.

The patient and caregivers must make many emotional adjustments because of disease unpredictability, the need for lifestyle changes, and the challenge of avoiding or decreasing precipitating factors. The uncertainty of disease progression, along with fatigue and decreased mobility, can cause anxiety and depression. The National Multiple Sclerosis Society and its local chapters offer a variety of services to meet the needs of patients with MS.

Evaluation

The expected outcomes are that the patient with MS will:

- Maintain or improve muscle strength and mobility
- Maintain urinary continence
- Make decisions about health and lifestyle modifications to manage MS
- Maintain independence in ADL

PARKINSON DISEASE

Parkinson disease (PD) is a chronic, progressive neurodegenerative disorder characterized by slowness in the initiation and execution of movement *(bradykinesia),* increased muscle tone *(rigidity),* tremor at rest, and gait changes. It is the most common form of *parkinsonism*, a syndrome of several disorders characterized by similar symptoms.

Almost 1 million Americans are living with PD in the United States. Around 60,000 persons are diagnosed each year. Occurrence of PD increases with age, with average age of onset around 70 years. Around 4% of people with PD are diagnosed before age 50 years. Men are 1.5 times more likely to have PD.[26]

Etiology and Pathophysiology

We do not know the exact cause of PD. We think it is an interplay of genetic and environment risk factors. Traumatic brain injury has been shown to increase the risk of PD. Exposure to

industrial manganese, pesticides, herbicides (paraquat), industrial solvents, and chemicals (polychlorinated biphenyl) may increase risk.[27]

Parkinsonism is a syndrome made up of disorders that mimic PD. Many forms of secondary *(atypical)* parkinsonism exist. Because of the similarity, PD and parkinsonism can be confused. Symptoms of parkinsonism have occurred after exposure to a variety of chemicals and metals. Drug-induced parkinsonism can follow therapy with metoclopramide, methyldopa, lithium, haloperidol, or chlorpromazine. It can be seen after the use of illicit drugs like methamphetamine. After removing the cause, symptoms of parkinsonism often disappear. Other causes include hydrocephalus, neurodegenerative disorders, hypoparathyroidism, infections, stroke, tumor, and trauma.

The changes in PD occur in many areas of the brain. There is degeneration of the DA-producing neurons in the substantia nigra of the midbrain (Figs. 63.6 to 63.8). This disrupts the normal balance between DA and acetylcholine (ACh) in the basal ganglia. DA is essential for normal function of the extrapyramidal motor system, including control of posture, support, and voluntary motion. Initial symptoms of PD do not occur until 60% to 80% of DA-producing neurons are lost.[28] Signals to the corpus striatum, which causes smooth and purposeful movement, are impaired. The loss of nerve endings that make norepinephrine also influence symptoms of PD.

Unusual clumps of protein called *Lewy bodies* are found in the brains of patients with PD.

We do not know what causes Lewy bodies to form. Their presence indicates abnormal brain function. Lewy body dementia is discussed in Chapter 64.

Genetic Link

We do not fully understand how genetic changes cause PD or influence the risk for developing PD. Around 20% to 25% of patients with PD have a family history of PD.[13] Several gene mutations have been linked to various forms of PD. These genes include SNCA, LRRK2, DJ1, PRKN, PINK1, and GBA. Despite these discoveries, causative genes have only been found in 10% of PD patients. Genetics plays a larger role in early onset PD. Up to 50% of those with disease onset before 50 have PARK2 mutations.[13]

Clinical Manifestations

The onset of PD is gradual, with ongoing progression. Only 1 limb or 1 side of the body may be involved at first. Common

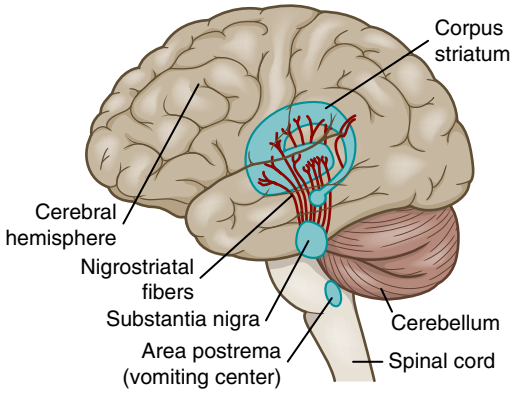

Fig. 63.6 Nigrostriatal disorders produce parkinsonism. Left-sided view of the human brain showing the substantia nigra and the corpus striatum *(shaded area)* lying deep within the cerebral hemisphere. Nerve fibers extend upward from the substantia nigra, divide into many branches, and carry dopamine to all regions of the corpus striatum.

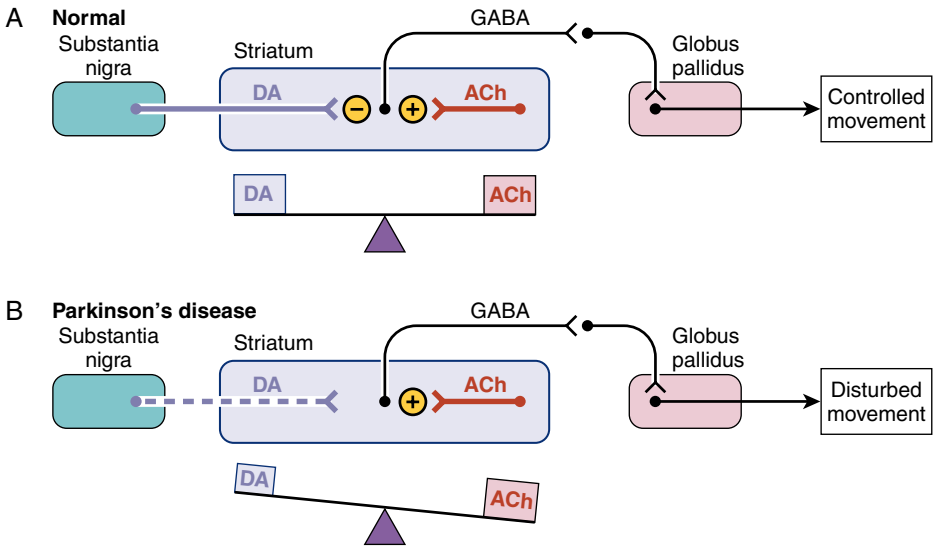

Fig. 63.7 A deficit in dopamine *(DA)* exists in PD. This deficit creates an imbalance between DA and the excitatory neurotransmitter acetylcholine *(ACh)*. (A) In a healthy person, DA released from neurons in the substantia nigra inhibits the firing of neurons in the striatum that release γ-aminobutyric acid *(GABA)*. Conversely, neurons in the striatum, which release ACh, excite the GABAergic neurons. Under normal conditions, inhibitory actions of DA are balanced by excitatory actions of ACh, and controlled movement results. (B) In PD, neurons in the substantia nigra that supply DA to the striatum degenerate. When a deficit of DA occurs, excitatory effects of ACh go unopposed and disturbed movements (tremor, rigidity) result. (From Lehne RA: *Pharmacology for nursing care,* ed 8, St Louis, 2013, Saunders.)

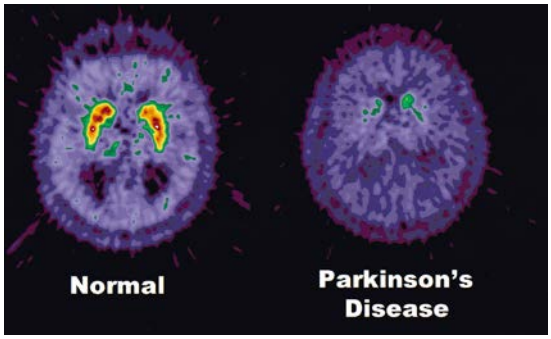

Fig. 63.8 In PD, PET scan showing reduced fluorodopa uptake in the basal ganglia *(right)* compared with a normal control *(left)*. (From Aminoff MJ, Daroff RB: *Encyclopedia of the neurological sciences,* Waltham, MA, 2003, Academic Press.)

manifestations are tremors, rigidity, bradykinesia, and postural instability.[28] Early in the disease, only a mild tremor, a flattened affect, slowing of ADLs (dressing, feeding), or decreased arm swing may be seen. Shoulder rigidity may be mistaken for arthritis. Later, the patient may have a shuffling gait and appear unable to stop. There may be speech problems *(hypokinetic dysarthria)* that affect communication.

Tremor

Tremor is often the first sign. Parkinsonian tremor is more prominent at rest and lessens with purposeful movement (*nonintention tremor*). It is worsened by stress or increased concentration. The hand tremor is described as "pill rolling" because the thumb and forefinger appear to move in a rotary fashion as if rolling a pill or coin. This tremor can affect handwriting, causing it to trail off toward the ends of words. Tremor can involve the diaphragm, tongue, lips, and jaw.

Some people have a benign *essential tremor* that is mistakenly diagnosed as PD. Essential tremor occurs during voluntary movement. It is not neurodegenerative and is usually familial.

Rigidity

Rigidity is the increased resistance to passive motion when the limbs are moved through their range of motion (ROM). Parkinsonian rigidity has a jerky quality *(cogwheel rigidity),* as if there were occasional catches in the passive movement of a joint. Sustained muscle contraction causes the patient to feel stiff with muscle soreness, feeling tired and achy. The muscles do not relax. They may cause the patient to have pain in the head, upper body, spine, or legs. Slow movement is another result of rigidity because the alternating contraction and relaxation in opposing muscle groups (e.g., biceps and triceps) is inhibited. Rigidity is partially responsible for symptoms including mask face, lack of arm swing, difficulty getting out of chairs, and trouble with buttoning clothing.

Bradykinesia

In PD, bradykinesia (slowness of movement) is present in both spontaneous and automatic movements. All movement is slower. Tasks that were once easy are now frustratingly slow. Bradykinesia is due to the decreased impulses from the basal ganglia. In the unaffected person, automatic movements are

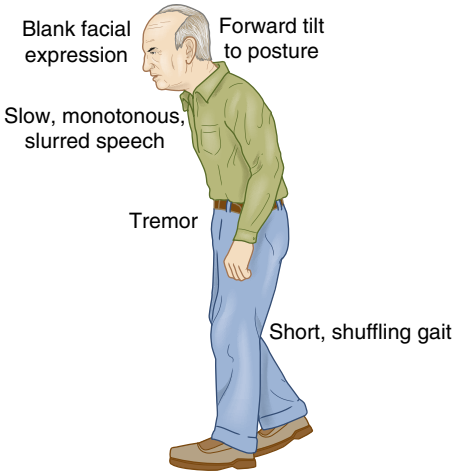

Fig. 63.9 Characteristic appearance of a patient with PD.

involuntary and occur subconsciously. They include blinking of the eyelids, swinging of the arms while walking, swallowing saliva, using facial and hand movements, and making minor movements to adjust posture. The patient with PD lacks this natural activity. This accounts for the stooped, bent forward posture, masked face (deadpan expression), drooling of saliva, and shuffling gait (festination) that are typical of a person with PD (Fig. 63.9).

Postural Instability

Postural instability is common. Patients may describe being unable to stop themselves from going forward *(propulsion)* or backward *(retropulsion)*. This increases their risk of falling. Assessment of postural instability includes the "pull test." The examiner stands behind the patient and gives a tug backward on the shoulder, causing the patient to lose their balance and fall backward.

Nonmotor symptoms are common and can be very disturbing. They include depression, anxiety, apathy, fatigue, inability to plan, poor attention, pain, urinary incontinence, constipation, erectile dysfunction, and memory changes. Problems with eating include early satiety and loss of taste. Patients have trouble communicating due to a lack of expressive voice and low volume (hypophonia).[28] Sleep problems are common. They include difficulty staying asleep at night, restless sleep, nightmares, and excessive daytime sleepiness. Rapid eye movement (REM) sleep behavior disorder occurs in about one-third of patients with PD. Violent dreams and potentially dangerous motor activity during REM sleep can occur.[32]

Complications

As PD progresses, complications increase. Swallowing becomes more difficult (dysphagia) and malnutrition or aspiration may result. Increasing weakness may lead to immobility problems. Orthostatic hypotension is common. Along with loss of postural reflexes, it can cause falls or other injury. The increased fall risk means caregivers must be aware of environment conditions that may contribute to falls.

Other complications include dyskinesias (spontaneous, involuntary movements), weakness, and neuropsychiatric

problems (e.g., depression, hallucinations). Dementia often results. It is associated with increased mortality.

Diagnostic Studies

No specific diagnostic test exists for PD. The diagnosis is based on the history and clinical features. Clinical diagnosis requires the presence of 2 of the 4 main manifestations (tremor, rigidity, bradykinesia, and postural instability) and asymmetric onset. Disease is confirmed with a positive response to antiparkinsonian drugs (levodopa or DA agonist). MRI and CT are usually normal in PD. They will be done to rule out other diagnosis. DaTscan, a special CT scan, may be done to detect DA function in the brain and distinguish PD from similar diseases.[29]

Interprofessional Care

Because PD has no cure, care focuses on symptom management (Table 63.16).

Drug Therapy

Table 63.17 outlines the drugs commonly used in PD. Drug therapy for PD is aimed at correcting the imbalance of neurotransmitters within the CNS. Antiparkinsonian drugs either enhance the release or supply of DA (dopaminergic) or block the effects of the overactive cholinergic neurons in the striatum (anticholinergic) (Fig. 63.7).

Drug doses are carefully adjusted. Excess amounts of dopaminergic drugs can worsen rather than relieve symptoms *(paradoxical intoxication)*. The use of only 1 drug is best. Fewer side effects occur. The dose is easier to adjust than when several drugs are used. However, as PD progresses, the patient often needs combination therapy.

Levodopa with carbidopa (Sinemet) is the primary treatment for symptomatic patients. Levodopa is a chemical precursor of DA. It can cross the blood-brain barrier. There, it is converted to DA in the basal ganglia. Carbidopa inhibits the enzyme dopa-decarboxylase, which breaks down levodopa before it reaches the brain. The net result of using this combination is that more levodopa reaches the brain. Levodopa has many side effects and drug interactions. Prolonged use often results in dyskinesias and "off/on" periods when the drug will unpredictably stop or start working.

DRUG ALERT

Carbidopa/Levodopa (Sinemet)

- Monitor for signs of dyskinesia.
- Stress that effects may be delayed for several weeks to months.
- Teach patient or caregiver to report any uncontrolled movement of face, eyelids, mouth, tongue, arms, hands, or legs; mental changes; palpitations; and problems urinating.

Many patients receive carbidopa/levodopa early in the disease course for the management of motor symptoms. While it will reduce symptoms, use does not stop the progression of PD.[28] HCPs may prefer to start therapy with a DA receptor agonist, a drug that directly stimulates DA receptors. Ropinirole (Requip) and pramipexole (Mirapex) may be used alone or in combination with carbidopa/levodopa. Many of these drugs are available in extended-release forms that improve the patient's ability to adhere to treatment plans. Rotigotine (Neupro), another DA receptor agonist, is a transdermal patch applied once daily. The DA receptor agonist apomorphine (Apokyn, Kynmobi) can improve movement in hypomobility ("off") episodes. Patients must take it with an antiemetic drug because it causes severe nausea and vomiting when taken alone. It cannot be taken with antiemetics in the serotonin (5-HT3) receptor antagonist class (e.g., ondansetron). This combination can lead to very low BP and loss of consciousness.

DRUG ALERT

Apomorphine

- May be taken up to 5 times per day.
- Take BP and pulse before and after administration.
- May cause falls, dizziness, and spontaneous sleepiness.
- Take with an antiemetic (not $5HT_3$ antagonist).

Anticholinergic drugs, such as trihexyphenidyl and benztropine (Cogentin), decrease the activity of Ach. Providing balance between cholinergic and dopaminergic actions can help with tremors and rigidity.

Monoamine oxidase type B (MAO-B) inhibitors like selegiline, rasagiline (Azilect), and safinamide (Xadago) may be used in combination with carbidopa/levodopa.[28] Inhibiting MAO-B, the enzyme that degrades DA, increases DA levels. However, MAO-B inhibitors are less effective at treating motor symptoms than DA receptor agonists.

Entacapone (Comtan) and opicapone (Ongentys) block the enzyme catechol *O*-methyltransferase (COMT), which breaks down levodopa in the peripheral circulation. This prolongs the effect of carbidopa/levodopa. They are used as adjuncts to therapy when the patient's response to levodopa is wearing off at the end of the dosing interval.

After 3 to 5 years of standard PD treatments, many patients have episodes of hypomobility (e.g., inability to

TABLE 63.17 Drug Therapy

Parkinson Disease

Drug	Mechanism of Action	Side Effects	Considerations
Dopaminergics			
Dopamine Precursors			
levodopa (L-dopa) levodopa/carbidopa (Sinemet)	Converted to dopamine (DA) in basal ganglia	Dry mouth GI distress	Do not take with meals. Limit Vitamin B6 intake. Teach about ways to decrease dry mouth.
Dopamine Receptor Agonists			
pramipexole (Mirapex) ropinirole (Requip, Requip XL) rotigotine (Neupro [transdermal patch])	Stimulate DA receptors	Dizziness GI distress Hallucinations Insomnia Orthostatic BP	Monitor orthostatic BP. Change positions slowly. Use safety measures if CNS effects occur. Rotate patch sites.
Dopamine Agonists			
amantadine	Blocks NMDA-type glutamate receptors, increases DA release, and blocks DA reuptake	Dizziness Insomnia	Do not stop abruptly. Use safety measures if CNS effects occur.
apomorphine (Apokyn)	Stimulates postsynaptic DA receptors	Chest pain Drowsiness GI distress Liver toxicity Sweating	Monitor liver function tests. Rotate injection sites. Give in abdomen, thigh, upper arm.
Anticholinergics			
benztropine (Cogentin) trihexyphenidyl	Block cholinergic receptors, thus helping to balance cholinergic and dopaminergic activity	Dizziness Dry mouth Urinary retention Vision changes	Stop if swallowing problems occur. Avoid alcohol, hot weather. Use safety measures if CNS effects occur.
Antihistamine			
diphenhydramine	Has anticholinergic effect	Drowsiness Dry mouth Urinary retention Vision changes	Avoid alcohol. Use safety measures if CNS effects occur. Do not take with MAO inhibitors.
Monoamine Oxidase Type B Inhibitors			
rasagiline (Azilect) safinamide (Xadago) selegiline	Block breakdown of DA	Dizziness Dry mouth Headache Orthostatic BP	Use safety measures if CNS effects occur. Avoid tyramine-containing foods. Many drug interactions. Avoid direct sunlight. Change positions slowly.
Catechol O-Methyltransferase (COMT) Inhibitors			
entacapone (Comtan) opicapone (Ongentys)	Block COMT and slow the breakdown of levodopa, thus prolonging the action of levodopa	Confusion Dizziness GI distress Hypotension	Only give with levodopa. Avoid pregnancy. Use safety measures if CNS effects occur.

rise from chair, speak, or walk; "off "episodes). Off episodes can occur toward the end of a dosing interval with standard medications (end-of-dose wearing off) or at unpredictable times (spontaneous "on/off"). A combination of carbidopa, levodopa, and entacapone (Stalevo) is available for patients with end-of-dose wearing off. This combination is typically prescribed for patients with advanced PD and intense motor fluctuations.[28] Rivastigmine (Exelon) or donepezil (Aricept) is used to treat dementia. Amitriptyline may be used to treat depression.

Surgical Therapy

Surgical procedures to relieve PD symptoms are used in patients who do not respond to drug therapy or have developed severe motor complications. Surgical procedures include DBS and ablation. The most common surgical treatment is DBS. This involves placing an electrode in the thalamus, globus pallidus, or subthalamic nucleus and connecting it to a generator placed in the upper chest (like a pacemaker) (Fig. 63.10). The device is programmed to deliver a specific current to the targeted brain location. DBS is preferred to ablation procedures

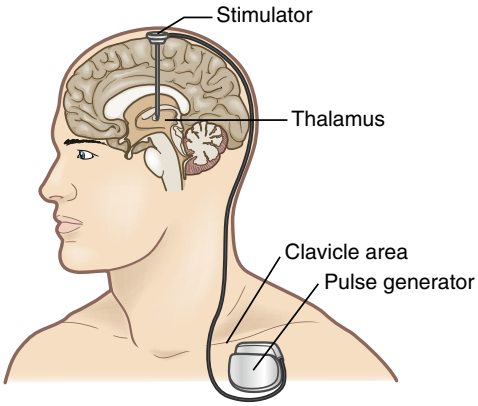

Fig. 63.10 DBS can be used to treat tremors and uncontrolled movements of PD. Electrodes are surgically placed in the brain and connected to a neurostimulator (pacemaker device) in the chest.

because it is reversible and programmable. DBS reduces the increased neuronal activity produced by DA depletion. It can improve motor function and reduce dyskinesia. DBS is indicated for patients who have had PD over 5 years, with dyskinesias, and are unable to tolerate or not controlled with drug therapy.[13]

Ablation surgery involves finding, targeting, and destroying an area of the brain affected by PD. The goal is to destroy tissue that produces abnormal chemical or electrical impulses leading to tremors or other symptoms. Typical targets of ablation are the thalamus *(thalamotomy)* and globus pallidus *(pallidotomy)*. Gamma knife surgery uses multiple radiation beams to target and destroy the target tissue. Unilateral focused ultrasound uses MRI-guided high-intensity ultrasound to destroy target tissue that is causing tremors and other symptoms.

❖ NURSING MANAGEMENT: PARKINSON DISEASE

◆ Assessment

Subjective and objective data that you should obtain from a patient with PD are outlined in Table 63.18.

◆ Clinical Problems

Clinical problems for the patient with PD may include:

- Neurologic problem
- Nutritionally compromised
- Risk for injury
- Impaired communication
- Difficulty coping

Additional information on clinical problems and interventions for the patient with PD is presented in eNursing Care Plan 63.4 (available on the website for this chapter).

◆ Planning

The overall goals are that the patient with PD will (1) maximize neurologic function, (2) maintain independence in ADLs for as long as possible, (3) prevent injury, and (4) optimize well-being.

TABLE 63.18 NURSING ASSESSMENT

Parkinson Disease

Subjective Data

Important Health Information

Health history: CNS trauma, cerebrovascular disorders, exposure to metals and carbon monoxide, encephalitis or other infections

Medications: Major tranquilizers, especially haloperidol (Haldol), and phenothiazines, reserpine, methyldopa, amphetamines

Functional Health Patterns

Health perception–health management: Fatigue

Nutritional-metabolic: Excessive salivation, dysphagia, weight loss

Elimination: Constipation, incontinence, excessive sweating

Activity-exercise: Difficulty in initiating movements, frequent falls, loss of dexterity, slowing of movements, micrographia (handwriting deterioration)

Sleep-rest: Insomnia, nightmares, daytime sleepiness

Cognitive-perceptual: Diffuse pain in head, shoulders, neck, back, legs, and hips. Muscle soreness and cramping

Self-perception–self-concept: Depression, mood swings, hallucinations

Objective Data

Cardiovascular

Postural hypotension

General

Blank (masked) facial expression, slow and monotonous speech, infrequent blinking

GI

Drooling

Musculoskeletal

Cogwheel rigidity, dysarthria, bradykinesia, contractures, stooped posture, shuffling gait

Neurologic

Tremor at rest, first in hands (pill rolling), later in legs, arms, face, and tongue. Aggravation of tremor with anxiety, absence in sleep. Poor coordination, cognitive impairment and dementia, impaired postural reflexes

Skin

Seborrhea, dandruff; ankle edema

Possible Diagnostic Findings

No specific tests. Diagnosis based on history and physical findings and ruling out of other diseases. Improvement with levodopa confirms diagnosis.

◆ Nursing Implementation

Because PD is a chronic degenerative disorder with no acute exacerbations, teaching and nursing care are directed toward maintaining good health, encouraging independence, and avoiding complications, such as contractures, aspiration, and falls. Problems due to bradykinesia can be addressed by relatively simple measures.

CHECK YOUR PRACTICE

You are working in a rehabilitation facility with a new patient, a 78-year-old man with PD. He was at your facility briefly 6 months ago with a fractured hip after falling in his yard. The family has asked to talk with you about their fear of taking him for a walk in the hallways because he is so unstable.

- What advice would you give them?

Promoting physical exercise is a major nursing concern. Exercise can limit the effects of decreased mobility, such as muscle atrophy, contractures, and constipation. Although exercise will not stop disease progress, it will enhance the patient's functional ability. The American Parkinson Disease Association (www.apdaparkinson.org) can connect patients and families with support groups, and they publish booklets and fact sheets with helpful exercises that can be used by caregivers and health care professionals.

A physical therapist can design a personal exercise program to strengthen and stretch specific muscles. Speech therapists can design a plan to help with speaking and swallowing. An occupational therapist can help the patient with ways to increase self-care measures, including eating and dressing.

Work with caregivers to find ways to promote independence and self-care. The patient can get out of a chair better by using an upright chair with arms and placing the back legs of the chair on small (2-inch) blocks. Encourage environmental changes to improve safety. These include removing rugs and excess furniture to avoid stumbling and using an elevated toilet seat to help the patient get on and off the toilet. Elevating the legs can decrease dependent ankle edema. Clothing can be simplified by using slip-on shoes and Velcro hook-and-loop fasteners or zippers on clothing, instead of buttons. Allow extra time for all ADL.

A well-balanced diet is important. Malnutrition and constipation can result from poor nutrition. Patients who have dysphagia and bradykinesia need appetizing foods that are easy to chew and swallow. The diet should have adequate fiber to reduce constipation.

Eating 6 small meals a day may be less tiring than eating 3 large meals a day. Plan ample time for eating to avoid frustration. Cut food into bite-sized pieces. Protein ingestion can impair the absorption of levodopa. Limiting protein intake to the evening meal can decrease this problem. Discuss with the HCP about including vitamin B_6 in a multivitamin and fortified cereals. Vitamin B_6 intake can inhibit levodopa, but this does not occur when taking carbidopa with levodopa.

Effective management of sleep problems can improve quality of life. Some patients find satin nightwear or satin sheets helpful. Teaching about sleep hygiene practices is discussed in Chapter 8.

In the early stages of PD, patients often have depression and anxiety. Patients need to adjust their lifestyle, including work and home responsibilities. As PD progresses, the impact on psychologic well-being increases. Help the patient by listening, providing teaching, gently correcting distorted thoughts, and encouraging social interactions. Psychologic therapy and counseling can be helpful.

The patient begins with subtle changes in cognitive function that can progress to dementia. This causes increased caregiver burden and may lead to long-term care placement. Information on care of the patient with dementia is discussed in Chapter 64.

Family members (e.g., spouse, children) care for most patients with PD. Their burden increases as the disease progresses. The caregiver's physical and mental health may also decline. Help them find appropriate resources.

◆ Evaluation

The expected outcomes are that the patient with PD will:

- Maintain optimal muscle function
- Use assistive devices appropriately
- Maintain adequate nutrition
- Have unimpaired swallowing
- Use methods of communication that allow interaction with others

MYASTHENIA GRAVIS

Myasthenia gravis (MG) is an autoimmune disease of the neuromuscular junction marked by fluctuating weakness of certain skeletal muscles that worsens with activity. MG can occur in anyone. Around 40 per 100,000 people have MG in the United States. It affects people of all ages and races. In women, MG often starts between ages 20 to 30. Men usually develop MG in their 50s.[30]

Etiology and Pathophysiology

MG is caused by an autoimmune process in which antibodies attack and destroy ACh receptors. This results in fewer ACh receptor (AChR) sites at the neuromuscular junction. This prevents ACh molecules from attaching to receptors and stimulating muscle contraction. We think the thymus gives incorrect instructions to developing immune cells causing them to make AChR antibodies. Anti-AChR antibodies are found in the serum of most patients with MG. MuSK and LRP4 antibodies, which also reduce AChR, are present in some patients as well. Some patients have no autoantibodies.

Clinical Manifestations and Complications

The key feature of MG is fluctuating weakness of skeletal muscles. MG affects multiple muscle groups. Muscles engaged in repetitive movements are affected the most. This includes muscles used to move the eyes and eyelids, chew, swallow, speak, and breathe. Muscles are often strongest in the morning. They become exhausted with continued activity. Muscle weakness is prominent by the end of the day. A period of rest usually restores strength.

In more than half of patients, the first muscles involved are the ocular muscles, causing ptosis (drooping of the eyelids) in 1 or both eyes and double vision (Fig. 63.11).[8] MG does not progress beyond the ocular muscles in most patients. When facial muscles are affected, facial mobility and expression can be impaired. Patients may have difficulty chewing and swallowing food. Speech is affected. The voice often is hoarse or fades after long conversations. The muscles of the trunk and limbs easily fatigue. Of these, the proximal muscles of the neck, shoulder, and hip are more often affected than the distal muscles. No other neural problems occur. No sensory loss occurs, and reflexes are normal. Muscle atrophy is rare.

The course of MG is highly variable. Patients may have short-term remissions, stabilize, or have severe progressive disease. Fatigue, pregnancy, illness, trauma, temperature extremes, stress, and hypokalemia can exacerbate MG. Some drugs can worsen MG symptoms, including β-adrenergic blockers,

Fig. 63.11 "Peek" sign in myasthenia gravis. During sustained forced eyelid closure, he is unable to bury his eyelashes *(left).* After 30 seconds, he cannot keep the lids fully closed *(right).* (From Sanders DB, Massey JM: Clinical features of myasthenia gravis. In AG Engel, editor: *Neuromuscular junction disorders: handbook of clinical neurology,* New York, 2008, Elsevier.)

calcium channel blockers, lithium, quinidine, and aminoglycoside antibiotics.[30]

Myasthenic crisis is an acute worsening of muscle weakness triggered by respiratory infection, surgery, stress, pregnancy, exposure to certain drugs, or starting corticosteroid treatment. The major complications of a myasthenic crisis results from muscle weakness in areas that affect swallowing and breathing. This can result in aspiration or respiratory insufficiency. The patient may need a ventilator or noninvasive respiratory support (BiPAP).

Diagnostic Studies

The diagnosis can be based on the history and physical assessment. Other tests may be used for confirmation. Single-fiber EMG is highly sensitive in confirming MG.[30] EMG may show a decreased response to repeated stimulation of the hand muscles that shows muscle fatigue.

The response to an edrophonium test can indicate MG. Edrophonium, an anticholinesterase agent, is given IV. It blocks the enzyme acetylcholinesterase, the enzyme that breaks down ACh. A patient with MG has rapid improvement in muscle strength for a short time after receiving edrophonium.[30] Atropine, a cholinergic antagonist, should be readily available to counteract the effects of edrophonium when it is used diagnostically. In patients with a confirmed diagnosis of MG, a chest CT scan may be done to evaluate the thymus.

Interprofessional Care

Drug Therapy

Drug therapy for MG includes anticholinesterase drugs, alternate-day corticosteroids, and immunosuppressants (Table 63.19). Anticholinesterase drugs enhance transmission at the neuromuscular junction. Inhibiting acetylcholinesterase with an anticholinesterase inhibitor prolongs the action of ACh and improves impulse transmission at the neuromuscular junction. Pyridostigmine (Mestinon) is the best drug of this group for the long-term treatment of MG.

Tailoring the dose to avoid a myasthenic or cholinergic crisis often presents a challenge. Inadequate dosing can cause myasthenic crisis. Excessive dosing will cause a cholinergic crisis, which occurs due to too much cholinesterase inhibition. Cholinergic crisis symptoms are very similar to myasthenic crisis. Features of a cholinergic crisis include involuntary muscle contraction, extreme weakness, flaccid muscle paralysis, sweating, excessive salivation, diarrhea, and constricted pupils. In a cholinergic crisis, giving edrophonium increases muscle weakness. The use of corticosteroids in addition to edrophonium have reduced the incidence of cholinergic crisis.

Corticosteroids (specifically prednisone) are used to suppress the immune response. Other drugs used for immunosuppression include azathioprine (Imuran), mycophenolate (CellCept), and cyclosporine (Sandimmune). Up to 80% of patients who receive corticosteroids have marked improvement. These benefits must be weighed with concerns about their chronic use. Eculizumab (Soliris), an IV monoclonal antibody, stops the autoimmune response. Over time, it improves symptoms.[31] Vyvgart (efgartigimod), another IV infusion, is the first drug in a class of drugs called FcRn Inhibitors. It is used to treat adults who are anti-AChR antibody positive.

TABLE 63.19 Interprofessional Care

Myasthenia Gravis

Diagnostic Assessment

- History and physical assessment
  - Fatigability with prolonged upward gaze (2–3 min)
  - Muscle weakness
- EMG
- Edrophonium test
- Acetylcholine receptor antibodies
- Chest x-ray

Management

- Drug therapy
  - Anticholinesterase agents
  - Corticosteroids
  - Immunosuppressive agents
  - FcRn inhibitors
- Surgery (thymectomy)
- Plasmapheresis
- IV immunoglobulin G

Surgical Therapy

Because the thymus gland in the patient with MG appears to enhance the production of AChR antibodies, removing the thymus gland causes improvement in most patients. A few patients achieve cure after thymectomy.

Other Therapies

Plasmapheresis and IV immunoglobulin G can yield short-term improvement in symptoms. They are indicated for patients in myasthenic crisis or before surgery when corticosteroids must be avoided. Plasmapheresis directly removes circulating AChR antibodies from the plasma, leading to a decrease in symptoms. IV immunoglobulin binds antibodies thus preventing their action.

TABLE 63.20 Comparison of Myasthenic and Cholinergic Crises

Myasthenic Crisis	Cholinergic Crisis
Causes	
Exacerbation of myasthenia after precipitating factors, failure to take drug as prescribed, or drug dose too low	Overdose of anticholinesterase drugs resulting in ↑ ACh at the receptor sites, remission (spontaneous or after thymectomy)
Differential Diagnosis	
Improved strength after IV administration of anticholinesterase drugs	Weakness within 1 h after ingestion of anticholinesterase drugs
↑ Weakness of skeletal muscles manifesting as ptosis, bulbar signs (e.g., difficulty swallowing, difficulty articulating words), dyspnea	↑ Weakness of skeletal muscles manifesting as ptosis, bulbar signs, dyspnea Effects on smooth muscle include pupillary miosis, salivation, diarrhea, nausea or vomiting, abdominal cramps, ↑ bronchial secretions, sweating, lacrimation

❖ NURSING MANAGEMENT: MYASTHENIA GRAVIS

◆ Assessment

Assess the severity of MG by asking the patient about fatigue, what body parts are affected, and how severely they are affected. Some patients become so fatigued they cannot work or even walk. Assess the patient's coping abilities and understanding of MG. Obtain a thorough medication history. Many drugs are contraindicated or must be used with caution in patients with MG.

Objective data should include respiratory rate and depth, O_2 saturation, arterial blood gas analyses, and pulmonary function tests. Assess for respiratory distress in patients with acute myasthenic crisis. Assess muscle strength of all face and limb muscles, swallowing, speech (volume and clarity), and cough and gag reflexes.

◆ Clinical Problems

Clinical problems for the patient with MG may include:

- Impaired respiratory function
- Activity intolerance
- Risk for injury
- Neurologic Problem

◆ Planning

The overall goals are that the patient with MG will (1) have a return of normal muscle strength, (2) manage fatigue, (3) avoid complications, and (4) maintain quality of life.

◆ Implementation

The patient with MG who is admitted to the hospital usually has a respiratory tract infection or is in acute myasthenic crisis. Nursing care is aimed at maintaining adequate ventilation, continuing drug therapy, and watching for side effects of therapy. Be able to tell a cholinergic from myasthenic crisis (Table 63.20) because their causes and treatment differ greatly.

As with other chronic illnesses, focus care on the neurologic deficits and their impact on daily living. Teach the patient about a balanced diet that can easily be chewed and swallowed. Semisolid foods may be easier to eat than solids or liquids. Scheduling doses of drugs to reach peak action at mealtime may make eating easier. Arrange diversional activities that need little physical effort and match the patient's interests. Help the patient plan ADLs to avoid fatigue. Focus teaching on adherence to the treatment plan, complications, potential adverse reactions to specific drugs, complications of therapy (crisis conditions), and what to do about them. Explore community resources, such as the Myasthenia Gravis Foundation of America and MG support groups.

◆ Evaluation

The expected outcomes are that the patient with MG will:

- Maintain optimal muscle function
- Be free from side effects of drugs
- Have no complications
- Maintain a quality of life appropriate to the disease course

AMYOTROPHIC LATERAL SCLEROSIS

Amyotrophic lateral sclerosis (ALS) is a rare progressive neuromuscular disorder marked by loss of motor neurons. ALS usually leads to death 3 to 5 years after diagnosis. A few patients may survive for more than 10 years. Many call ALS *Lou Gehrig's disease* after the famous baseball player who was stricken with it in 1939. The best-known patient with ALS is physicist Stephen Hawking. He was diagnosed at age 21 years and lived with ALS for over 50 years. The median age of onset is 55 years. ALS is more common in Whites, men, and military veterans. About 30,000 Americans have ALS.[32]

In ALS, upper and lower motor neurons in the brainstem and spinal cord gradually degenerate. We do not know the cause. Early in the disease mitochondrial changes occur and excess glutamate (an excitatory neurotransmitter) damages the neurons.[33] Destroyed motor neurons cannot produce or transport signals to muscles. Consequently, electrical and chemical messages originating in the brain do not reach the muscles to activate them. Factors that we suspect affect ALS include smoking, athleticism, metals, solvents, radiation, electromagnetic fields, pesticides, and viruses.[32]

About 10% of ALS cases are genetic. We have found mutations in more than a dozen genes that cause familial ALS (FALS). The most common genes are *C9ORF72* and SOD1.[8]

Progressive muscle weakness and atrophy are the classic sign of ALS. Early symptoms of weakness vary. Some have "limb-onset ALS," initially affecting the arms or legs. The person may have trouble with tasks requiring fine motor skills (e.g., writing, typing) or notice they are tripping, dropping things, or stumbling more often. Those who first have problems with slurred speech or swallowing have "bulbar onset" ALS.

Muscle wasting and involuntary contractions and twitching result from the denervation of the muscles and lack of stimulation and use. Other symptoms include pain, sleep disorders, spasticity and hyperreflexia, drooling, emotional lability,

constipation, and esophageal reflux. Eventually the patient may not be able to communicate. As the ability to move decreases, swallowing is impaired leading to aspiration. ALS does not affect intelligence but affected people may have problems with decision making and memory. Death often results from compromised respiratory function due to muscle weakness and paralysis.

No cure exists for ALS. Two drugs may slow the decline. Riluzole (Rilutek) reduces damage to motor neurons by decreasing the release of glutamate. Edaravone (Radicava) is a free radical scavenger that we think relieves effects of oxidative stress, a likely factor in progression of ALS.[32] It is given IV in 14-day cycles.

The course of ALS is devastating because the patient is cognitively intact while wasting away. Common problems are grief and impaired role performance. Care focuses on (1) facilitating communication, (2) reducing aspiration risk, (3) early identification of respiratory problems, (4) decreasing pain from muscle weakness, (5) decreasing risk for fall-related injury, (6) providing diversional activities, such as reading and companionship, and (7) providing compassionate end-of-life care. Moderate-intensity, endurance-type exercises for the trunk and limbs may help to reduce spasticity.

Support the patient and caregivers emotionally. This includes grieving related to the loss of motor function and impending death. Discuss advance directives and artificial ventilation with the patient and caregiver. Provide the caregiver with support and resources to combat the fatigue and stressors they experience.

HUNTINGTON DISEASE

Huntington disease (HD) is a progressive, degenerative brain disorder causing deterioration of physical, emotional, and cognitive abilities. It is a genetically transmitted, autosomal dominant disorder (Box 63.2). The offspring of a person with HD have a 50% risk for inheriting it. Diagnosis is often made after the affected person has had children. The United States has about 30,000 affected people. The onset of HD is usually between ages 30 and 55 years.[34] Patients live 15 to 20 years after diagnosis.[34]

The diagnostic process begins with a review of the family history and clinical symptoms. Genetic testing confirms excessive CAG protein repeats in the *HTT* gene.[35] People who are asymptomatic but who have a positive family history of HD must decide if they want genetic testing. If the test is positive, the person will develop HD. However, we do not know when the disease will develop. If a person has HD in the family, genetic testing is recommended to aid in family planning. Refer those wishing to have a child who does not carry the gene to a fertility specialist.

The pathologic process of HD involves the basal ganglia and extrapyramidal motor system. HD involves a deficiency of the neurotransmitters ACh and γ-aminobutyric acid (GABA). The net effect is an excess of DA, which leads to symptoms that are the opposite of those of parkinsonism.

Manifestations include movement disorder and cognitive and psychiatric problems. The movement disorder is marked by abnormal and excessive involuntary movements *(chorea)*. These are writhing, twisting movements of the face, limbs, and body. The movements get worse as the disease progresses. Movements are uncoordinated. Patients have difficulty with movement sequences (getting out of bed, getting out of a chair). Inability to sustain movement occurs. Because facial movements involving speech, chewing, and swallowing are affected, aspiration and malnutrition are likely. The gait deteriorates. Ambulation eventually becomes impossible. Eventually all psychomotor processes, including the ability to eat and talk, are impaired.

Psychiatric symptoms are often present in the early stage of HD, even before the onset of motor symptoms. Depression is common. Other psychiatric symptoms include anxiety, agitation, impulsivity, apathy, social withdrawal, moodiness, and stubbornness.[35] Cognitive deterioration is more variable. Many have slowed mental processing. They have difficulty thinking through a problem and will have trouble putting tasks in order. HD involves perception, memory, attention, and learning problems. Cognitive problems will progress to dementia. At the end of the disease, the patient will be nonverbal, bedridden, and require help with all ADLs.

The most common cause of death is pneumonia, followed by suicide. Other causes of death include injuries related to falls and other complications.

Because HD has no cure, treatment is palliative. Drugs are available to control movements and behavioral problems. Tetrabenazine (Xenazine) and Deutetrabenazine (Austedo) are used to treat chorea. They decrease the amount of DA available at synapses of the nerves and thus reducing the involuntary movements. Other medications to lessen the chorea disorder include neuroleptics and benzodiazepines.

BOX 63.2 GENETICS IN CLINICAL PRACTICE

Huntington Disease (HD)

Genetic Basis
- Autosomal dominant disorder
- Caused by mutation in *HTT* gene found on chromosome 4
- A single copy of altered gene (heterozygous) is enough to cause HD
- Offspring of a person with HD have a 50% chance of inheriting the disease-causing allele

Incidence
- Occurs in 3 to 7 in 100,000 people of European ancestry
- Less common in other populations

Genetic Testing
- DNA testing is available
- DNA testing can be done on fetal cells obtained by amniocentesis or chorionic villus sampling
- Preimplantation genetic diagnosis can be done on embryos before implantation and pregnancy
- No test is available to predict when symptoms will develop

Clinical Implications
- Consider genetic counseling if there is a family history of HD
- A positive result means the patient will eventually develop HD
- A negative test means the person does not carry the mutated gene and will not develop HD

Cognitive disorders are treated as needed with nondrug therapies (e.g., counseling, memory books). Selective serotonin reuptake inhibitors, such as sertraline (Zoloft), are an option for depression. Antipsychotic medication, such as haloperidol or risperidone, may be needed.

The goal of nursing management is to provide the most comfortable environment possible for the patient and caregiver by maintaining physical safety, treating symptoms, and providing emotional and psychologic support.

Because of the chorea, caloric requirements are high. The patient may need as many as 4000 to 5000 cal/day to maintain body weight. As HD progresses, meeting caloric needs becomes a greater challenge when the patient has difficulty swallowing and holding the head still. Depression and mental deterioration can compromise nutrition intake. Enteral or parenteral nutrition may be needed as the disease progresses.

End-of-life issues need to be discussed with the patient and caregiver. These include care in the home or long-term care facility, artificial methods of feeding, advance directives, use of antibiotics to treat infections, and guardianship. Address these topics throughout the course of the disease as the patient and caregiver adapt to increasing disability.

Case Study

Seizure Disorder With Headache

(© Purestock/ Thinkstock.)

Patient Profile

C.A. is a 28-year-old woman diagnosed with seizure disorder at age 17. At that time, she had a heat-related injury and electrolyte imbalance causing a tonic-clonic seizure. She had a second seizure 2 months later and was placed on divalproex. She has had no further seizures until 6 months ago. In the past 6 months, she has had 2 generalized onset seizures and developed throbbing headaches after both episodes. She now has frequent headaches. C.A. says she is planning a wedding and taken on more responsibilities at work. She is afraid the headaches and seizures will cause her to lose her job and interfere with her wedding.

Subjective Data

- Describes throbbing headache pain on the right side of her forehead
- Has vomited during headaches
- Describes vision changes, including blurring and flashing zig zag lights before the start of a headache
- Headache occurs several times a week and last several hours
- Headaches have not improved with ibuprofen or acetaminophen

Objective Data

- Neurologic assessment shows no abnormal findings
- Serum divalproex levels are within therapeutic range
- EEG and CT of head normal
- CBC and metabolic panel are within normal limits

Discussion Questions

1. ***Recognize:*** What assessment findings are important?
2. ***Analyze:*** What type of headache is C.A. describing?
3. ***Plan:*** What therapy do you expect for her headaches and seizures?
4. ***Prioritize:*** Based on the assessment data, what are the priority clinical problems?
5. ***Act:*** What teaching will you provide so C.A. can manage her care?
6. ***Act:*** What lifestyle changes would you recommend?
7. ***Evaluate:*** What outcomes would indicate C.A.'s care has been successful?
8. ***Safety:*** To ensure C.A.'s safety, what nursing interventions are needed?

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A patient in urgent care reports a stabbing headache around his left eye and nasal stuffiness. He says, "This pain is horrible; it is worse than my heart attack last year." The provider orders sumatriptan nasal spray now for headache relief. The nurse would take what action?
   - **a.** Administer a puff to each nostril now.
   - **b.** Take vital signs prior to administration.
   - **c.** Contact the provider about administering the medication to this patient.
   - **d.** Teach the patient to self-administer the medication at the start of the migraine.
2. The rapid response team is called to the cafeteria. They find a 22-year-old with a known seizure disorder having a tonic-clonic seizure. What actions will be taken during the seizure? *(select all that apply)*
   - **a.** Establish IV access.
   - **b.** Insert an oral airway.
   - **c.** Gently hold the arms to prevent injury.
   - **d.** Administer the patient's intranasal midazolam.
   - **e.** Turn the person to their side and pad their head.
3. A 28-year-old patient whose mother has Huntington disease is discussing family planning with the nurse. The patient says they want to have a child but are concerned. What statement will the nurse make?
   - **a.** "Both parents must have the gene for your child to inherit this disease."
   - **b.** "If you have the Huntington mutation, you will not be able to have children."
   - **c.** "Only about 1 in 10 people who have the gene pass it to their children."
   - **d.** "Genetic testing can be done to determine if you can pass this trait to a child."
4. The nurse conducts a home visit for a patient with Parkinson disease taking levodopa/carbidopa daily. The patient has stopped eating meals with his family and has lost 3 pounds since the last visit a week ago. What action will the nurse take?
   - **a.** Plan 6 small high-protein meals a day.
   - **b.** Provide information on a high-fat ketogenic diet.

c. Evaluate their ability with eating, swallowing, and use of assistive devices.
d. Collaborate with the HCP about every other day levodopa/carbidopa dosing.

5. A patient with multiple sclerosis receives natalizumab every 6 months and modafinil and dalfampridine daily. What assessment findings would indicate that the treatment plan was successful? *(select all that apply)*
a. Blurred vision
b. Improved walking
c. Decreased fatigue
d. No change in spasticity
e. Reduced exacerbation frequency

1. c; 2. a, d; 3. e; 4. d; 5. b, c, e.

Dementia and Delirium

Janice Smolowitz

http://evolve.elsevier.com/Lewis/medsurg/

CONCEPTUAL FOCUS

Caregiving
Cognition
Family Dynamics
Functional Ability
Safety

LEARNING OUTCOMES

1. Define dementia and delirium.
2. Classify the different etiologies of dementia.
3. Explain the pathophysiology for different types of dementia.
4. Discuss the clinical manifestations of mild cognitive impairment.
5. Describe the clinical manifestations, diagnostic studies, and nursing and interprofessional care for a patient with dementia.
6. Discuss the clinical manifestations, diagnostic studies, and nursing and interprofessional care for a patient with Alzheimer disease.
7. Explain the etiology, pathophysiology, clinical manifestations, diagnostic studies, and nursing and interprofessional care for a patient with delirium.

KEY TERMS

Alzheimer disease (AD)
delirium
dementia
dementia with Lewy bodies (DLB), Table 64.3
frontotemporal lobar degeneration (FTLD), Table 64.3
mild cognitive impairment (MCI)
mixed dementia
retrogenesis
sundowning

This chapter discusses dementia and delirium, with a focus on the nursing management of patients with Alzheimer disease (AD). Cognitive impairment refers to any deficit in intellectual functioning, including problems with memory, orientation, attention, and concentration. The consequences of cognitive impairment can be devastating for the person and caregivers. Dementia adversely affects functional ability and the person's ability to work, fulfill responsibilities, and perform activities of daily living (ADL). There is a high risk for many problems, including injury, impaired nutrition, and social isolation.

Persons with dementia and delirium may have symptoms of depression. Depression and dementia are often mistaken for one another, especially among older adults. Manifestations of depression, especially among older adults, may include sadness, difficulty concentrating, fatigue, apathy, feelings of despair, and inactivity. When depression is severe, poor concentration and inattention may result, causing memory and functional impairment. When dementia and depression occur together, there can be marked intellectual decline. Table 64.1 compares key features of dementia, delirium, and depression. Your ability to interview the patient and family members about presenting symptoms and signs can help with early diagnosis and treatment.

DEMENTIA

Dementia is a disorder characterized by a decline from the previous level of function in 1 or more cognitive domains: complex attention, executive function, language, learning and memory, perceptual-motor, and social cognition.[1,2] The cognitive decline interferes with the ability to function and perform daily activities. This decline does not occur with the onset of acute confusion, such as delirium, or the onset of another major mental problem, such as depression.

The number of patients diagnosed with dementia is increasing. AD is the most common form of dementia.[3] It accounts for 60% to 80% of all cases of dementia (Fig. 64.1).

TABLE 64.1 Comparison of Dementia, Delirium, and Depression

Feature	Dementia	Delirium	Depression
Onset	Subtle, gradual	Abrupt, although initially can be subtle	Often coincides with life changes. Often abrupt
Progression	Slow	Abrupt. Can fluctuate from day to day	Variable, rapid to slow but may be uneven
Duration	Years (average of 8, can be longer)	Hours to days to weeks. Can be prolonged	Can be several months to years, especially if not treated
Thinking	Difficulty with abstract thinking, impaired judgment, words difficult to find	Disorganized, distorted. Slow or accelerated incoherent speech	Intact but with apathy, fatigue. May be indecisive. Feels a sense of hopelessness. May not want to live
Perception	Misperceptions often present. Delusions and hallucinations	Distorted. Delusions and hallucinations	May deny or be unaware of depression. May have feelings of guilt
Psychomotor behavior	May pace or be hyperactive. As disease progresses, may not be able to perform tasks or movements when asked	Variable. Can be hyperactive or hypoactive, or mixed	Often withdrawn and hypoactive
Sleep-wake cycle	Sleeps during the day. Frequent awakenings at night. Fragmented sleep	Disturbed sleep. Reversed sleep-wake cycle	Disturbed, often with early morning awakening

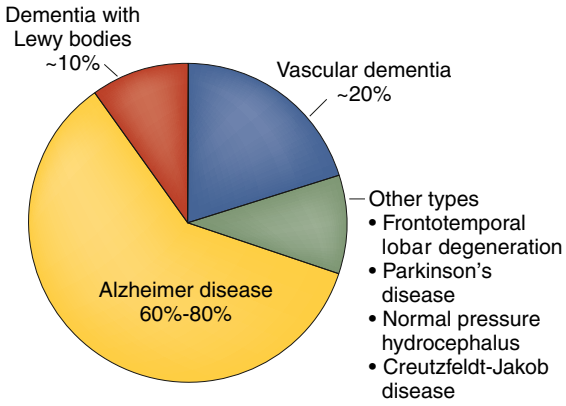

Fig. 64.1 Causes of dementia.

Etiology and Pathophysiology

Dementia is caused by treatable and untreatable conditions. Table 64.2 describes types of dementia and their underlying causes. Treatable causes may initially be reversible. However, irreversible changes can occur with prolonged exposure or disease.

The most common causes are neurodegenerative conditions that cannot be reversed (Table 64.3). Most of these are due to AD.[4] Other causes include dementia with Lewy bodies (DLB), frontotemporal dementia (FTD), and Parkinson disease with dementia (PDD). Vascular or multi-infarct dementia (VaD) is a loss of cognitive function caused by vascular disease. VaD may be caused by a single infarct (stroke) or multiple strokes.[5] It is more common in men. Subcortical dementia is the most common type of VaD. It occurs when small vessels deep in the brain develop thick walls and become stiff. This reduces blood flow, which damages the nerve fibers that carry signals to white matter. This process can cause infarcts near the base of the brain.[6]

Mixed dementia occurs when 2 or more types of dementia are present at the same time. It is characterized by the hallmark abnormalities of AD and another type of dementia. Usually, the other type of dementia is VaD, but it can be other types.

Normal pressure hydrocephalus is a rare disorder characterized by an obstruction in the flow of cerebrospinal fluid (CSF). This causes a buildup of CSF in the brain. Manifestations include dementia, urinary incontinence, and difficulty walking. Meningitis, encephalitis, or head injury may cause the condition. If diagnosed early, it is treatable by surgery in which a shunt is inserted to divert the fluid away from the brain.

Clinical Manifestations

The onset of manifestations varies depending on the cause. Manifestations of neurologic degeneration usually occur gradually and progress over time. Symptoms of VaD may appear abruptly or progress in a stepwise pattern. While the cause of dementia cannot be determined based only on the history of symptom progression, patterns can guide your thinking about the cause. An acute change that occurs over days to weeks or subacute change that occurs over weeks to months may indicate an infectious or metabolic cause of dementia, such as encephalitis, meningitis, hypothyroidism, or drug-related dementia. Other manifestations of dementia are discussed in the section on clinical manifestations of AD.

Diagnostic Studies

The diagnosis is focused on determining the cause (e.g., reversible versus irreversible). An important first step is a thorough medical, neurologic, and psychologic history. During the history, give special attention to the cognitive and behavior changes that have occurred. Family members and significant others can give important information. Obtain information about (1) problems with judgment; (2) reduced interest in hobbies/activities; (3) repeating questions, stories, or statements; (4) trouble learning how to use a tool or appliance; (5) forgetting the month or year; (6) problems handling financial affairs; (7) difficulty remembering appointments; and (8) consistent problems with thinking and/or memory.

Obtain information about diet and nutrition, alcohol use, and medications. Include herbal supplements and recreational substances in the medication history. Ask about drugs that can

TABLE 64.2 Causes of Dementia

Type of Dementia	Cause
Neurodegenerative disorders	• AD • Amyotrophic lateral sclerosis (ALS) • Dementia with Lewy bodies (DLB) • Down syndrome • Frontotemporal lobar degeneration (FTLD) • Huntington disease • Parkinson disease
Vascular diseases	• Chronic subdural hematoma[a] • Subarachnoid hemorrhage[a] • Vascular (multi-infarct) dementia
Immunologic diseases or infections	• AIDS • Encephalitis[a] • Infections (e.g., Creutzfeldt-Jakob disease) • Meningitis[a] • Multiple sclerosis • Neurosyphilis[a] • Systemic exertion intolerance disease • Systemic lupus erythematosus[a]
Medications[b]	• Anticholinergics • Antiparkinsonian drugs • Cardiac drugs: digoxin, methyldopa • Cocaine • Heroin • Hypnotics • Opioids • phenytoin (Dilantin) • Tranquilizers
Metabolic or nutrition diseases	• Alcohol use disorder • Cobalamin (vitamin B12) deficiency[a] • Folate deficiency[a] • Hyperthyroidism[a] • Hypothyroidism[a] • Thiamine (vitamin B1) deficiency[a]
Systemic diseases	• Dialysis dementia[a] • Hepatic encephalopathy[a] • Uremic encephalopathy[a] • Wilson disease
Trauma	• Head injury[a]
Tumors	• Brain tumors (primary)[a] • Metastatic tumors[a]
Ventricular disorders	• Hydrocephalus[a]

[a]Potentially reversible.
[b]These are examples of drugs that may cause cognitive impairment that is potentially reversible.

impair cognition, such as analgesics, anticholinergics, psychotropics, and sedative-hypnotics.

The physical assessment is done to assess for other potential medical conditions. For example, slow movement, rigidity, asymmetric tremor of an extremity, and shuffling gait suggest Parkinsonism. Dementia, urinary incontinence, and ataxic gait suggest normal pressure hydrocephalus. The neurologic assessment includes a mental status examination or screening test. Agreement among findings from the assessment, screening tests, and history help confirm the presence of dementia.

Based on the history and physical assessment, diagnostic studies are ordered to confirm the most likely cause and exclude other possible conditions. Routine screening tests include electrolyte panel, liver function tests, serum vitamin B_{12} level, complete blood count (CBC), and thyroid function tests.[3–5] Specialized laboratory tests, such as red blood cell folate in a patient with alcohol use disorder or ionized serum calcium in a patient with multiple myeloma, are ordered based on history. Head CT or MRI may show strokes, tumors, and other changes. Positron emission tomography (PET) can examine brain activity. In some instances, genetic testing may be considered based on family history.

Interprofessional and Nursing Care

If there is an identifiable cause, treatment is aimed at treating that cause. Other management measures are similar to the care of patients with AD (described later in this chapter). Preventive measures for VaD include treating risk factors, such as hypertension, diabetes, smoking, hypercholesterolemia, and dysrhythmias. Stroke is discussed in Chapter 62. Drugs given to patients with AD are also useful for patients with VaD.

ALZHEIMER DISEASE

Alzheimer disease (AD) is a chronic, progressive, irreversible neurodegenerative brain disease. It most often affects persons age 65 and older. More than 6.2 million people are currently living with AD in the United States.[3] It is thought that by 2050, this number will increase to 12.7 million people.[3] AD is the 6th leading cause of death in the United States. It is the 5th-leading cause of death among persons age 65 and older.

Only a small number of people younger than 60 years of age develop AD. When AD develops in someone younger than 60 years, it is called *early-onset AD.* AD that occurs in people over 60 years old is called *late-onset AD.*

AD progresses slowly. It has a long preclinical phase, which may last up to 20 years. The average clinical duration is 4 to 8 years. Some patients have lived for 20 years after diagnosis.

The burden of caring for a patient with AD is well documented. In 2020, family members and friends provided $257 billion of informal (unpaid) care for persons with AD.[3] This estimate includes 15.3 billion hours of assistance. Reasons for providing informal care include wanting the person to remain at home (65%), being able to stay close to the person (48%), and feeling obligated to provide care (38%). Many informal caregivers are women. More than 60% of caregivers are married and living with a partner or are in a long-term relationship. 30% of caregivers are age 65 or older. 64% of informal caregivers report that caregiving is stressful (Box 64.1). Nearly 92% say it is also rewarding.[4,5]

Etiology

We do not know the exact cause of AD.[7,8] It is likely a combination of multiple factors (Box 64.2).

Aging

The greatest risk factor for AD is age. Most people with AD are diagnosed at age 65 or older. While age is the greatest risk factor,

TABLE 64.3 Neurodegenerative Causes of Dementia

Neurodegenerative Disorder	Characteristics	Management
Dementia With Lewy Bodies (DLB)		
• Characterized by presence of Lewy bodies (abnormal deposits of protein α-synuclein) in brainstem and cortex • Has features of both AD and Parkinson disease	• Diagnosis based on manifestations • Typically have manifestations of parkinsonism (extrapyramidal signs [bradykinesia, rigidity, postural instability, but not always a tremor]), hallucinations, short-term memory loss, unpredictable cognitive shifts, sleep problems • Pneumonia is a common complication	• Drugs may include levodopa/carbidopa and acetylcholinesterase inhibitors • Manage dementia and problems related to dysphagia and immobility • Swallowing problems can lead to impaired nutrition • At risk for falls from impaired mobility and balance
Frontotemporal Lobar Degeneration (FTLD)		
• Due to atrophy of frontal and temporal lobes of brain • In Pick disease, a type of FTLD, brain may have abnormal microscopic deposits called Pick bodies • Often misdiagnosed as a psychiatric problem because of strange behaviors	• Changes in behavior, sleep, eventually memory • Progresses relentlessly • May lead to language impairment, erratic behavior, dementia • Tends to occur at a younger age than does AD, typically about age 60	• No specific treatment • Antidepressants and antipsychotics to treat behavior manifestations
Vascular (Multi-Infarct) Dementia		
• Due to a single infarct (stroke) or multiple strokes • Prognosis is poor • Symptoms may begin suddenly, with decline after each small stroke	• More common in men • Typically begins between the ages 60 and 75 • Symptoms are similar to AD • Often occurs with AD	• See Chapter 62 • No treatment • Focus is on preventing future strokes by controlling problems that put people at high risk for stroke

BOX 64.1 PROMOTING HEALTH EQUITY

AD

- 36% of Blacks, 18% of Hispanics, and 19% of Asian Americans believe discrimination is a barrier to care for persons with AD.
- More than 50% of non-White caregivers report discrimination when navigating health care services, feeling that providers do not listen because of their race, color, or ethnicity.
- 41% of persons who provide unpaid care for a Black person and 32% of persons who provide unpaid care for a Hispanic persons say race makes it harder for them to obtain health care.

BOX 64.2 BIOLOGIC SEX CONSIDERATIONS

AD

Women

- Nearly two-thirds of people with AD are women.
- Women are more likely to develop AD than men, mainly because they live longer.
- About twice as many women as men die each year from AD.

AD is not a normal part of aging and age alone does not cause the disease.

Family History

Family history of AD is an important risk factor. Persons with a first-degree relative (parent or sibling) with dementia are more likely to develop AD. Those who have more than 1 first-degree relative with dementia are at even higher risk for developing AD.

Genetic Link

Persons with a clear pattern of inheritance within a family have familial AD (FAD). FAD is associated with onset before age 60 and a more rapid disease course. We refer to cases as sporadic when there is no familial connection.

The first gene associated with late-onset and sporadic forms of AD was the epsilon (E)-4 allele of the apolipoprotein E *(ApoE)* gene on chromosome 19. *ApoE* contains the instructions to make a protein that helps to carry cholesterol and other types of fat in the bloodstream. *ApoE* may have a role in clearing amyloid plaques. *ApoE* mutations result in more amyloid deposits.

ApoE comes in several different alleles or forms. Three alleles occur most often. People inherit 1 allele (e.g., *ApoE-2, ApoE-3, ApoE-4*), from each parent. The presence of *ApoE-4* increases the risk of developing late-onset AD (Box 64.3).

In patients with early-onset AD, we have identified 3 key genes: presenilin-1 *(PSEN1)*, presenilin-2 *(PSEN2)*, and amyloid precursor protein *(APP)*. When these genes mutate, they cause brain cells to overproduce β-amyloid. *PSEN1* mutations cause AD before age 60 and often before age 50. *PSEN2* causes early-onset FAD.

Cardiovascular Factors

Brain health is closely linked to the health of the heart and blood vessels. Brain functioning depends on a good blood supply and nutrients delivered to it by that blood supply.

Many factors increase the risk for CVD. These include diabetes, hypertension, obesity, hypercholesterolemia, and smoking. Diabetes dramatically increases the risk of developing AD and other types of dementia. Diabetes can contribute to dementia in several ways. Chronic high levels of insulin and glucose may be directly toxic to brain cells. Insulin resistance, which causes high

BOX 64.3 GENETICS IN CLINICAL PRACTICE

AD

Genetic Basis

Early Onset (Familial) (<60 Years Old at Onset)

- Autosomal dominant disorder
- Various mutations in the following genes:
  - Amyloid precursor protein *(APP)* gene on chromosome 21
  - Presenilin-1 *(PSEN1)* gene on chromosome 14
  - Presenilin-2 *(PSEN2)* gene on chromosome 1

Late Onset (Sporadic) (>60 Years Old at Onset)

- Genetically more complex than early-onset AD
- Apolipoprotein E-4 *(ApoE-4)* allele on chromosome 19 increases risk for developing AD
- Presence of the *ApoE-2* allele is associated with a lower risk for AD

Incidence

Early Onset

- Rare form of AD, accounts for <5% of cases
- 50% risk for disease for children of affected parents
- May occur in people as young as 30 years

Late Onset

- *ApoE-4* is present in 40%–65% of people with late-onset AD
- Many *ApoE-4*–positive people do not develop AD

Genetic Testing

Early Onset

- Genetic screening is available for mutations on chromosomes 1, 14, and 21

Late Onset

- Blood test can identify which *ApoE* allele a patient has but cannot predict who will develop disease
- In a patient who meets the clinical criteria for AD, finding *ApoE-4* increases the reliability of the diagnosis

Clinical Implications

- Genetic testing for family members of patients with early-onset AD may be appropriate.
- Testing should be done only with formal genetic counseling, especially when asymptomatic family members are involved.
- If a person tests positive for *ApoE-4*, it does not mean they will develop AD.

blood glucose and can lead to type 2 diabetes, may interfere with the body's ability to break down amyloid, a protein that forms brain plaques in AD. High blood glucose and high cholesterol have a role in atherosclerosis, which contributes to VaD.[8]

Diabetes may contribute to poor memory and decreased mental function in other ways. Diabetes causes microangiopathy, which damages small blood vessels throughout the body. Ongoing damage to blood vessels in the brain may be one reason people with diabetes are at a higher risk for cognitive problems as they age. People with diabetes may lose brain volume, especially gray matter, as the disease progresses.

Head Trauma

Head trauma is a risk factor for dementia. Professional football players and military veterans who had a traumatic brain injury or posttraumatic stress disorder have an increased risk for AD and other types of dementia.[4,6]

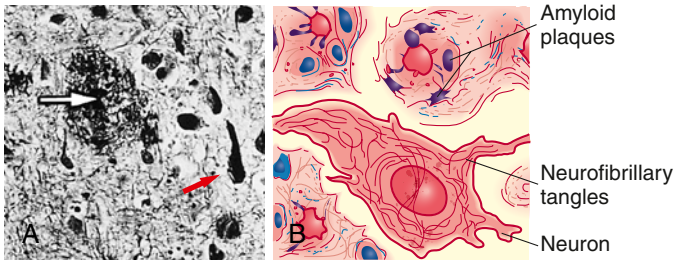

Fig. 64.2 Pathologic changes in AD. (A) Plaque with central amyloid core *(white arrow)* next to a neurofibrillary tangle *(red arrow)* on the histologic specimen from a brain autopsy. (B) Schematic representation of amyloid plaque and neurofibrillary tangle.

Pathophysiology

Changes in the brain's structure and function with AD include (1) amyloid plaques, (2) neurofibrillary tangles, (3) loss of connections between neurons, and (4) neuron death.[7,8] Fig. 64.2 shows the pathologic changes in AD.

As a part of aging, people develop some plaques in their brain tissue. In AD, more plaques appear in certain parts of the brain affecting memory. In AD, plaques develop first in areas of the brain used for memory and cognitive function, including the hippocampus. The hippocampus is important in forming and storing short-term memories. Eventually, AD attacks the cerebral cortex, especially the areas responsible for language and reasoning.

Plaques consist of clusters of insoluble deposits of a protein called β-amyloid, other proteins, remnants of neurons, non-nerve cells such as microglia (cells that surround and digest damaged cells or foreign substances), and other cells, such as astrocytes. β-Amyloid is cleaved from APP, which is associated with the cell membrane (Fig. 64.3). We do not know the normal function of APP. Genetic factors may play a critical role in how the brain processes the β-amyloid protein. Overproduction of β-amyloid is an important risk factor for AD. Abnormally high levels of β-amyloid cause cell damage either directly or by eliciting an inflammatory response and ultimately neuron death.

Neurofibrillary tangles are abnormal collections of twisted protein threads inside nerve cells. The main component of these structures is a protein called tau. Tau proteins in the central nervous system (CNS) provide support for intracellular structure through their support of microtubules. Tau proteins hold the microtubules together like railroad ties. In AD, tau protein is altered. As a result, the microtubules twist together in a helical fashion (Fig. 64.3). This forms the neurofibrillary tangles found in the neurons of people with AD.

Plaques and neurofibrillary tangles are not unique to patients with AD or dementia. They are also found in the brains of people without cognitive impairment. However, they are more abundant in the brains of those with AD.

The other feature of AD is the loss of connections between neurons and neuron death. These processes result in structural damage. Affected parts of the brain begin to shrink in a process

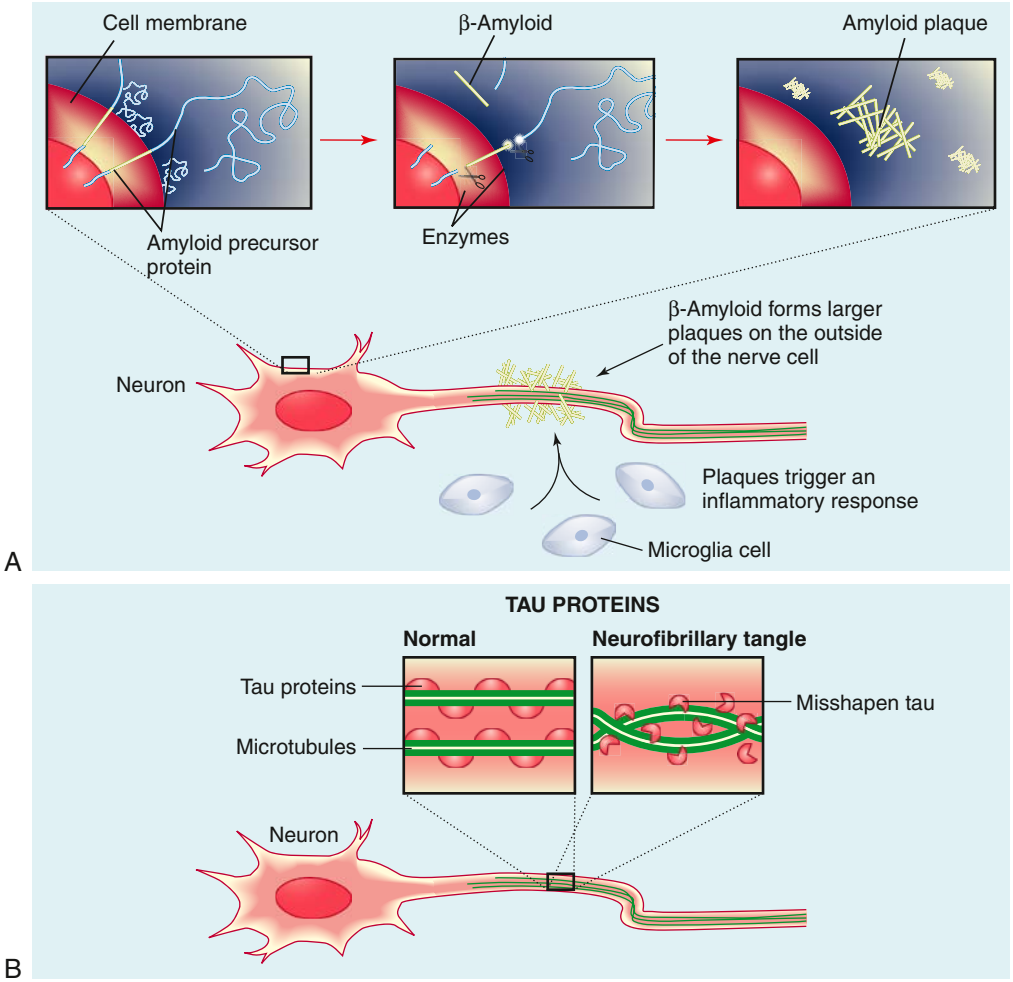

Fig. 64.3 Current theories about the development of AD. (A) Abnormal amounts of β-amyloid are cleaved from the amyloid precursor protein (APP) and released into the circulation. The β-amyloid fragments come together in clumps to form plaques that attach to the neuron. Microglia react to the plaque. This results in an inflammatory response. (B) Tau proteins provide structural support for the neuron microtubules. Chemical changes in the neuron cause structural changes in tau proteins. This results in twisting and tangling (neurofibrillary tangles).

called brain atrophy. By the final stage of AD, brain tissue has shrunk significantly (Fig. 64.4).

Clinical Manifestations

Research suggests AD causes pathologic changes in the brain at least 15 years before manifestations appear.[9] The Alzheimer's Association has developed a list of 10 warning signs that are common manifestations of AD (Table 64.4).

Symptoms do not always directly relate to abnormal changes in the brain caused by AD. We describe the stages of AD as mild, moderate, and severe (Table 64.5). The rate of progression from mild to severe is highly variable and ranges from 3 to 20 years.

The initial manifestations are usually related to changes in cognitive functioning. The person may have memory loss, mild disorientation, or trouble with words and numbers. Often, a family member reports the patient's declining memory to the HCP.

Normal age-related memory decline is characterized by mild changes that do not interfere with ADLs (Table 64.6). In AD, the memory loss initially relates to recent events, with remote memories still intact. With time and progression of AD, memory loss includes both recent and remote memory. It affects the ability to perform self-care.

Fig. 64.4 Effects of AD on the brain. This figure compares a normal brain *(left)* with a brain affected by AD *(right)*.

As AD progresses, personal hygiene deteriorates, as does the ability to concentrate and maintain attention.[10,11] Ongoing loss

TABLE 64.4 PATIENT & CAREGIVER TEACHING

Early Warning Signs of AD

Include the following information in the teaching plan for the patient with AD:

1. Memory loss that affects job skills
   - Frequent forgetfulness or unexplainable confusion at home or in the workplace may signal that something is wrong.
   - This type of memory loss goes beyond forgetting an assignment, colleague's name, deadline, or phone number.
2. Problems with abstract thinking
   - For the patient with AD, this goes beyond challenges, such as balancing a checkbook.
   - The patient with AD may not be able to recognize numbers or do basic calculations.
3. Difficulty doing familiar tasks
   - It is normal for most people to become distracted and to forget something (e.g., leave something on the stove too long).
   - People with AD may cook a meal, then forget not only to serve it but also that they made it.
4. Poor or decreased judgment
   - Many people from time to time may choose not to dress appropriately for the weather (e.g., not bringing a coat or sweater on a cold evening).
   - The patient with AD may dress inappropriately in more noticeable ways, such as wearing a bathrobe to the store or a sweater on a hot day.
5. Problems with language
   - Most people have trouble finding the "right" word from time to time.
   - People with AD may forget simple words or substitute inappropriate words, making their speech difficult to understand.
6. Misplacing things
   - For many people, temporarily misplacing keys, purses, or wallets is a normal, albeit frustrating, event.
   - The patient with AD may put items in inappropriate places (e.g., eating utensils in clothing drawers) but have no memory of how they got there.
7. Changes in mood
   - Most people have mood changes.
   - The patient with AD tends to have more rapid mood swings for no apparent reason.
8. Changes in personality
   - As most people age, they may have some change in personality (e.g., become less tolerant).
   - The patient with AD can change dramatically, either suddenly or over time. For example, someone who is easygoing may become angry, suspicious, or fearful.
9. Loss of initiative
   - The patient with AD may become and remain uninterested and uninvolved in many or all their usual pursuits.

Adapted from Alzheimer's Association: 10 Early signs and symptoms of Alzheimer's. Retrieved from https://www.alz.org/alzheimers_disease_know_the_10_signs.asp.

of neurons can cause the person to act in unpredictable ways. Behavior manifestations, such as agitation or aggression, result from changes that take place within the brain. These behaviors are neither intentional nor controllable by the person. Some people have delusions and hallucinations.

As AD progresses, more cognitive impairments occur. These include aphasia (difficulty comprehending language and oral communication), apraxia (inability to manipulate objects or perform purposeful acts), visual agnosia (inability to recognize objects by sight), and dysgraphia (difficulty communicating by writing). Eventually, they cannot recall long-term memories. The person may not recognize family members and friends. Later in the disease, the ability to communicate and perform ADLs is lost. Some tend to wander. In the late stages of AD, the person is unresponsive, incontinent, and needs total care.[12]

Retrogenesis

Retrogenesis is the process in which the decline in AD mirrors, in reverse order, brain development that occurs from birth.[13] Thus, it compares the developmental stages of childhood with the deterioration of patients with AD. As seen in Fig. 64.5, a relationship exists between developmental stage and deterioration of function. For example, it is appropriate for a patient in the moderate stage to feel good about putting together puzzles that belong to his 3-year-old grandson. In fact, they may play well together on the same task or project.

Diagnostic Criteria

The National Institute on Aging and the Alzheimer's Association have criteria and guidelines for diagnosing AD. Guidelines address the use of imaging and biomarkers that may help determine whether changes are due to AD.

AD is considered on a spectrum (Table 64.7). The stages are preclinical AD, mild cognitive impairment, and dementia due to AD. Dementia is the last stage.

Preclinical Stage

A long lag exists between pathologic changes in the brain and manifestations of AD. The future goal would be to modify the disease process of AD before it becomes symptomatic. Once plaques and tangles have formed in sufficient quantity, it may be too late to intervene to prevent the disease or its progression. Although current attempts at modifying the disease process have not been successful, research is ongoing.

Mild Cognitive Impairment

Mild cognitive impairment (MCI) is the second stage in the AD spectrum. It is a state of cognitive function in which persons have problems with memory, language, or other essential cognitive functions. The problems are severe enough to be noticed by the person having them and by others and can be found on screening tests. Family members may see changes in the person's abilities (Table 64.6). To the casual observer, the person with MCI may seem normal. Because the problems do not interfere with daily activities, the patient does not meet the criteria for being diagnosed with dementia.

We classify MCI based on the cognitive skills affected. MCI that primarily affects memory is called amnestic MCI. With amnestic MCI, a person may forget important information that they would have recalled easily, such as appointments. The person is often aware of the change in memory. MCI that affects other cognitive skills is non-amnestic MCI. Skills that may be affected include the ability to make sound decisions or complete a complex task.[11]

Between 15% and 20% of people 65 years and older have MCI. They are at high risk for developing AD. Some people with

TABLE 64.5 Stages of AD

Mild	Moderate	Severe
• Forgetfulness beyond what is seen in a normal person • Short-term memory impairment, especially for new learning • Loss of initiative and interests • May forget recent events or the names of people or things • Impatient • May no longer be able to solve simple math problems • Slowly loses the ability to plan and organize	• Memory loss and confusion become more obvious • Has more trouble organizing, planning, and following directions • May need help getting dressed • May start having incontinence • Trouble recognizing family members and friends • Agitation, restlessness • May lack judgment and begin to wander, gets lost • May have trouble sleeping • Delusions, hallucinations, paranoia • Behavior problems	• Severe impairment of all cognitive functions • Little memory, unable to process new information • Unable to perform self-care activities • Often needs help with daily needs • May not be able to talk • Cannot understand words • May have problems eating, swallowing • May not be able to walk or sit up without help • Immobility • Incontinence

TABLE 64.6 Comparison of Normal Forgetfulness and Memory Loss

Normal Forgetfulness	Memory Loss in Mild Cognitive Impairment	Memory Loss in AD
• Sometimes misplaces keys, eyeglasses, or other items	• Often misplaces items	• Forgets what an item is used for or puts it in an inappropriate place
• Momentarily forgets an acquaintance's name	• Often forgets people's names and is slow to recall them	• May not remember knowing a person
• Sometimes has to search for a word	• Has increasing difficulty finding desired words	• Begins to lose language skills and may withdraw from social interaction
• Sometimes forgets to run an errand	• Begins to forget important events and appointments	• Loses sense of time, does not know what day it is
• May forget an event from the distant past	• May forget recent events or newly learned information	• Seriously impaired recent memory and problems learning and remembering new information
• When driving, may momentarily forget where to turn, but quickly orients self	• Becomes temporarily lost more often, may have trouble understanding and following a map	• Becomes easily disoriented or lost in familiar places, sometimes for hours
• Jokes about memory loss	• Worries about memory loss, family and friends notice lapses	• May have little or no awareness of cognitive problems

Adapted from Rabins P: Memory. In *The Johns Hopkins white papers,* Baltimore, 2007, Johns Hopkins University.

MCI show no progression and do not go on to develop AD. An estimated 15% of people with MCI will eventually develop AD.

Treatment consists of ongoing monitoring. Assessing for changes in memory and thinking skills that indicate a worsening of symptoms or a progression to AD or another dementia is critical (Table 64.4).

Diagnostic Studies

No definitive diagnostic test exists for AD. The diagnosis is primarily a diagnosis of exclusion. In patients with cognitive impairment, there is increased emphasis on early and careful evaluation. Many conditions can cause manifestations of dementia. Some are treatable or reversible (Table 64.2).

When all other conditions that can cause cognitive impairment have been excluded, a clinical diagnosis of AD can be made. A comprehensive evaluation includes a health history, physical assessment, neurologic and mental status assessments, and laboratory tests (Table 64.8). A definitive diagnosis of AD requires an examination of brain tissue at autopsy and findings of neurofibrillary tangles and plaques.

Neuroimaging allows us to detect changes early in the disease and monitor treatment response. In AD, multiple brain structures atrophy and the volume of the brain correlates with neurodegeneration. CT or MRI may show brain atrophy in the later stages of the disease. This finding occurs in other diseases and can be seen in people without cognitive impairment. PET scanning can help discern AD from other forms of dementia (Fig. 64.6). PET determines brain metabolism using glucose tracers. PET can detect amyloid.

Guidelines identify 2 biomarker categories: (1) those that show the level of β-amyloid accumulation in the brain and (2) those that show if nerve cells in the brain are injured or degenerating. Biomarkers include (1) CSF neurochemical markers: β-amyloid and tau proteins, and (2) imaging biomarkers: volumetric MRI and PET. The level of tau in the CSF is an indication of neurodegeneration. Plasma levels of tau or β-amyloid are not of any value in diagnosing AD. There are some other imaging biomarkers we use in special clinical settings. They may help in some cases to increase the level of certainty about a diagnosis of AD.

Neuropsychologic testing is important for diagnostic purposes and to establish a baseline for evaluating changes over time. They are repeated at regular intervals during the course of care to assess changes in cognitive status. Common tools include the Mini-Cog (Table 64.9), Mini-Mental State Examination (MMSE) (Table 64.10), and Montreal Cognitive Assessment (MoCA). Brief screenings, such as the Mini-Cog, are useful for ongoing screening, especially when time is limited. The clock drawing test can be used as part of the Mini-Cog or by itself to assess cognitive function (Fig. 64.7). The MMSE takes about

Stage	Alzheimer's Disease	Reisberg Stage*	Developmental Age	Diversion/Distraction Activities
Mild	No difficulty at all	1		
	Some memory trouble begins to affect job/home. Forgets familiar names.	2		
	Much difficulty maintaining job performance. Withdrawal from difficult situations.	3	12+ yr	Can function with understanding. Enjoy things previously enjoyed—watch TV, play and listen to music, play games.
	Can no longer hold a job, plan and prepare meals, handle personal finances, etc. Driving becomes difficult, although can drive to familiar places.	4	8–12 yr	Can still enjoy simple games, watch TV and videos. Enjoys family photos and memories.
Moderate	Can no longer select proper clothing for occasion or season. Needs help to remain safe in home. Forgets to bathe.	5	5–7 yr	Needs age-appropriate toys and games.
	Requires assistance with dressing.	6a	4–5 yr	Enjoy many of the same activities as preschoolers.
	Requires assistance with bathing.	6b	4–5 yr	
	Can no longer use toilet without assistance.	6c	4 yr	
	Urinary incontinence	6d	3–4.5 yr	
	Fecal incontinence	6e	2–3 yr	
Severe	Speech now limited to about words per day.	7a	15 mo	Enjoys infant toys, mobiles, dangling ribbons.
	Speech now limited to 1 word per day.	7b	1 yr	
	Can no longer walk without assistance.	7c	1 yr	
	Can no longer sit up without assistance.	7d	6–10 mo	
	Can no longer smile.	7e	2–4 mo	
	Can no longer hold up head.	7f	1–3 mo	

Fig. 64.5 Retrogenesis (back to birth) in AD. *Based on Functional Assessment Staging. (From Reisberg B: Functional Assessment Staging [FAST], *Psychopharmacol Bull* 24:653, 1988.)

TABLE 64.7 Diagnostic Criteria

AD

Stage	Description	Recommendations for Biomarkers
Preclinical AD	• Brain changes, including amyloid buildup and other early neuron changes, may already be in process • At this point, significant symptoms are not yet evident • In some people, PET scans and CSF analysis can detect amyloid buildup	• Use of imaging and biomarker tests at this stage are only for research • Biomarkers are still being developed, not used by clinicians in general practice
Mild cognitive impairment (MCI) due to AD	• MCI stage is marked by symptoms of memory problems, enough to be noticed and measured, but not compromising a patient's independence • May or may not progress to AD	• Used primarily by researchers • May be used in specialized clinical settings to supplement standard tests to help determine possible causes of MCI • May help confirm that the patient's impairment is related to AD
Dementia due to AD	• Characterized by memory, thinking, and behavior symptoms that impair a patient's ability to function in daily life • Dementia marks the terminal stage of AD • Encompasses all stages shown in Table 64.5	• Can increase the level of certainty about a diagnosis of AD • May be used to discern AD from other dementias

AD

Diagnostic Assessment

- History and physical assessment,
  - Psychologic evaluation, including depression screening
  - Neuropsychologic testing, including Mini-Cog (Table 64.9) and Mini-Mental State Examination (Table 64.10)
- Brain imaging tests: CT, MRI, PET
- CBC
- ECG
- Glucose, creatinine, BUN
- Vitamin B1, B6, B12 levels
- Thyroid function tests
- Liver function tests

Management

- Drug therapy for cognitive problems (Table 64.11)
- Behavior modification
- Moderate exercise
- Assistance with functional independence
- Assistance and support for caregivers

7 minutes to complete. It gives information about orientation, recall, attention, calculation, language manipulation, and constructional praxis. The MoCA takes about 10 minutes to do. It assesses memory, language, attention, visuospatial, and executive functions.

Interprofessional Care

There is no cure for AD. Treatment does not stop the deterioration of brain cells. Care is aimed at controlling undesirable behavior manifestations and providing support for family caregivers.

Drug Therapy

Although medication for AD is available, these drugs do not cure or reverse the progression of AD (Table 64.11). They help many people for a period of time by leading to a modest decrease in the rate of decline of cognitive function. There is no effect on overall disease progression.[3,7]

Cholinesterase inhibitors block cholinesterase, the enzyme that breaks down acetylcholine in the synaptic cleft (Fig. 64.8). These drugs include donepezil (Aricept), rivastigmine (Exelon), and galantamine (Razadyne). Rivastigmine is available as a patch.

Memantine (Namenda) protects the brain's nerve cells against excess amounts of glutamate, which is released in large amounts by cells damaged by AD. The attachment of glutamate to *N*-methyl-D-aspartate (NMDA) receptors permits calcium to flow freely into the cell, which in turn may lead to cell degeneration. Memantine may prevent this destructive sequence by blocking the action of glutamate.

Treating the depression that is often associated with AD may improve cognitive function. Depression is often treated with selective serotonin reuptake inhibitors. These include fluoxetine (Prozac), sertraline (Zoloft), and citalopram (Celexa). The antidepressant trazodone may help with sleep problems.

Antipsychotic drugs can be used for managing agitation and aggressive behavior, which occurs in some patients. These drugs increase the risk for death and cognitive decline in patients with AD. They should be used only when agitation and psychosis symptoms are severe, are dangerous, and/or cause significant distress to the patient.

❖ NURSING MANAGEMENT: ALZHEIMER DISEASE

◆ Assessment

Subjective and objective data that you should obtain from a patient with AD are outlined in Table 64.12. Useful questions for the patient and caregiver are, "When did you first notice the memory loss?" and "How has the memory loss progressed since then?"

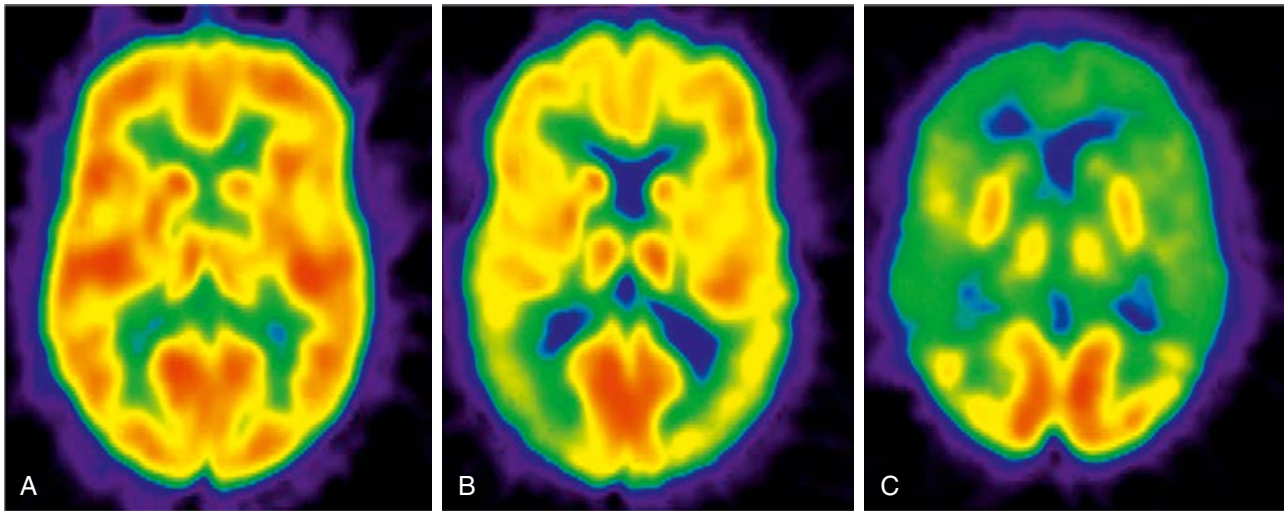

Fig. 64.6 PET scan assist in diagnosing AD. Radioactive fluorine is applied to glucose (fluorodeoxyglucose), and the yellow areas show metabolically active cells. (A) A normal brain. (B) Early AD. (C) Advanced AD, with hypometabolism in many areas of the brain. (From Rice L, Bisdas S: The diagnostic value of FDG and amyloid PET in Alzheimer's disease, *Eur J Radiol* 94:16, 2017.)

TABLE 64.9 The Mini-Cog

The Mini-Cog is used as a brief assessment tool for cognitive impairment. It can be quickly administered and can guide the need for further evaluation.

Administration

- Tell the patient to listen carefully to and remember 3 unrelated words and then to repeat the words. *Example:* apple, table, penny. (This initial step is not scored.) The same 3 words may be repeated to the patient up to 3 times to register all 3 words.
- Tell the patient to draw the face of a clock, either on a blank sheet of paper or on a sheet with the clock circle already drawn on the page. After the patient puts the numbers on the clock face, ask them to draw the hands of the clock to read a specific time (11:10). The test is considered normal if all numbers are present in the correct sequence and position and the hands readably display the requested time.
- Ask the patient to repeat the 3 previously stated words.

Scoring (out of 5 Total Points)

Give 1 point for each recalled word after the clock drawing test.

- Patients recalling none of the 3 words are classified as cognitively impaired (score = 0).
- Patients recalling all 3 words are classified as not cognitively impaired (score = 3).
- Patients with intermediate word recall of 1 or 2 words are classified on the clock drawing test:

The clock drawing test is scored 2 if normal and 0 if abnormal.

Interpretation of results

0–2: Positive screen for dementia

3–5: Negative screen for dementia

Source: Borson S, Scanlan J, Brush M, et al.: The Mini-Cog: a cognitive "vital signs" measure for dementia screening in multi-lingual elderly, *Intern J Geriatr Psychiatry* 15:1021, 2000.

TABLE 64.10 Mini-Mental State Examination (MMSE)

Sample Items

Orientation to Time

"What is the date?"

Registration

"Listen carefully. I am going to say 3 words. You say them back after I stop. Ready? Here they are HOUSE (pause), CAR (pause), LAKE (pause). Now repeat those words back to me." (Repeat up to 5 times but score only the first trial.)

Naming

"What is this?" (Point to a pencil or pen.)

Clinical Problems

Clinical problems for AD may include:

- Impaired cognition
- Risk for injury
- Impaired role performance

Additional information on clinical problems and interventions for the patient with AD is presented in eNursing Care Plan 64.1 (available on the website for this chapter).

Planning

The overall goals are for the patient with AD to (1) maintain functional ability for as long as possible, (2) be in a safe environment, (3) have personal care needs met, and (4) have dignity maintained. The overall goals for the caregiver of a patient with AD are to (1) reduce caregiver stress, (2) maintain personal, emotional, and physical health, and (3) cope with the long-term effects of caregiving.

Implementation

Health Promotion

Can AD be prevented? Although there is no known definitive way to prevent AD, there are several things that we can do to keep our brain healthy and lower the risk of developing dementia (Table 64.13).

Early recognition and treatment of AD are important. Review early signs of AD with patients and families (Table 64.4). In the early stages of AD, patients are often aware that their memory is faulty and do things to mask the problem.

Acute Care

Nursing management of the patient with AD is outlined in Table 64.14. The diagnosis of AD is traumatic for both the patient and family. It is not unusual for the patient to have depression, denial, worry, fear, and feelings of loss and dread. You are in an important position to assess for depression. Antidepressant drugs and counseling may be needed. Family caregivers may be in denial and may not seek medical attention early in the disease. Assess their ability to accept and cope with the diagnosis.

Ongoing monitoring of both the patient and caregiver is important. Patients with AD move through the stages at variable rates. The health care team works with caregivers and patients to manage manifestations, which change over time.

The care the patient needs changes as the disease progresses, which emphasizes the need for regular assessment and support. The severity of the problems and amount of care needed increase over time. The specific manifestations depend on the area of the brain involved. Nursing care focuses on decreasing manifestations, preventing harm, and supporting the patient and caregiver throughout the disease process.

Patients with AD may have other acute and chronic illnesses that require hospitalization or surgery. Hospitalization can be traumatic for the patient with AD and the caregiver. It can precipitate a worsening of dementia or the development of delirium. Caregivers and health care professionals need to help patients who have difficulty explaining their symptoms or recalling their health and medical histories. In the acute care setting, we must observe patients with AD more closely because of safety concerns. They should be frequently reassured and oriented to place and time. Anxiety or disruptive behavior may be reduced by using consistent nursing staff.

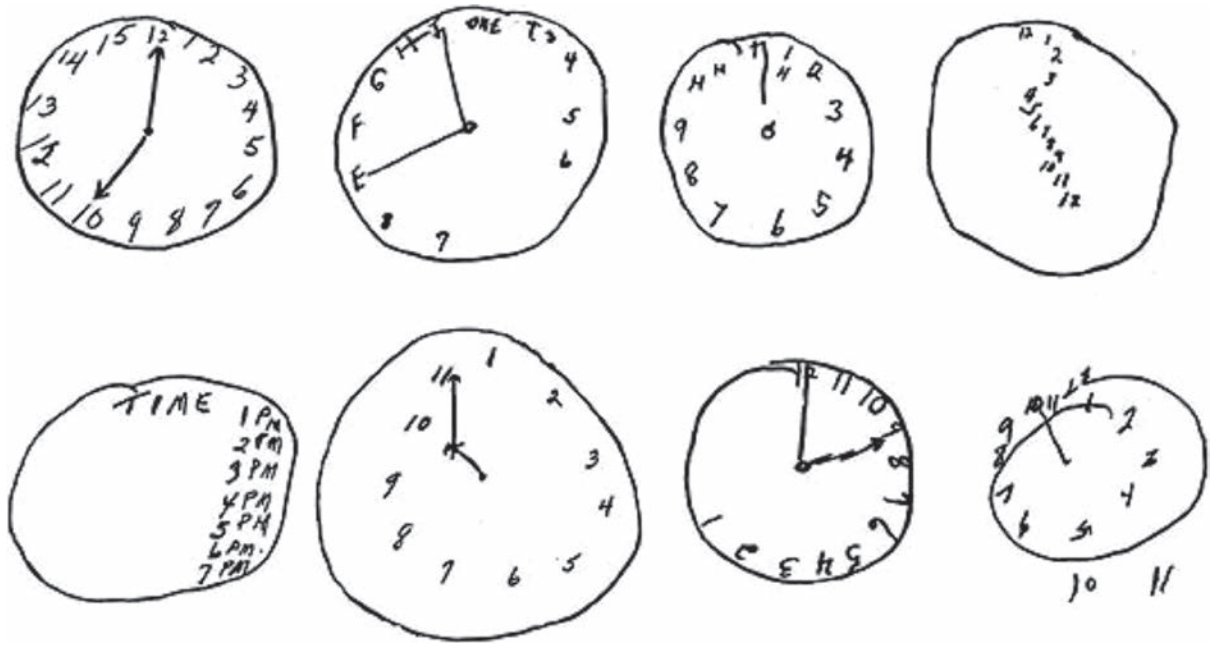

Fig. 64.7 Clock drawing is a simple test that can be used to assess for dementia. The patient is asked to draw a clock, put in all the numbers, and set the hands at 11:10. Clocks drawn by people with AD. (From Mendez M: *Mental status examination handbook*, St. Louis, 2022, Elsevier.)

TABLE 64.11 Drug Therapy

AD

Problem	Drugs
Decreased memory and cognition	Cholinesterase inhibitors • donepezil (Aricept) • galantamine (Razadyne) • rivastigmine (Exelon) N-methyl-d-aspartate (NMDA) receptor antagonist • memantine (Namenda)
Depression	Selective serotonin reuptake inhibitors (SSRIs) • citalopram (Celexa) • fluoxetine (Prozac) • sertraline (Zoloft) • fluvoxamine (Luvox) Atypical antidepressants • mirtazapine (Remeron) • trazodone
Behavior problems (e.g., agitation, physical aggression, disinhibition)	Antipsychotics • aripiprazole (Abilify) • haloperidol (Haldol) • olanzapine (Zyprexa) • quetiapine (Seroquel) • risperidone (Risperdal) Benzodiazepines • clonazepam (Klonopin) • lorazepam (Ativan)
Sleep problems	• zolpidem (Ambien)

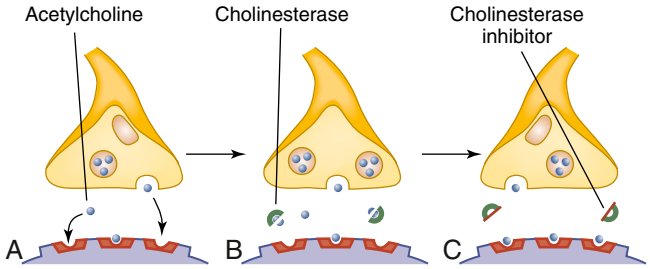

Fig. 64.8 Mechanism of action of cholinesterase inhibitors. (A) Acetylcholine is released from the nerve synapses and carries a message across the synapse. (B) Cholinesterase breaks down acetylcholine. (C) Cholinesterase inhibitors block cholinesterase, thus giving acetylcholine more time to transmit the message.

◆ Ambulatory Care

Currently, family members and friends care for many people with AD in their homes. Other patients with AD live in various types of facilities, including long-term care and assisted living. A facility that is good for one patient may not be good for another. What is helpful for a patient at one point in the disease process may be completely different from what is best when the disease progresses.

After the initial diagnosis, patients need to be aware that the progression of the disease is variable. Effective management may slow symptom progression and decrease the burden on the patient, caregiver, and family. Decisions related to care should be made with the patient, family members, and health care team early in the disease. You have a role in advising the patient and caregiver to initiate health care decisions, including advance directives, while the patient has the capacity to do so. This can ease the burden for the caregiver as the disease progresses.

In the early stages of AD, memory aids, such as calendars, may be helpful. Patients often become depressed during this phase. Depression may be related to the diagnosis of an incurable disorder and the impact of the disease on ADL, including

TABLE 64.12 NURSING ASSESSMENT

AD

Subjective Data

Important Health Information

Health history: Repeated head trauma, stroke, CNS infection, family history of dementia

Medications: Use of any drug to decrease symptoms (e.g., tranquilizers, hypnotics, antidepressants, antipsychotics)

Functional Health Patterns

Health perception–health management: Positive family history. Emotional lability

Nutritional-metabolic: Anorexia, malnutrition, weight loss

Elimination: Incontinence

Activity-exercise: Poor personal hygiene, gait instability, weakness, inability to perform activities of daily living

Sleep-rest: Frequent nighttime awakening, daytime napping

Cognitive-perceptual: Forgetfulness, inability to cope with complex situations, difficulty with problem solving (early signs), depression, withdrawal, suicidal ideation (early)

Objective Data

General

Disheveled appearance, agitation

Neurologic

Mild: Loss of recent memory, disorientation to date and time, flat affect, lack of spontaneity. Impaired abstraction, cognition, and judgment

Moderate: Agitation, impaired ability to recognize close family and friends, loss of remote memory, confusion, apraxia, agnosia, alexia (inability to understand written language); aphasia, inability to do simple tasks

Severe: Inability to do self-care, incontinence, immobility, limb rigidity, flexor posturing

Possible Diagnostic Findings

Diagnosis by exclusion, cerebral cortical atrophy on CT scan, poor scores on mental status tests, hippocampal atrophy on MRI scan, abnormal changes on PET

TABLE 64.13 PROMOTING POPULATION HEALTH

Decreasing Risk for Cognitive Decline

The following are tips to reduce the risk for cognitive decline and dementia:

1. Avoid harmful substances.
   Excessive drinking and drug use can damage brain cells. Stop smoking because it increases the risk for cognitive decline.
2. Challenge your mind.
   Read often, do crossword puzzles. Play games Keep mentally active. Learn new skills. Go back to school. This strengthens the brain connections and promotes new ones.
3. Exercise regularly.
   Even low to moderate level activity, such as walking or gardening 3 to 5 times per week, can make you feel better. Daily physical activity, even in older adults, can decrease the risk for cognitive decline.
4. Stay socially active.
   Pursue social activities that have meaning to you. Family, friends, church, and a sense of community may all contribute to better brain health.
5. Avoid trauma to the brain.
   Because traumatic brain injury may be a risk factor for developing AD, promote safety in physical activities and driving. Use the car seat belt. Wear a helmet when playing contact sports or riding a bike. Fall proof your home.
6. Take care of mental health.
   Recognize and treat depression early. Depression may cause or worsen memory loss and other cognitive problems.
7. Treat diabetes.
   Better blood glucose control can help prevent the cognitive decline from diabetes.
8. Take care of your heart.
   Risk factors for cardiovascular disease and stroke (hypertension, obesity) negatively affect your cognitive health. Heart health is linked to brain health.
9. Get enough sleep.
   Not getting enough sleep may result in problems with memory and thinking.
10. Get the right fuel.
    A healthy and balanced diet low in fats and sugary foods and high in vegetables and fruits helps to reduce the risk for cognitive decline.

Adapted from Alzheimer's Association: 10 Ways to love your brain. Retrieved from https://www.alz.org/help-support/brain_health/10_ways_to_love_your_brain.

driving, socializing, and taking part in recreational activities. Teach caregivers to perform tasks needed to maximize quality of life and safety of the patient.

Adult day care is one of the options available. They can provide respite for the family and a protective environment. Programs vary in size, structure, physical environment, and staff experience. During the early and moderate stages of AD, the patient can still benefit from stimulating activities that encourage independence and decision making in a protective environment. The patient returns home tired, content, less frustrated, and ready to be with the family. The respite from the demands of care allows the caregiver to be more responsive to the patient's needs.

As the disease progresses, the demands on the caregiver eventually exceed the resources, and the patient may need to be placed in a long-term care facility. Special dementia units are increasingly common. The dementia unit is designed with an emphasis on safety. Many have designated areas that allow the patient to walk freely within the unit. The unit is secured so that the patient cannot wander outside.

As the disease progresses to the late stage, the patient is severely impaired. They have difficulty with basic functions, including walking and talking. Total care is needed. Specific problems relate to the care of the patient in all phases of AD. These problems are described next.

Behavior problems. Behavior problems occur in about 90% of patients with AD. These problems include repetitiveness or asking the same question repeatedly, delusions, hallucinations, agitation, aggression, altered sleeping patterns, wandering, hoarding, and resisting care. Many times, these behaviors are unpredictable and may challenge caregivers. Caregivers must be aware that these behaviors are not intentional and are often difficult to control. Behavior problems are often the reason that patients are placed in a facility.[10]

These behaviors are often the patient's way of responding to pain, frustration, temperature extremes, or anxiety. When

TABLE 64.14 NURSING MANAGEMENT

Caring for the Patient With AD

Assess the patient on an ongoing basis, including:
- Memory and level of function
- Presence of any co-existing problems
- Ability to perform basic and instrumental activities of daily living
- Diet and fluid intake and develop a plan to ensure adequate intake
- Ability to meet self-care needs related to elimination and hygiene
- Safety concerns

Determine possible precipitating factors for behavior changes and develop strategies to address difficult behavior.

Assess family caregivers' stress level and coping strategies.

Implement a plan to meet areas of identified need in terms of elimination, nutrition, hydration, and hygiene.

Provide for patient needs:
- Communicate with the patient in a therapeutic manner (Table 64.15)
- Use memory aids and reorient to time, place, and person often
- Use distraction to manage agitated behavior
- Institute measures to manage pain, fever, nausea, and other symptoms
- Maintain a consistent daily routine
- Encourage continued mobility if appropriate
- Present changes in the patient's routine gradually, if possible
- If the patient uses eyeglasses or a hearing aid, have them available

Provide a safe, optimal environment by:
- Implement measures to decrease fall risk and address wandering
- Reducing noise and providing adequate nonglare lighting
- Providing a soothing atmosphere
- Assigning consistent nursing staff

Implement measures to promote sleep (see Chapter 8).

Provide caregiver support:
- Make referrals for community services, such as adult day care and respite care
- In long-term care, encourage visitation by significant others as appropriate and include them in planning, providing, and evaluating care to the extent desired
- Teach the patient and caregiver about measures to manage AD (Table 64.16)

Delegate to LPN/VN:
- Monitor for behavior changes that may indicate physiologic problems.
- Check the environment for potential safety hazards.
- Give enteral feedings to patients who are unable to swallow, if ordered.
- Give ordered medications.

Supervise AP:
- Help patients to use the toilet, commode, or bedpan at frequent intervals.
- Provide personal hygiene, skin care, and oral care.
- Help patients with eating.
- Aid patients with daily activities.
- Use bed alarms and surveillance to decrease risk for falls.

Collaborate With Other Team Members

Dietitian
- Assess nutrition status and provide prescribed nutrition support.
- Offer practical suggestions to enhance dietary intake.

Occupational Therapist
- Suggest ways to help patients retain self-care ability as long as possible.

Social Worker
- Help caregivers identify and obtain needed resources.
- Provide support and counseling to caregivers.

these behaviors become problematic, you must plan interventions carefully. Assess the patient's physical status. Check for changes in vital signs, urinary and bowel patterns, and pain that could account for behavior problems. Are there factors in the environment triggering the behavior? Extremes in temperature or excessive noise may lead to behavior changes. When environmental conditions are agitating the patient, either move the patient or remove the stimulus.

When a patient resists or pulls tubes or dressings, cover these items with stretch tube gauze or remove them from the visual field. Reassure the patient that you are present to keep them safe. If the patient cannot state distress, validate their mood. Rephrase the patient's statement to validate its meaning. Closely observe the patient's emotional state.

Nursing strategies that address difficult behavior include redirection, distraction, and reassurance. Table 64.15 lists tips for promoting communication. When a patient is restless or agitated, use redirecting. Change the patient's focus by having them perform activities, such as sweeping, raking, or dusting. Providing snacks, taking a car ride, sitting on a porch swing or rocker, listening to favorite music, watching videotapes, looking at family photographs, or walking may distract an agitated patient. Reassure patients by telling them that they will be protected from danger, harm, or embarrassment. Repetitive activities, including songs, poems, music, massage, aromas, or a favorite object can be soothing. Animal-assisted therapy helps some persons.[14]

Do not threaten to restrain an agitated patient. Ask a calming family member to stay with them. Monitor the patient frequently and record all interventions. As verbal skills decline, you and the caregiver must rely more on the patient's body language to communicate care needs. Positive nursing actions can reduce the use of chemical (drug therapy) restraints.

Antipsychotic drugs may be used to treat disruptive behaviors (Table 64.11). However, they have adverse effects. We should exhaust all other ways of treating behavior issues before starting drug treatment.

CHECK YOUR PRACTICE

You are working in a secure Alzheimer's unit. While making rounds at 1600, you see Dan, one of the APs, screaming at an 84-year-old male resident. When you approach Dan and the resident, you ask what is going on. Dan responds, "Every day about this time he gets so agitated and starts yelling at me, so I yell back."
- How would you handle the situation? What teaching does Dan need?

A specific type of agitation, **sundowning**, is when the patient becomes more confused and agitated in the late afternoon or evening. Behaviors related to sundowning include agitation, aggressiveness, wandering, resistance to redirection, and increased verbal activity, such as yelling. The cause of sundowning is unclear. It may be due to a disruption of circadian rhythms. Other causes include pain, hunger, unfamiliar environment and noise, medications, reduced lighting, and fragmented sleep.[15]

TABLE 64.15 NURSING MANAGEMENT

Promoting Communication With the Patient With AD

Do

- Treat the adult with respect and dignity, even when behavior is childlike.
- Use gentle touch and direct eye contact.
- Remain patient, flexible, calm, and understanding.
- Expect challenging behaviors since AD affects the patient's ability to think logically.
- Give directions using gestures or pictures.
- Simplify tasks. Focus on one thing at a time.
- Avoid questions or topics that require extensive thought, memory, or words.
- Be flexible. If one approach does not work, try another.
- Use distraction, changing the subject, redirecting to another activity.
- Provide reassurance. Praise sincerely for success.

Do Not

- Criticize, correct, or argue.
- Rush or hurry the patient.
- Force participation in activities or events.
- Talk about the patient as if they are not there.
- Blame the patient with AD. Instead, blame the disease.
- Take challenging behaviors personally. These behaviors are due to the disease.
- Use condescending terms, such as "honey" or "sweetie."
- Use threatening gestures.
- Overreact to the patient with AD.
- Try to explain "why" or rationalize.

Managing sundowning can be challenging for you, the patient, and the family. When a patient has sundowning, remain calm and avoid confrontation. Assess the situation for possible causes of the agitation. Helpful interventions include (1) creating a quiet, calm environment; (2) maximizing exposure to daylight by opening blinds and turning on lights during the day; (3) evaluating medications to determine if any could cause sleep problems; (4) limiting naps and caffeine; and (5) consulting with the HCP about drug therapy.

Safety. The patient is at risk for problems related to personal safety. Hazards include falling, ingesting dangerous substances, wandering, injuring others and self with sharp objects, being burned, and being unable to respond to crisis situations. These concerns require careful attention in the home environment to minimize risk. Supervision is needed. As the patient's cognitive function declines over time, they may have problems navigating physical spaces and interpreting environmental cues. Help the caregiver assess the home environment for safety risks.

! SAFETY ALERT

Preventing Falls

Teach the caregiver to take the following steps:

- Have stairwells well lit.
- Make sure the patient can grasp the handrails.
- Tack down carpet edges.
- Remove throw rugs and extension cords.
- Use nonskid mats in the tub or shower.
- Install handrails in the bath and by the commode.

Wandering is a major concern for caregivers. Wandering may be related to loss of memory or to side effects of medications. It may be an expression of a physical or emotional need, restlessness, curiosity, or stimuli that trigger memories of earlier routines. As with other behaviors, observe for factors or events that may precipitate wandering. For example, the patient may be sensitive to stress and tension in the environment. In such cases, wandering may reflect an attempt to leave.

When someone with AD is discovered missing, every second counts. To assist caregivers with finding them, the Alzheimer's Association and the MedicAlert Foundation have created an alliance called MedicAlert + Alzheimer's Association Safe Return.[16] This program includes identification products (e.g., bracelet, necklace, wallet cards), a national photo and information database, a 24-hour toll-free emergency crisis line, local chapter support, and wandering behavior education and training for caregivers and families.

Tracking devices (e.g., global positioning system [GPS]) can be used to find people who wander. These devices can be placed in shoes, sewn into pockets, worn as a bracelet or pendant, or clipped to a belt.

Pain management. Because of difficulties with oral and written language, patients may have a hard time expressing physical problems, including pain. You need to rely on other clues, such as their behavior. Pain can result in changes in behavior, including increased vocalization, agitation, withdrawal, and changes in function. Pain should be recognized and treated promptly and the patient's response monitored.

Eating and swallowing difficulties. Undernutrition is a problem in the moderate and severe stages of AD. Loss of interest in food and decreased ability to self-feed *(feeding apraxia),* as well as co-morbid conditions, can result in significant nutrition problems. In long-term care facilities, inadequate aid with feeding may add to the problem.

Use pureed foods, thickened liquids, and nutrition supplements when chewing and swallowing become problematic. The patient may need reminders to chew their food and to swallow. A quiet and unhurried environment without distractions (e.g., television) at mealtimes can help. Low lighting, music, and simulated nature sounds may improve eating behaviors. Easy-grip eating utensils and finger foods may allow the patient to self-feed. Offer liquids frequently.

When oral feeding is not possible, explore alternative routes. Nasogastric (NG) feeding may be used for short periods. However, for the long term, the NG tube is uncomfortable and may add to the patient's agitation. A percutaneous endoscopic gastrostomy (PEG) tube is another option. PEG tubes can be problematic since patients with AD are vulnerable to aspiration of feeding formula and tube dislodgment. The potential positive outcomes from nutrition therapies must be considered in light of overall goals and potential adverse effects of the specific therapy. Nutrition therapy is described in Chapter 44.

Oral care. In the late stages, the patient is unable to perform oral self-care. With decreased tooth brushing and flossing, dental problems are likely to occur. Because of swallowing difficulties, patients may retain food in the mouth, adding to the risk for tooth decay. Dental caries and tooth abscess can

cause discomfort and increase agitation. Inspect the mouth regularly. Provide mouth care to those who cannot perform self-care.

Infection prevention. Urinary tract infection and pneumonia are the most common infections in patients with AD. Such infections are the cause of death in many patients with AD. Because of feeding and swallowing problems, the patient is at risk for aspiration pneumonia. Immobility can predispose the patient to pneumonia.

Reduced fluid intake, prostate enlargement in men, poor hygiene, and urinary drainage devices can predispose patients to bladder infection. Any manifestations of infection, such as a change in behavior, fever, cough, or pain on urination, require prompt evaluation and treatment.

Skin care. It is important to monitor the patient's skin over time. Note and treat rashes, areas of redness, and skin breakdown. In the late stages, incontinence along with immobility and undernutrition can place the patient at risk for skin breakdown. Keep the skin clean and dry. Change the patient's position regularly to avoid areas of pressure over bony prominences.

Elimination problems. During the moderate and severe stages of AD, urinary and fecal incontinence lead to an increased need for nursing care. Scheduled toileting may help decrease incontinence.

Constipation is a common problem. Causes include immobility, reduced fiber intake, and decreased fluid intake. Treatment includes increased dietary fiber, fiber supplements, and stool softeners. Ways to manage constipation are discussed in Chapter 47.

Caregiver support. More than 16 million Americans provide unpaid care for people with AD or other dementias.[3] Most of these are family members providing care in the home (Fig. 64.9). AD disrupts all aspects of patient and family life. Caregivers for people with AD describe it as very stressful. They often have adverse consequences to their own health.

The chronic and often severe stress of dementia caregiving increases the risk for dementia in spouse caregivers. It could be that the effects from the chronic stress of caregiving affect the hippocampus, a region of the brain responsible for memory.

Fig. 64.9 Caregivers of patients with dementia face incredible challenges. (© KatarzynaBialasiewicz/iStock.com.)

As the disease progresses, the relationship between the caregiver and patient changes. Family roles may be altered or reversed. A child may care for a parent. Decisions must be made, including when to have the patient stop driving or doing activities that may have become dangerous, ask for assistance, and place the patient in adult day care or a long-term care facility. With early-onset AD, the patient is affected during their most productive years in terms of career and family. The consequences can be devastating to the patient and family.

AD seriously affects sexual relationships. As the disease progresses, sexual interest may decline for both the patient and partner. Several reasons account for this, including fatigue, memory impairment, and incontinence. Some patients become sexually driven and uninhibited as the disease progresses.

Work with the caregiver to assess stressors and identify coping strategies to reduce the burden of caregiving. For example, ask which behaviors are most disruptive to family life at a given time. This is likely to change as the disease progresses. Determining what is most disruptive or distressful to the caregiver can help establish priorities.

Patient safety is a high priority. Assess what the caregiver's expectations are about the patient's behavior. Are the expectations reasonable given the progression of the disease? A family and caregiver teaching guide based on the disease stages is shown in Table 64.16. A nursing care plan for the family caregiver (eNursing Care Plan 64.2) is available on the website for this chapter.

Support groups for caregivers and family members (Fig. 64.10) can provide an atmosphere of understanding and give current information about the disease itself and related topics, such as safety, legal, ethical, and financial issues. The Alzheimer's Association has many educational and support systems available to help family caregivers *(www.alz.org)*.

◆ Evaluation

Expected outcomes are that the patient with AD will:

- Function at the highest level of cognitive ability
- Perform basic personal care ADLs, by self or with assistance, as needed
- Be injury free

DELIRIUM

Delirium is a state of confusion that develops over days to hours.[1] The patient has decreased ability to direct, focus, sustain, and shift attention and awareness. Deficits in memory, orientation, language, visuospatial ability, or perception may be present. The patient may be hypoactive or hyperactive. Emotional problems include fear, depression, euphoria, or perplexity. Sleep may be disturbed.

These symptoms represent a change from the patient's baseline. They tend to fluctuate throughout the day. They do not occur in the context of a severely reduced level of arousal, such as coma, and cannot be explained by another preexisting, evolving, or established neurocognitive disorder.

Etiology and Pathophysiology

We do not know the exact cause of delirium. A main contributing factor is impaired cerebral oxidative metabolism, in which

TABLE 64.16 PATIENT & CAREGIVER TEACHING

AD

Include the following instructions when teaching families and caregivers the management of the patient with AD:

Mild Stage

- Many treatable (and potentially reversible) conditions can mimic dementia (Table 64.2). Try to establish a diagnosis.
- Get the patient to stop driving. Confusion and poor judgment can impair driving skills and potentially put others at risk.
- Encourage activities such as visiting with friends and family, listening to music, enjoying hobbies, and exercising.
- Provide cues in the home, establish a routine, and determine a specific location where essential items (e.g., glasses) must be kept.
- Do not correct misstatements or faulty memory.
- Register with MedicAlert + Alzheimer's Association Safe Return, a program established by the MedicAlert Foundation and the Alzheimer's Association to locate those who wander from their homes.
- Make plans in terms of advance directives, care options, financial concerns, and personal preference for care.

Moderate Stage

- Install door locks for patient safety.
- Provide protective wear for incontinence.
- Ensure that the home has good lighting, install handrails in stairways and bathrooms, and remove area rugs.
- Label drawers and faucets (hot and cold) to ensure safety.
- Develop ways, such as distraction and diversion, to cope with behavior problems. Identify and reduce potential triggers (e.g., reduce stress, extremes in temperature) for disruptive behavior.
- Provide memory triggers, such as pictures of family and friends.

Severe Stage

- Follow a regular schedule for toileting to reduce incontinence.
- Provide care to meet needs, including oral care and skin care.
- Monitor diet and fluid intake to ensure their adequacy.
- Continue communication through talking and touching.
- Consider placement in a long-term care facility when providing total care becomes too difficult.

Fig. 64.10 Support groups are an effective way to help caregivers cope. (© SDI Productions/iStock.com.)

the brain gets less oxygen and has problems using it. Multiple neurotransmitter abnormalities may be involved. Cholinergic deficiency, excess release of dopamine, and both increased

TABLE 64.17 Risk Factors for Delirium

Demographic Characteristics
- Age 65 years or older
- Male gender

Cognitive Status
- Cognitive impairment
- Dementia
- Depression
- History of delirium

Decreased Oral Intake
- Dehydration
- Malnutrition

Drugs
- Alcohol or drug use or withdrawal
- Aminoglycosides
- Anticholinergics
- Opioids
- Sedative-hypnotics
- Treatment with multiple drugs
- Vasopressors

Environmental
- Admission to ICU
- Pain (especially untreated)
- Restraints use
- Sleep deprivation
- Stress

Functional Status
- Functional dependence
- History of falls
- Immobility

Medical Problems
- Acute infection, sepsis, fever
- Chronic kidney or liver disease
- Electrolyte imbalances
- Fracture or trauma
- Hemodynamic instability
- History of stroke
- Hypertension
- Hypoxia
- Neurologic disease
- Severe acute illness
- Terminal illness

Sensory
- Sensory deprivation
- Sensory overload
- Vision or hearing impairment

Surgery
- Cardiac surgery
- Noncardiac surgery
- Orthopedic surgery
- Prolonged cardiopulmonary bypass

TABLE 64.18 Mnemonic for Causes of Delirium

Dementia, dehydration
Electrolyte imbalances, emotional stress
Lung, liver, heart, kidney, brain
Infection, intensive care unit
Rx drugs
Injury, immobility
Untreated pain, unfamiliar environment
Metabolic disorders

and decreased serotonin activity may contribute to delirium. Proinflammatory cytokines, including interleukin-1 (IL-1), IL-2, IL-6, tumor necrosis factor-α (TNF-α), cytokines, and interferon, appear to play a role.

Delirium is rarely caused by a single factor. Common factors that can lead to delirium are listed in Tables 64.17 and 64.18. Major risk factors include increased age, preexisting dementia, hypertension, alcohol use, and severe illness on admission. Dementia is the leading risk factor for delirium. Likewise, delirium is a risk factor for developing dementia. Delirium may cause permanent neuronal damage and lead to dementia.

Environmental factors that can contribute to delirium include sleep deprivation, stress, sensory overload, and immobilization. Physical conditions such as electrolyte imbalances and

severe infections can lead to delirium. Last, certain drugs (e.g., sedatives [benzodiazepines], opioids) are linked with delirium, especially in older or vulnerable patients.[17]

Delirium most often occurs among hospitalized older adults.[18] Up to 60% of older adults hospitalized for medical conditions have delirium at some time during their hospitalization. It is the most common surgical complication among older adults. Older adults have limited compensatory mechanisms to deal with physiologic insults, such as hypoxia, hypoglycemia, and dehydration.

The prevalence of delirium in ICU patients is as high as 87%. It is related to longer hospital stays and higher mortality rates.

Delirium may be the first symptom of life-threatening problems such as pneumonia, urosepsis, or meningitis. It can occur after a relatively minor insult in a vulnerable patient. For example, a patient with underlying health problems, such as heart failure (HF), cancer, cognitive impairment, or sensory limitations, may develop delirium in response to a minor change, such as using a sleeping medication. In other less vulnerable patients, it may take a combination of factors, such as anesthesia, major surgery, mechanical ventilation, infection, and prolonged sleep deprivation, to precipitate delirium. Pain and depression contribute to delirium, especially among older adults.

Clinical Manifestations

Delirium can have a variety of manifestations, ranging from hypoactivity and lethargy to hyperactivity, agitation, and hallucinations. Patients can have mixed delirium, with both hypoactive and hyperactive symptoms. Delirium can develop over the course of hours to days. It usually develops over a 2- to 3-day period. Delirium can last from 1 to 7 days. However, delirium may persist for months or years. Some patients do not fully recover.

During a delirious state, the patient often has a reduced ability to focus, sustain, and shift attention. Memory, judgment, and orientation are impaired. Speech is rapid, rambling, and/or incoherent. Other manifestations often include disorganized thinking, irritability, insomnia, loss of appetite, and restlessness. Later manifestations may include agitation, misperception, misinterpretation, and hallucinations.

Manifestations of delirium are sometimes confused with those of dementia. A key distinction between them is that the patient who has sudden cognitive impairment, disorientation, or clouded sensorium is more likely to have delirium rather than dementia. Table 64.1 compares delirium and dementia.

Diagnostic Studies

Diagnosing delirium is complicated because many critically ill patients cannot communicate their needs. A careful medical, psychologic history, and physical assessment are the first steps in diagnosing delirium and its underlying cause. This includes careful attention to medications, both prescription and OTC. The Confusion Assessment Method (CAM) is a reliable tool for assessing delirium (Table 64.19). The version of the CAM may vary depending on the clinical setting. Determine if delirium is related to underlying dementia.

TABLE 64.19 Confusion Assessment Method (CAM)

Delirium is diagnosed with the presence of features 1 and 2 and either 3 or 4.

Feature 1

Acute Onset and Fluctuating Course

Data usually obtained from a family member or nurse.

Shown by positive responses to the following questions:

- Is there evidence of an acute change in mental status from the patient's baseline?
- Did the (abnormal) behavior fluctuate during the day (i.e., tend to come and go, or increase and decrease in severity)?

Feature 2

Inattention

Shown by positive response to the following question:

- Did the patient have problem focusing attention (e.g., being easily distractible, or having problem keeping track of what was being said)?

Feature 3

Disorganized Thinking

Shown by a positive response to the following question:

- Was the patient's thinking disorganized or incoherent, such as rambling or irrelevant conversation, unclear or illogical flow of ideas, or unpredictable switching from subject to subject?

Feature 4

Altered Level of Consciousness

Shown by any answer other than "alert" to the following question:

- Overall, how would you rate this patient's level of consciousness (alert [normal], vigilant [hyper alert], lethargic [drowsy, easily aroused], stupor [difficult to arouse], or coma [unarousable])?

Adapted from Inouye S, van Dyck C, Alessi C, et al: Clarifying confusion: the confusion assessment method, *Ann Intern Med* 113:941, 1990.

Once delirium has been diagnosed, explore potential causes. Review the health history and medication record. Laboratory tests include CBC, serum electrolytes, blood urea nitrogen (BUN), and creatinine levels; ECG; urinalysis; liver and thyroid function tests; and O_2 saturation. Drug and alcohol levels may be obtained. If unexplained fever or nuchal rigidity is present and meningitis or encephalitis is suspected, a lumbar puncture may be done. CSF is examined for glucose, protein, and bacteria. If the patient's history includes head injury, appropriate x-rays or scans may be ordered. In general, brain imaging studies, such as CT and MRI, are used only when head injury is known or suspected.

❖ NURSING AND INTERPROFESSIONAL MANAGEMENT: DELIRIUM

Treatment is important as many cases of delirium are potentially reversible. In caring for a patient with delirium, you are responsible for prevention, early recognition, and treatment (Table 64.20). Prevention involves recognition of patients at high risk, including those with neurologic disorders, such as dementia or stroke. Table 64.17 lists common risk factors. (Box 64.4)

Care focuses on eliminating precipitating factors. If it is drug induced, medications are discontinued. Keep in mind

TABLE 64.20 NURSING MANAGEMENT

Caring for the Patient With Delirium

Determine the potential cause for delirium and initiate measures to address the cause if appropriate

Regularly assess for manifestations of delirium

- Administer screening tools, such as the CAM (Table 64.19)
- Screen for the presence of any co-existing problems
- Review the results of diagnostic tests

Determine their ability to meet self-care needs related to nutrition, elimination, hydration, and hygiene and implement a plan to meet any areas of identified need

Provide for patient needs:

- Provide the patient with reassurance
- Talk to the patient and reorient to time, place, and person often
- Use distraction to manage agitated behavior
- Institute measures to manage pain, fever, nausea, and other symptoms
- Encourage early mobility if appropriate
- If the patient uses eyeglasses or a hearing aid, have them available

Provide a safe, optimal environment by:

- Reducing noise and providing adequate nonglare lighting
- Providing a soothing atmosphere
- Plan for consistent nursing staff

Implement measures to promote sleep (see Chapter 8)

Teach the patient and caregivers about causes and manifestations of delirium

that delirium can accompany drug and alcohol withdrawal. Depending on the history, drug screening may be done. Fluid and electrolyte imbalances and nutrition deficiencies (e.g., thiamine) are corrected if appropriate. If delirium is from infection, appropriate antibiotic therapy is started. Similarly, if delirium is due to chronic illness, such as chronic kidney disease or HF, treatment focuses on these conditions.

If the problem is related to an overstimulating or an understimulating environment, then changes should be made. Reduce environmental stimuli, including noise and light levels. Limit noise levels by muting phones, setting alarms based on the patient's condition, and reducing unnecessary alarms. Limit overhead paging and all unnecessary noise in patient care areas.

Conversation is an especially stressful noise, especially when it concerns the patient and is held in the presence of, but without participation from, the patient. Reduce this source of stress by finding suitable places for patient-related discussions. Whenever possible, include the patient and caregiver in the discussion.

CHECK YOUR PRACTICE

You are working in the medical ICU. Your patient is an 82-year-old man who had a hip replacement 3 days ago. He was doing well after surgery and then developed bilateral pneumonia. He was transferred to the ICU yesterday. When you walk into his room, you notice his daughter is staring out the window and does not respond to your greeting. When you approach her, you notice she is very upset. When you ask her what is wrong, she bursts out crying, "How can this be? My dad is a brilliant man. Now look at him. He talks to himself. He screams at me. He thinks I am his wife. Mom died 5 years ago. What happened to him?"

- How would you assess the situation?
- What can you do to help the daughter?

BOX 64.4 EVIDENCE-BASED PRACTICE

Postoperative Delirium

You are caring for S.L., an 82-year-old patient who fell and sustained a femoral neck fracture. Fracture repair is scheduled this morning. The patient's daughter is with S.L. During your assessment, S.L. is unable to identify a pain intensity score but tells you, "It doesn't hurt much when I lay very still." S.L. is alert and oriented to person and place but does recall falling. S.L. tells you, "I couldn't find my glasses!" The history includes hypertension and type 2 diabetes, with a recent glycosylated hemoglobin result of 8.2. BP at 0800 was 148/82 mm Hg. You administer the scheduled atenolol 100 mg with a sip of water.

Making Clinical Decisions

Synthesis of Best Available Evidence

Cognitive changes often occur in older adults after surgery, ranging from a transient problem to a persistent decline. The 2 main conditions have been identified as postoperative delirium and postoperative cognitive dysfunction.

Clinician Expertise

S.L.'s risk factors for postoperative delirium, include age, history of diabetes and hypertension, impaired vision, lack of sleep, and current cognitive state. You are prepared to use an assessment tool for delirium as part of your assessment when S.L. returns from surgery. Your interventions would include managing stressors that could precipitate delirium.

Patient Preferences and Values

S.L.'s daughter tells you during her preoperative visit, "My mother seems much calmer and more comfortable. I was really concerned to see her so restless and unsettled. I don't believe she's slept much since the fall."

Implications for Nursing Practice

1. What would you do if your assessment findings suggest delirium?
2. What stressors should be managed to decrease the risk of postoperative delirium?

Reference for Evidence

Hasan TF, Kelley RE, Cornett EM, et al.: Cognitive impairment assessment and interventions to optimize surgical patient outcomes, *Best Practice & Research Clinical Anaesthesiology* 34:225, 2020.

Implement measures to protect the patient from harm. Give priority to creating a calm and safe environment. The presence of a caregiver may help. Provide familiar objects and family photos, transfer the patient to a private room or one closer to the nurses' station, and plan for consistent nursing staff if possible. Use reorientation and behavior interventions. Provide the patient with reassurance and reorienting information as to place, time, and procedures. Clocks, calendars, and lists of scheduled activities are helpful. Removing lines no longer needed and early mobility are effective.

Reorient patients who are confused during assessments to provide comfort and direction. Personal contact through touch and verbal communication can be an important reorienting strategy. If the patient uses eyeglasses or a hearing aid, they should be available because sensory deprivation can precipitate delirium. Avoid the use of restraints. Other interventions, including relaxation techniques, music therapy, and massage, may be appropriate for some patients with delirium.

You may need to address polypharmacy, pain, nutrition status, and potential for incontinence. The patient with delirium

is at risk for the adverse consequences of immobility, including skin breakdown. Give attention to increasing physical activity or providing range-of-motion exercises, when appropriate, and maintaining skin integrity.

Focus on supporting the family and caregivers during episodes of delirium. Family members need to understand factors that may have precipitated the delirium, as well as the potential outcomes. Patient education materials are available at www.ICUdelirium.org.

Drug Therapy

Drug therapy is reserved for patients with severe agitation, especially when it interferes with needed medical treatments. Agitation can put the patient at risk for falls and injury. Drug therapy is used cautiously because many of the drugs used to manage agitation have psychoactive properties. Drugs should be used only when nonpharmacologic interventions have failed.

Dexmedetomidine (Precedex), an α-adrenergic receptor agonist, has been used in ICU settings for sedation. The use of low-dose antipsychotics (e.g., haloperidol, risperidone [Risperdal]), though common practice, is controversial. Their use does not change the duration of delirium or the length of hospitalization.

Haloperidol can be given IV, IM, or orally. It will produce sedation. Other side effects include hypotension; extrapyramidal side effects, including *tardive dyskinesia* (involuntary muscle movements of face, trunk, and arms) and *athetosis* (involuntary writhing movements of the limbs); muscle tone changes; and anticholinergic effects. Monitor older patients receiving antipsychotic agents.

Short-acting benzodiazepines (e.g., lorazepam [Ativan]) can be used to treat delirium from sedative and alcohol withdrawal or in conjunction with antipsychotics to reduce extrapyramidal side effects. However, these drugs may worsen delirium caused by other factors and must be used cautiously.

Case Study

Alzheimer Disease

(© iStock/Thinkstock.)

Patient Profile

M.Y., a 78-year-old man, was diagnosed with AD 3 years ago, shortly after his wife died. Today, his 45-year-old son brings him to the emergency department because he wandered from his son's home, fell, and injured his left hip.

Subjective Data

- Can say his name, confused as to place and time
- Denies memory of wandering or falling
- Agitated, trying to get up
- Denies pain

Objective Data

Physical Assessment

- Left leg shorter than the right leg
- Tense and anxious

Diagnostic Studies

- X-ray of left hip indicates a fracture
- Mini-Cog testing indicates cognitive impairment

Discussion Questions

1. ***Recognize:*** What is the pathogenesis of AD?
2. ***Analyze:*** What precipitating factors may have resulted in M.Y.'s fall?
3. ***Plan:*** Surgery is planned to repair his fractured hip. Why is he at risk for delirium?
4. ***Prioritize:*** Based on the assessment data, what are the priority clinical problems?
5. ***Prioritize:*** What is the priority nursing intervention for M.Y.?
6. ***Act:*** What nursing activities can you delegate to assistive personnel (AP)?
7. ***Act:*** What teaching plan should you develop for M.Y. and his son?
8. ***Safety:*** What safety precautions need to be taken when caring for M.Y.?

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Dementia is defined as a
   - **a.** syndrome that results only in memory loss.
   - **b.** disease associated with abrupt changes in behavior.
   - **c.** disease that is always due to reduced blood flow to the brain.
   - **d.** syndrome characterized by cognitive dysfunction and loss of memory.
2. Vascular dementia is associated with
   - **a.** transient ischemic attacks.
   - **b.** viral infection of nerve tissue.
   - **c.** cognitive changes from cerebral ischemia.
   - **d.** abrupt changes in cognitive function that are irreversible.
3. Assessment findings in a patient with dementia with Lewy bodies (DLB) include
   - **a.** remissions and exacerbations over many years.
   - **b.** memory impairment, muscle jerks, and blindness.
   - **c.** parkinsonian symptoms, including muscle rigidity.
   - **d.** increased intracranial pressure from decreased CSF drainage.
4. Which statement(s) accurately describe(s) mild cognitive impairment? *(select all that apply)*
   - **a.** Cannot be detected by screening tests
   - **b.** The person may appear normal to the casual observer
   - **c.** Family members may see changes in the patient's abilities
   - **d.** Problems the person is experiencing interfere with daily activities
   - **e.** The person is usually aware that there is a problem with their memory
5. A patient with cognitive impairment would receive a clinical diagnosis of dementia based on
   - **a.** CT or MRI.
   - **b.** brain biopsy.
   - **c.** electroencephalogram.
   - **d.** history and cognitive assessment.
6. A priority goal of treatment for the patient with Alzheimer disease is to
   - **a.** maintain patient safety.
   - **b.** maintain or increase body weight.
   - **c.** return to a higher level of self-care.
   - **d.** enhance functional ability over time.

7. Which patient is at the highest risk for developing delirium?
   a. A 50-year-old woman with cholecystitis
   b. A 19-year-old man with a fractured femur
   c. A 42-year-old woman having an elective total hysterectomy
   d. A 78-year-old man admitted to the medical unit with complications of heart failure

1. d; 2. c; 3. c; 4. b, c, e; 5. d; 6. a; 7. d.

CONCEPTUAL FOCUS

Family Dynamics
Functional Ability
Mobility
Pain
Sensory Perception

LEARNING OUTCOMES

1. Outline the classification of spinal cord injuries and associated clinical manifestations.
2. Describe the clinical manifestations and interprofessional and nursing management of neurogenic and spinal shock.
3. Relate the clinical manifestations of spinal cord injury to the level of disruption and rehabilitation potential.
4. Describe the nursing management of the patient with a spinal cord injury.
5. Explain the types, clinical manifestations, and interprofessional and nursing management of spinal cord tumors.
6. Explain the etiology, clinical manifestations, and interprofessional and nursing management of trigeminal neuralgia and Bell's palsy.
7. Describe the etiology, clinical manifestations, and interprofessional and nursing management of Guillain-Barré syndrome and inflammatory demyelinating polyneuropathy.

KEY TERMS

autonomic dysreflexia
Bell's palsy
Guillain-Barré syndrome (GBS)
neurogenic bladder
neurogenic bowel
neurogenic (vasogenic) shock
paraplegia
spinal cord injury (SCI)
spinal shock
tetanus
tetraplegia
trigeminal neuralgia (TN)

This chapter discusses spinal cord and peripheral nerve problems, including spinal cord injuries, spinal cord tumors, cranial nerve disorders, and polyneuropathies. We focus on the nursing management of the problems encountered by the patient with spinal cord injury (SCI). The potential for disruption of individual growth and development, altered family dynamics, economic loss from unemployment, and the high cost of rehabilitation and long-term health care make SCI a major problem. While many people with SCI can care for themselves independently, those with the highest level of injury need around-the-clock care at home or in a long-term care facility. The nurse's role in providing holistic care can significantly impact the patient's general health and well-being.

SPINAL CORD PROBLEMS

SPINAL CORD INJURY

Spinal cord injury (SCI) is caused by trauma or damage to the spinal cord. It can result in temporary or permanent alteration in spinal cord function. About 17,000 Americans have SCIs each year. Some 282,000 persons in the United States are living with SCI. The average life expectancy for persons with SCI is shortened and has not improved since the 1980s. In the first year after injury, mortality rates are high. There is a 30% chance of rehospitalzation.[1]

Etiology and Pathophysiology

SCI is usually a result of trauma. The 4 most common causes are motor vehicle collisions (38%), falls (30.5%), violence (13.5%), and sports injuries (9%).[1]

Types of Injury

Neurologic damage caused by SCI occurs in 2 phases: *primary injury* (initial physical disruption of the spinal cord) and *secondary injury* (from processes such as ischemia, hypoxia, hemorrhage, edema).

Primary injury. *Primary injury* results from direct physical trauma to the spinal cord due to blunt or penetrating trauma. Trauma can cause spinal cord compression by bone displacement, interruption of blood supply, or distraction from pulling. Penetrating trauma, such as gunshot and stab wounds, can cause tearing and transection.

Secondary injury. *Secondary injury* refers to the ongoing, progressive damage that occurs after the primary injury. Secondary injury causes further permanent damage. It begins a few minutes after injury and lasts for months. The cascade of events results in edema, ischemia, and inflammation. This causes cell death, disruption of the blood-brain barrier, and demyelination. This can extend the level of deficit and worsen long-term outcomes.

The edema from the inflammatory response is especially harmful because of limited space for tissue expansion. Thus, compression of the spinal cord occurs. Edema extends above and below the injury, increasing ischemic damage. Within 24 hours, permanent damage may occur from edema.

Apoptosis (programmed cell death) continues for weeks. It contributes to post-injury demyelination. The inflammatory response at the site of the initial injury focuses on clearing up the initial cellular debris without damaging normal tissue. This results in a central non-neural core of connective tissue that we refer to as a glial scar (Fig. 65.1). The glial scar creates a physical barrier. It restricts the cells in the spinal cord from migration and regeneration. This leads to irreversible nerve damage and permanent neurologic deficit.

Spinal and Neurogenic Shock

Spinal shock may occur shortly after acute SCI. It is characterized by loss of deep tendon and sphincter reflexes, loss of sensation, and flaccid paralysis below the level of injury. This syndrome lasts days to weeks. It often masks post-injury neurologic function.[2]

In contrast to spinal shock, **neurogenic (vasogenic) shock** can occur in cervical or high thoracic injury (T6 or higher). It occurs from unopposed parasympathetic response due to loss of sympathetic nervous system (SNS) innervation. It causes peripheral vasodilation, venous pooling, and decreased cardiac output. Manifestations include significant hypotension (<90 mm Hg), bradycardia, and temperature dysregulation. Neurogenic shock may persist for as long as 5 weeks after injury.[3] Hypotension can result in poor perfusion and oxygenation to the spinal cord and worsen spinal cord ischemia.[3]

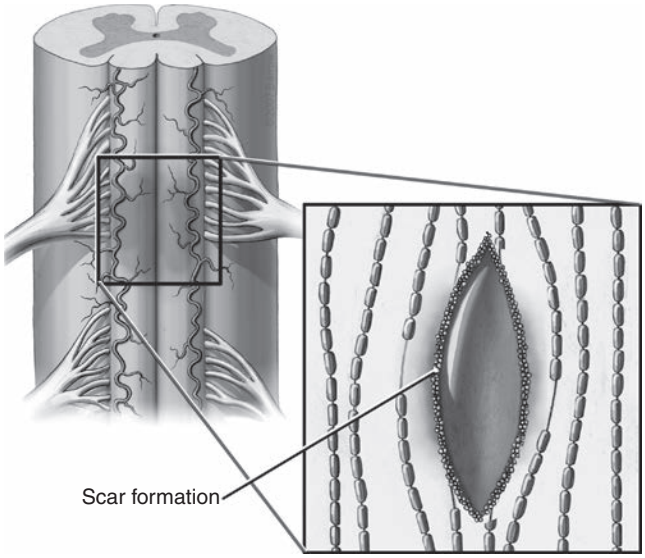

Fig. 65.1 1 to 2 days after the injury, astrocytes proliferate and surround the edges of the fibrotic scar. This confines inflammation to the area of injury protects and neighboring neural tissue from further damage. This process may take 7 to 10 days. (Used with permission from Barrow Neurological Institute, Phoenix, AZ.)

Classification of SCI

SCI is classified by the (1) mechanism of injury, (2) level of injury, and (3) degree of injury.

Mechanisms of injury. The major mechanisms of injury include flexion, flexion-rotation, hyperextension, vertical compression, extension-rotation, and lateral flexion (Fig. 65.2). Flexion-rotation injury is often the most unstable because ligaments that stabilize the spine are torn. This injury most often contributes to severe neurologic deficits.

Level of injury. *Skeletal level* of injury is the vertebral level with the most damage to vertebra and related ligaments. *Neurologic level* is the lowest segment of the spinal cord with normal sensory and motor function on both sides of the body. The level of injury may be cervical, thoracic, lumbar, or sacral. Cervical and lumbar injuries are most common because those areas of the spine are associated with the greatest flexibility and movement.

Injury from C1 to T1 can cause paralysis of all 4 extremities, resulting in **tetraplegia** (formerly called *quadriplegia*). The degree of impairment in the arms after cervical injury depends on the level of injury. The lower the level, the more function is retained in the arms.

Paraplegia (paralysis and loss of sensation in the legs) can occur in SCI below the level of T2.[4] Fig. 65.3 shows affected structures and functions at different levels of cord injury.

Degree of injury. The degree of spinal cord involvement may be complete or incomplete (partial). *Complete cord involvement* results in total loss of sensory and motor function below the level of injury. *Incomplete cord involvement* results in a mixed loss of voluntary motor activity and sensation and leaves some tracts intact. The degree of sensory and motor loss depends on the level of injury and reflects specific damaged nerve tracts.

Five major syndromes are associated with incomplete injuries: central cord syndrome, anterior cord syndrome,

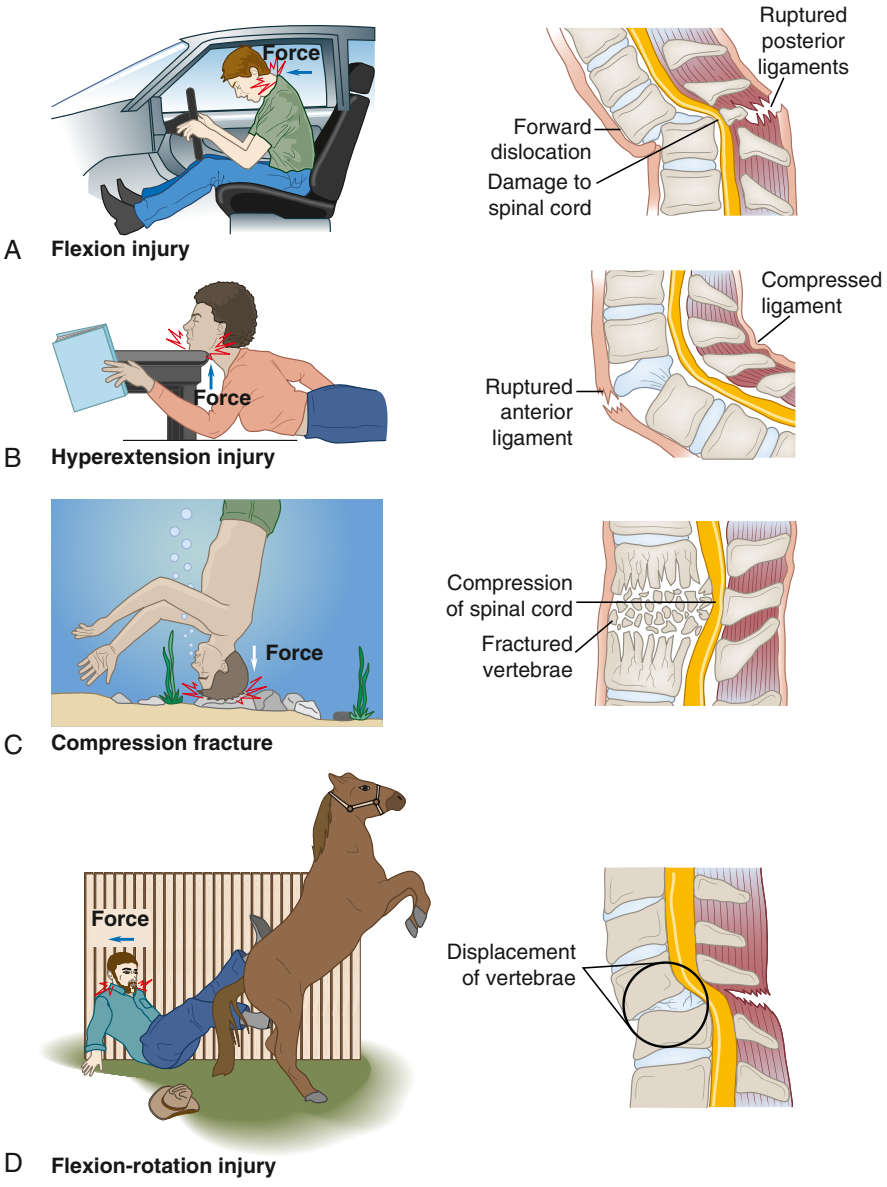

Fig. 65.2 Examples of mechanisms of spinal cord injury. (A) Flexion injury of the cervical spine ruptures the posterior ligaments. (B) Hyperextension injury of the cervical spine ruptures the anterior ligaments. (C) Compression fractures crush the vertebrae and force bony fragments into the spinal canal. (D) Flexion-rotation injury of the cervical spine often results in tearing of ligamentous structures that normally stabilize the spine. (A–C, From Copstead-Kirkhorn LC, Banasik JL: *Pathophysiology,* ed 5, St Louis, 2014, Mosby.)

Brown-Séquard syndrome, cauda equina syndrome, and conus medullaris syndrome (Table 65.1).

Clinical Manifestations

Manifestations of SCI are the result of trauma that causes cord compression, ischemia, edema, and possible cord transection. They are related to the level and degree of injury. The patient with an incomplete injury may have a mix of manifestations.

Motor and Sensory Effects

The American Spinal Injury Association (ASIA) Impairment Scale is used to classify the severity of impairment from SCI. It combines motor and sensory function assessments to determine neurologic level and completeness of injury (Fig. 65.4).[5]

We call the sensory regions *dermatomes*. Each segment of the spinal cord innervates a specific area of skin. A dermatome map is shown in Fig. 60.7. Each dermatome has a recommended point for testing.

The ASIA Impairment Scale is useful for recording changes in neurologic status. It helps us identify rehabilitation goals. Movement and rehabilitation potential related to specific locations of SCI are described in Table 65.2. In general, sensory function closely matches motor function at all levels.

Respiratory System

Respiratory complications closely correspond to the level of injury. Cervical injuries above C3 present special problems because of the total loss of respiratory muscle function.

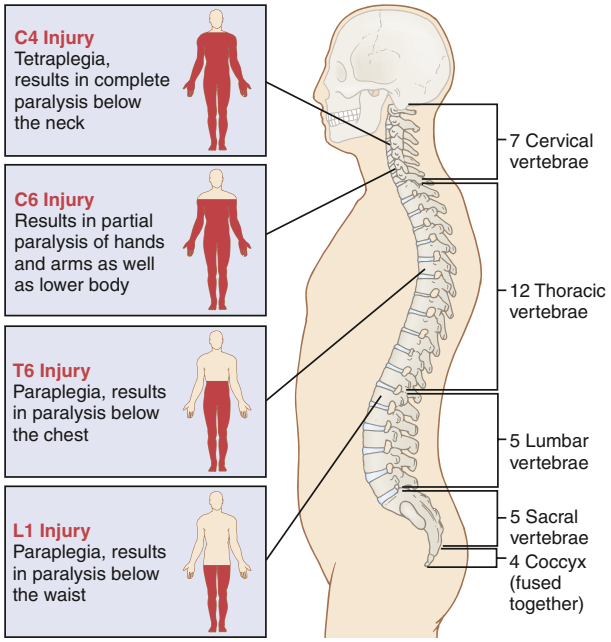

Fig. 65.3 Symptoms, degree of paralysis, and potential for rehabilitation depend on level of spinal injury.

These patients have respiratory arrest within minutes of injury if not intubated. Patients with high cervical injury (C3–5) have respiratory insufficiency due to loss of phrenic nerve innervation to the diaphragm and decreased chest and abdominal wall strength.[6] Patients with complete SCI above C5 should be intubated at once. Patients with incomplete SCI injury will have a high degree of variability in their respiratory function.

Cervical and thoracic injuries cause paralysis of abdominal muscles and often the intercostal muscles. The patient cannot cough effectively enough to remove secretions. This increases the risk for aspiration, atelectasis, and pneumonia. Hypoventilation and impairment of the intercostal muscles lead to decreased vital capacity and tidal volume.

Associated traumatic injuries, such as lung contusions, can further compromise lung function. Fluid overload can cause pulmonary edema. Neurogenic pulmonary edema may occur due to a dramatic increase in SNS activity at the time of injury.

Maintaining an arterial saturation above 92% reduces hypoxemia, which can lead to bradycardia and worsen secondary injury. Patients are assessed for respiratory distress, including dyspnea, decreased vital capacity, and pCO_2 greater than 20 mm Hg above baseline, and their ability to manage their secretions. Patients in distress may need mechanical ventilation.

Cardiovascular System

Any cord injury above T6 leads to SNS dysfunction. The result may be bradycardia, peripheral vasodilation, and hypotension (neurogenic shock). Peripheral vasodilation causes relative hypovolemia because of the increase in the capacity of the dilated veins. It reduces venous return of blood to the heart. Cardiac output then decreases, leading to hypotension. Other injuries can cause hemorrhagic shock and further reduce BP. It is essential to identify all causes of hypotension in the person with SCI. Those on β-blockers, young, healthy patients, and older adults may not be tachycardic with bleeding.[6]

TABLE 65.1 Incomplete Spinal Cord Injury Syndromes

Description	Manifestations
Anterior Cord Syndrome	
• Damage to anterior spinal artery • Results in compromised blood flow to anterior spinal cord • Typically results from acute compression of anterior part of the spinal cord • Common with flexion injury	• Motor paralysis and loss of pain and temperature sensation below level of injury • Since posterior cord tracts are not injured, sensations of touch, position, vibration, and motion remain intact
Brown-Séquard Syndrome	
• Damage to half of the spinal cord • Typically results from penetrating injury to spinal cord	• *Contralateral* (opposite side of injury): Loss of pain and temperature sensation below level of injury • *Ipsilateral* (same side as injury): Loss of motor function, light touch, pressure, position, and vibratory sense
Cauda Equina Syndrome	
• Damage to cauda equina (lumbar and sacral nerve roots)	• Asymmetric distal weakness, patchy sensation in lower extremities • May cause flaccid paralysis of lower extremities • Complete loss of sensation between legs and over buttocks, inner thighs, and backs of legs (*saddle area*) • Areflexic (flaccid) bladder and bowel • Severe, radicular, asymmetric pain
Central Cord Syndrome	
• Damage to central spinal cord • Occurs most often in cervical cord region • More common in older adults • Caused by hyperextension injury in people with degenerative disease	• Motor weakness and altered sensation present in upper extremities • Lower extremities not usually affected • Burning pain in upper extremities
Conus Medullaris Syndrome	
• Damage to conus medullaris (lowest part of spinal cord)	• Motor function in legs may be preserved, weak, or flaccid • Decrease in or loss of sensation in perianal area • Areflexic bowel and bladder • Impotence

Urinary System

Urinary dysfunction occurs in most patients after SCI. **Neurogenic bladder** describes any type of bladder dysfunction related to abnormal or absent bladder innervation. After SCI, the ability of the bladder muscles and the micturition center in the brain to transmit information is impaired. Both the detrusor muscle (bladder wall) and sphincter muscle (a valve around the

American Spinal Injury Association (ASIA) Impairment Scale

- ☐ **A = Complete.** No sensory or motor function is preserved in the sacral segments S4-5.
- ☐ **B = Sensory Incomplete.** Sensory but not motor function is preserved below the neurologic level and includes the sacral segments S4-5 (light touch or pin prick at S4-5 or deep anal pressure) AND no motor function is preserved more than three levels below the motor level on either side of the body.
- ☐ **C = Motor Incomplete.** Motor function is preserved at the most caudal sacral segments for voluntary anal contraction (VAC) OR the patient meets the criteria for sensory incomplete status (sensory function preserved at the most caudal sacral segments [S4-S5]), and has some sparing of motor function more than three levels below the ipsilateral motor level on either side of the body.
- ☐ **D = Motor Incomplete.** Motor incomplete status as defined above, with at least half (half or more) of key muscle functions below the single neurologic level of injury (NLI) having a muscle grade ≥ 3.
- ☐ **E = Normal.** If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments, and the patient had prior deficits, then the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.
- ☐ **ND = Not Determined.** To document the sensory, motor, and NLI levels, the ASIA Impairment Scale grade, and/or the zone of partial preservation (ZPP) when they are unable to be determined based on the examination results.

Fig. 65.4 The ASIA Impairment Scale. (From American Spinal Injury Association.)

top of the urethra) may be overactive due to the lack of brain control. This may cause high bladder pressures and urinary retention. Incontinence results from reflex emptying and failure to store urine.

Depending on the injury, a neurogenic bladder may (1) have no reflex detrusor contractions *(flaccid, hypotonic),* which can result in bladder stretching from overdistention; (2) have hyperactive reflex detrusor contractions *(spastic),* seen in SCI above T12, leading to incontinence; or (3) lack coordination between detrusor contraction and urethral relaxation *(dyssynergia),* resulting in reflux of urine into the kidneys. Reflux into the kidneys can lead to stone formation, hydronephrosis, pyelonephritis, and renal failure.[7]

Gastrointestinal System

Decreased gastrointestinal (GI) motor activity contributes to gastric distention and paralytic ileus. Gastric emptying may be delayed, especially in patients with higher-level SCI. Excessive release of hydrochloric acid (HCl) in the stomach may cause stress ulcers. Dysphagia may be present in patients who need mechanical ventilation, tracheostomy, or anterior spine surgery.

Intraabdominal bleeding may be hard to diagnose because the person with SCI may not have pain or tenderness. Continued hypotension and decreases in hemoglobin and hematocrit may be the only signs of bleeding.

Loss of voluntary control of the bowel results in **neurogenic bowel**. SCI above the level of the conus medullaris results in a *hyperreflexic* bowel with increased rectal and sigmoid compliance. Combined with increased anal sphincter tone and the inability to sense a full rectum, this causes stool retention and constipation.[8] SCI at or below the conus medullaris causes the bowel to be *areflexic*. Peristalsis is impaired, and stool movement is slow. The defecation reflex may be damaged and anal sphincter tone relaxed. This leads to constipation, increased risk for incontinence, and possible impaction, ileus, or megacolon. Hemorrhoids can occur.

Skin

The risk for skin breakdown over bony prominences in areas of decreased or absent sensation is a major consequence of immobility. Pressure injuries can occur quickly and lead to infection and sepsis.

Thermoregulation

*Poikilothermi*a is the inability to maintain a constant core temperature, with the patient assuming the temperature of the environment. It occurs in SCI because interruption of the SNS prevents peripheral temperature sensations from reaching the hypothalamus. There is a decreased ability to sweat or shiver below the level of injury, which affects the ability to regulate body temperature. The degree of poikilothermia depends on the level of injury. Cervical injuries are associated with a greater loss of ability to regulate temperature than are thoracic or lumbar injuries.

Metabolic Needs

The person with SCI has increased nutrition needs due to increased metabolism and more protein breakdown. Lean body mass decreases and muscles atrophy, leading to weight loss. In the acute injury phase, stress on the body from hemodynamic instability and medical interventions, such as surgery, can worsen stress. We should start nutrition support within 72 hours after injury.[6] Adequate nutrition helps prevent skin breakdown, reduce infection, and decrease muscle atrophy. We may give enteral nutrition (EN) or parenteral nutrition (PN) to meet nutrient needs.

Peripheral Vascular Problems

Venous thromboembolism (VTE) is a common problem due to hypercoagulability, venous stasis, and venous endothelial injury.[9] Immobilization promotes venous stasis and thrombi of the lower extremities. It may be hard to detect a deep venous thrombosis (DVT) because usual signs and symptoms, such as pain and tenderness, are not present.

Pain

Pain after SCI differs in type and severity. The patient's physical functioning and emotions influence pain. Pain can be nociceptive or neuropathic.

Nociceptive pain can result from musculoskeletal, visceral, and/or other types of injury (e.g., skin ulceration, headache). Patients often describe musculoskeletal pain as dull or aching. It starts or worsens with movement. Visceral pain is in the thorax, abdomen, and/or pelvis. It may be dull, tender, or cramping.

TABLE 65.2 Level of SCI and Rehabilitation Potential

Movement Remaining	Rehabilitation Potential
Tetraplegia	
C1-3	
• Often fatal • Movement in neck and above, loss of innervation to diaphragm, absence of independent respiratory function	• Able to drive electric wheelchair equipped with portable ventilator by using chin control or mouth stick, headrest to stabilize head • Computer use with mouth stick, head wand, or noise control • Attendant care 24 h/day, able to instruct others
C4	
• Sensation and movement in neck and above • May be able to breathe without ventilator	• Same as C1–3
C5	
• Full neck, partial shoulder, back, biceps • Gross elbow, inability to roll over or use hands • ↓ Respiratory reserve	• Able to drive electric wheelchair with mobile hand supports • Indoor mobility in manual wheelchair • Able to feed self with setup and adaptive equipment • Attendant care 10 h/day
C6	
• Shoulder and upper back abduction and rotation at shoulder • Full biceps to elbow flexion, wrist extension, weak grasp of thumb • ↓ Respiratory reserve	• Able to help with transfer and perform some self-care • Feed self with hand devices • Push wheelchair on smooth, flat surface • Drive adapted van from wheelchair • Independent computer use with adaptive equipment • Attendant care 6 h/day
C7-8	
• All triceps to elbow extension, finger extensors, and flexors • Good grasp with some decreased strength • ↓ Respiratory reserve	• Able to transfer self to wheelchair • Roll over and sit up in bed • Push self on most surfaces • Perform most self-care • Independent use of wheelchair • Able to drive car with powered hand controls (in some patients) • Attendant care 0–6 hr/day
Paraplegia	
T1–6	
• Full innervation of upper extremities • Back, essential intrinsic muscles of hand • Full strength and dexterity of grasp • ↓ Trunk stability, decreased respiratory reserve	• Full independence in self-care and in wheelchair • Able to drive car with hand controls (in most patients) • Independent standing in standing frame
T6–12	
• Full, stable thoracic muscles and upper back • Functional intercostal muscles, resulting in ↑ respiratory reserve	• Full independent use of wheelchair • Able to stand erect with full leg brace, ambulate on crutches with swing (although gait difficult) • Unable to climb stairs
L1–2	
• Varying control of legs and pelvis • Instability of lower back	• Good sitting balance • Full use of wheelchair • Ambulation with long leg braces
L3–4	
• Quadriceps and hip flexors • Absence of hamstring function, flail ankles	• Completely independent ambulation with short leg braces and canes • Unable to stand for long periods

Neuropathic pain occurs from damage to the spinal cord or nerve roots. The pain can be at or below the level of injury. Patients often describe the pain as hot, burning, tingling, pins and needles, cold, and/or shooting. They may be very sensitive to stimuli. Even light touch can cause significant pain. Pain is discussed in Chapter 9.

Diagnostic Studies

CT scan is the preferred imaging study to diagnose the location and degree of injury and the degree of spinal canal compromise. Cervical x-rays are done when a CT scan is not readily available. However, it is hard to see C7 and T1 on a cervical x-ray, decreasing the ability to fully evaluate a cervical spine injury. MRI can assess soft tissue injury, neurologic changes, unexplained neurologic deficits, or worsening neurologic conditions.

We perform a comprehensive neurologic examination and assess the head, chest, and abdomen for other injuries or trauma. Patients with cervical injuries who have altered mental status may need a CT angiogram to rule out vertebral artery damage. Table 41.9 describes studies used to assess the site and extent of a VTE.

Interprofessional Care

Prehospital

Goals immediately after injury include maintaining a patent *airway,* adequate ventilation/*breathing,* and adequate *circulating* blood volume (ABCs) and preventing extension of spinal cord damage (secondary injury). Table 65.3 outlines emergency management of the patient with SCI. Spinal motion should be restricted with a combination of a rigid cervical collar and a supportive backboard with straps. Most patients are kept supine. Some may be placed in reverse Trendelenburg position. Sedation may be given to keep combative patients safe from further injury.

Intubation to secure the airway is done as soon as possible for patients with respiratory distress. End-tidal CO_2 monitoring can help determine the need for rapid sequence intubation (RSI). Patients with stable airways in the field may need intubation at the medical facility. After cervical injury, all body systems must be maintained until we evaluate the full extent of the damage. After stabilization at the injury scene, the person should be transferred to the nearest medical facility. The

TABLE 65.3 EMERGENCY MANAGEMENT

SCI

Etiology	Assessment Findings	Interventions
Blunt Trauma • Compression, flexion, extension, or rotation injuries to spinal column • Diving • Falls • Motor vehicle crash • Pedestrian accidents • Sports injuries **Penetrating Trauma** • Gunshot wounds • Stab wounds • Stretched, torn, crushed, or lacerated spinal cord	• Bowel and bladder incontinence • Changes in sensation • ↓ Rectal sphincter tone • Muscle weakness, paralysis, or flaccidity • Neurogenic shock: hypotension, bradycardia, cool or warm dry skin • Numbness, paresthesia • Pain, tenderness, deformities, or muscle spasms adjacent to vertebral column • Priapism • Spinal shock • Respiratory distress/difficulty breathing • Urinary retention • Wounds, cuts; bruises; on head, face, neck, or back	**Initial** • Ensure patent airway and adequate breathing. • Maintain SaO_2 >90%. Apply O_2 via nasal cannula, nonrebreather mask, or endotracheal tube. • Maintain SBP >90 mm Hg. • Establish IV access with 2 large-bore catheters to infuse normal saline or lactated Ringer's solution. • Immobilize and stabilize cervical spine. • Assess for other injuries. • Control external bleeding. • Obtain appropriate imaging. **Ongoing Monitoring** • Monitor vital signs, level of consciousness, motor and sensory function, O_2 saturation, cardiac rhythm, urine output. • Anticipate need for intubation if in respiratory distress or gag reflex absent. • Maintain normal temperature.

preferred facility is one that specializes in acute SCI care. A thorough assessment determines the degree of deficit and the level and degree of injury.

Acute Care

Interprofessional care during the acute phase for a patient with a cervical injury is described in Table 65.4. Compared to cervical injury, patients with SCI of the thoracic and lumbar vertebrae need less intense support. Respiratory compromise is not as severe at this level of injury. Bradycardia is usually not a problem. Other problems are treated symptomatically.

Obtain a history. How did the incident occur? Assess the extent of injury perceived by the patient or the emergency response system (ERS) personnel right after the event. Initial assessment occurs in the emergency department (ED). It includes managing the person's ABCs and vital signs. Ensure a secure airway. Maintain oxygenation saturation (SaO_2) greater than 92% and mean arterial pressure (MAP) greater than 85 mm Hg. Avoid systolic BP (SBP) less than 90 mm Hg. Neurogenic shock is treated with IV fluids and vasopressors to maintain SBP greater than 90 mm Hg after other causes of hypotension, including bleeding, are ruled out. Appropriate medical interventions and diagnostics are implemented to ensure the patient is hemodynamically stable.

Perform a complete neurologic assessment using the ASIA tool (Fig. 65.5). Muscle groups are tested with and against gravity, alone and against resistance, on both sides of the body. Record strength, symmetry, and spontaneous movement. Complete a sensory assessment, including touch and pain, as tested by pinprick. Start at the toes and work upward toward the head. Assess rectal tone. Note the presence of *priapism.* Voluntary anal contractions indicate incomplete SCI. If time and conditions permit, assess position sense and vibration.

Mechanisms of injury that cause spinal cord trauma, especially involving the cervical cord, may result in brain injury and/or vertebral artery injury. Is there a history of unconsciousness? Note signs of concussion and increased intracranial pressure (see Chapter 61). Assess for musculoskeletal injuries and trauma to internal organs. Because the patient may have altered or no muscle, bone, or visceral sensations below the level of injury, the only clue to internal trauma with bleeding may be a rapidly decreasing BP and increasing pulse. Imaging and diagnostic tests are done to evaluate injuries.

Move the patient in alignment as a unit *(logroll)* during transfers and when repositioning to prevent further injury. Monitor respiratory, cardiac, urinary, and GI functions. The patient may go directly to surgery after the initial evaluation or to the intensive care unit (ICU) for monitoring and management.

Nonoperative stabilization. Nonoperative treatments involve stabilization of the injured spinal segment and decompression, either through traction or realignment. Stabilization eliminates damaging motion at the injury site. It is meant to prevent secondary spinal cord damage caused by narrowing of the spinal canal or continued contusion or compression of the spinal cord at the level of the injury. Early realignment of an unstable fracture-dislocation injury by closed reduction through craniocervical traction is effective and safe.

Surgical therapy. Surgical treatment after acute SCI is used to manage instability and decompress the spinal cord. It may reduce secondary injury and improve the patient's outcome. Early surgery (within 24 hours after the injury) is recommended for persons with central cord syndrome and for adults with acute SCI at any level.[10] The type of surgery depends on the severity and level of the injury, mechanism of injury, and location and degree of compression.

Surgery to stabilize the spine can be done from the back of the spine *(posterior approach)* or from the front of the spine *(anterior approach).* In some cases, both approaches are needed. Fixation involves attaching metal screws, plates, or other devices to the bones of the spine to help keep them aligned. This procedure is

TABLE 65.4 Interprofessional Care

Cervical Cord Injury

Diagnostic Assessment

- History and physical assessment, including complete neurologic examination
- ABGs
- Electrolytes, serum glucose, coagulation profile, hemoglobin, hematocrit
- Urinalysis
- CT scan, MRI, EMG (measure evoked potentials)
- Spinal x-rays
- Serial bedside pulmonary function tests (PFTs)

Management

Acute Care

- Immobilization and stabilization of vertebral column
- ABCs (airway, breathing, circulation)
  - O_2 by high-humidity mask (PaO_2 > 60 mm Hg)
  - Intubation (if indicated by ABGs and PFTs)
  - Maintain heart rate (e.g., atropine) and BP (e.g., dopamine) (SBP > 90 mm Hg, MAP > 85)
  - Administer IV fluids
- Insert NG tube and attach to suction.
- Assessment and management of nutrition
- Maintain normal body temperature
- Indwelling urinary catheter
- Pain management
- VTE prophylaxis
- Pressure injury prevention
- Stress ulcer prophylaxis
- Bowel and bladder care and training
- Mobilization once spine stabilized
- Physical, occupational, speech therapy and physiatrist consults

Rehabilitation and Home Care

- Physical therapy (ROM, mobility, strength, equipment)
- Occupational therapy (splints, ADLs training)
- Speech therapy (swallow and cognition)
- Pain management
- Spasticity management
- Bowel and bladder training
- Autonomic dysreflexia prevention
- Pressure injury prevention
- Recreational therapy
- Patient and caregiver teaching

usually done when 2 or more vertebrae are injured. Small pieces of bone may be attached to the injured bones to help them fuse into 1 solid piece. The bone used is obtained from the patient's spinal bone harvested during surgery, from another bone in the patient's body, or from donor bone.

Drug Therapy

Evidence for using methylprednisolone is mixed. Guidelines for managing spinal cord injuries issued by both the American Association of Neurological Surgeons and Congress of Neurological Surgeons do not recommend its use for treating acute SCI.[11] However, the AOSPine 2017 Guidelines suggest a 24-hour infusion of high-dose methylprednisolone within 8 hours of acute SCI.[12] So, some HCPs may give an infusion.

VTE prophylaxis with low-molecular-weight heparin (LMWH) (e.g., enoxaparin) or fixed, low-dose heparin should start within 72 hours after injury unless contraindicated. Contraindications include internal or external bleeding and recent surgery. For those with abnormal kidney function, heparin is best as LMWH is mainly excreted via the kidneys.

Vasopressor agents (e.g., phenylephrine, norepinephrine) are used in the acute phase of injury as adjuvant treatment. They maintain the MAP to improve perfusion to the spinal cord. Use of vasopressors has significant risk for complications. These include ventricular tachycardia, troponin elevation, metabolic acidosis, and atrial fibrillation. Dopamine has more complications than phenylephrine in SCI. Considerations for vasopressor selection include level of injury, patient age, and comorbidities (e.g., heart problems).

❖ NURSING MANAGEMENT: SPINAL CORD INJURY

◆ Assessment

Subjective and objective data you should obtain from a patient with recent SCI are outlined in Table 65.5.

◆ Clinical Problems

Clinical problems for the patient with SCI depend on the severity of the injury and level of dysfunction. Clinical problems for a patient with SCI may include:

- Impaired respiratory function
- Neurologic problem
- Nutritionally compromised
- Inadequate tissue perfusion
- Impaired tissue integrity
- Impaired urinary elimination
- Difficulty coping

Additional information on clinical problems and interventions for the patient with complete cervical SCI is presented in eNursing Care Plan 65.1 (available on the website for this chapter).

◆ Planning

Overall goals are that the patient with an SCI will (1) maintain an optimal level of neurologic functioning; (2) have minimal or no complications of immobility; (3) be able to care for self or direct others to do so; and (4) return home at an optimal level of functioning.

◆ Implementation

◆ Health Promotion

Nursing interventions for the prevention of SCI include identifying high-risk persons and providing teaching. Support measures to combat distracted and impaired driving. Teach people to use child safety seats and helmets for motorcyclists and bicyclists. Promote programs for older adults (e.g., STEADI) aimed at preventing accidental death and injury.[13]

Emphasize the importance of health promotion and screening behaviors after SCI. Health-promoting behaviors after SCI

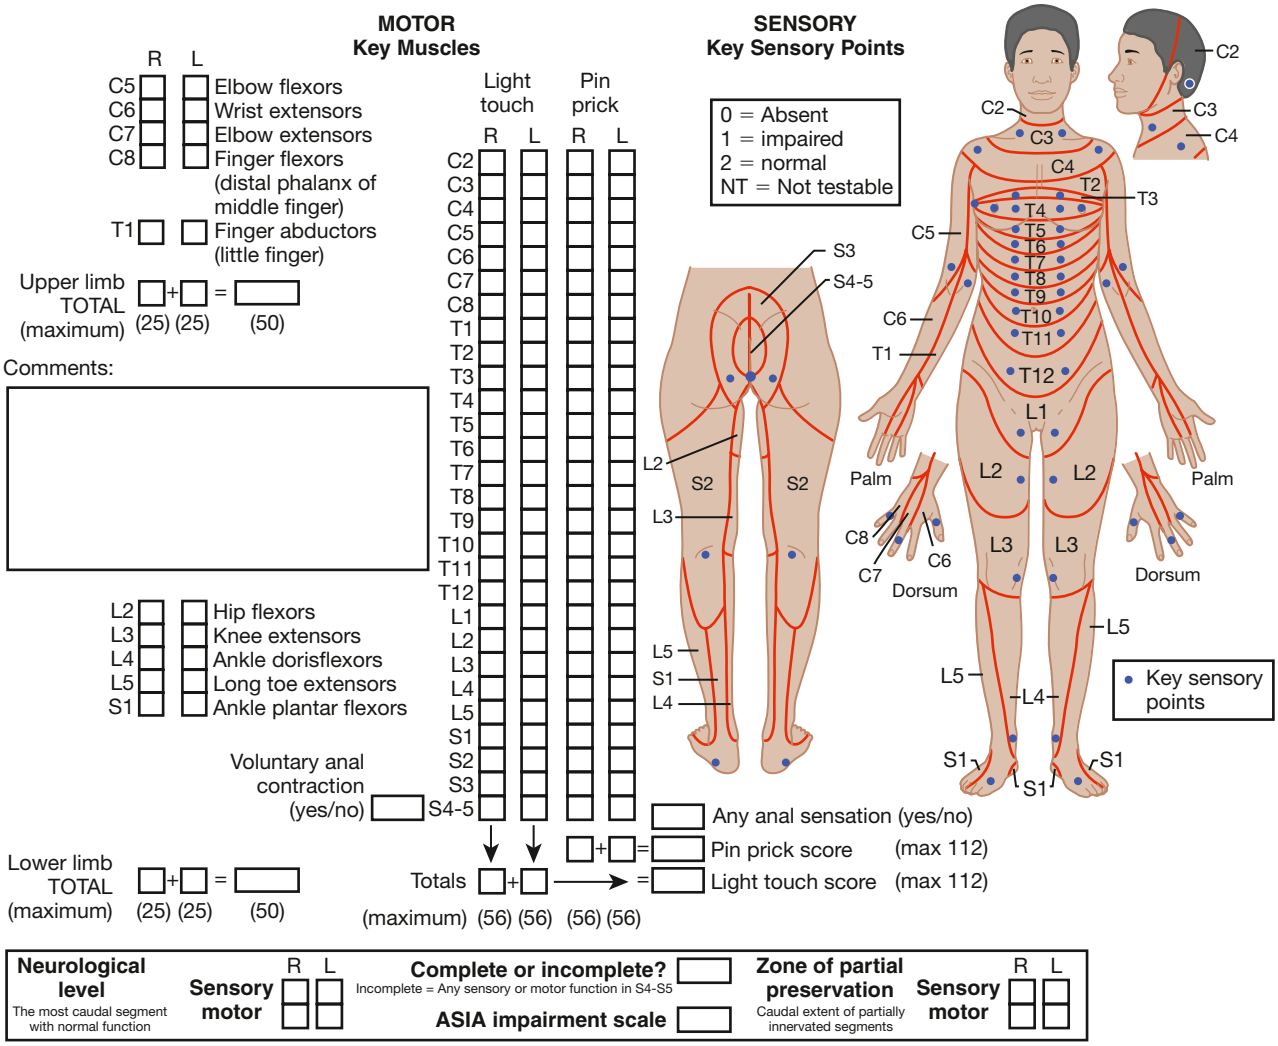

Fig. 65.5 The ASIA Standard Neurological Classification of Spinal Cord Injury is an assessment used to score the motor and sensory impairment and severity of a SCI.

can have a significant impact on the patient's overall health and well-being. Provide teaching and counseling. Refer the patient as needed to smoking cessation or alcohol treatment programs. Explore available recreation programs. They should continue to receive routine care for non-neurologic problems. Make sure facilities are accessible to and accommodate people with SCI. Schedule wheelchair-accessible examination rooms and allow extra time, if needed, for appointments.

Acute Care

High cervical cord injury caused by flexion-rotation is the most complex SCI. It is the focus of this section. Interventions for this type of injury can be modified for patients with less severe injuries.

Immobilization. To restrict spinal motion, maintain the neck in a neutral position. For cervical injuries, closed reduction with skeletal traction is used for early realignment *(reduction)*. Crutchfield (Fig. 65.6) or Gardner-Wells tongs or halo (halo ring) can provide this type of traction. A rope extends from the center of the device over a pulley to weights attached at the end. Traction must be maintained at all times. Possible displacement of the skull pins is a disadvantage of tongs. If pin displacement occurs, hold the patient's head in a neutral position and get help. Immobilize the head while the HCP reinserts the tongs.

! SAFETY ALERT

Cervical Spine Injuries

- Always keep the patient's body in correct alignment.
- Turn the patient as a unit (e.g., logrolling) to prevent movement of the spine.

No specific guidelines address the maximum weight for traction. The HCP may start with 10 lb and add 5 lb for each level to the injury. The goal is spinal reduction. Awake patients are monitored with x-ray and neurologic and pain assessment. Comatose patients need serial x-rays to evaluate the effects of traction. The need for surgery is determined after the spine is reduced. After cervical fusion or other stabilization surgery, the patient may have a hard cervical collar or sternal-occipital-mandibular immobilizer brace (Fig. 65.7).

TABLE 65.5 NURSING ASSESSMENT

SCI

Subjective Data

Important Health Information

Health history: Motor vehicle crash, sports injury, industrial incident, gunshot or stabbing injury, falls

Functional Health Patterns

Health perception–health management: Use of alcohol or recreational drugs. Risk-taking behaviors

Activity-exercise: Loss of strength, movement, and sensation below level of injury. Dyspnea, inability to breathe adequately ("air hunger")

Cognitive-perceptual: Tenderness, pain at or above level of injury. Numbness, tingling, burning, twitching of extremities

Coping–stress tolerance: Fear, denial, anger, depression

Objective Data

Cardiovascular

Injury above T6: Bradycardia, hypotension, postural hypotension, absence of vasomotor tone

General

Poikilothermia (unable to regulate body heat)

GI

↓ Or absent bowel sounds (paralytic ileus in injuries above T5), abdominal distention, constipation, fecal incontinence, fecal impaction

Musculoskeletal

Muscle atony (in flaccid state), contractures (in spastic state)

Neurologic

Complete: Areflexic, flaccid paralysis and anesthesia below level of injury resulting in tetraplegia (injuries above C8) or paraplegia (injuries below C8), hyperactive deep tendon reflexes and bilaterally positive Babinski test (after resolution of spinal shock)

Incomplete: Mixed loss of voluntary motor activity and sensation

Pain

Neuropathic, musculoskeletal, and/or visceral

Reproductive

Priapism, altered sexual function

Respiratory

Injury at C1–3: Apnea, inability to cough

Injury at C4: Poor cough, diaphragmatic breathing, hypoventilation

Injury at C5–T6: ↓ Respiratory reserve

Skin

Warm, dry skin below level of injury (neurogenic shock)

Urinary

Retention (for injuries at T1–L2), flaccid bladder (acute stages), spasticity with reflex bladder emptying (later stages)

Possible Diagnostic Findings

Location of level and type of bony involvement on spinal x-ray. Injury, edema, compression on CT scan and MRI; positive finding on myelogram

Some patients with spinal fractures with or without acute SCI may not be able to have surgery but still need immobilization for their cervical fracture. In these patients, the

Fig. 65.6 Cervical traction is attached to tongs inserted in the skull. (Courtesy Michael S. Clement, MD, Mesa, AZ.)

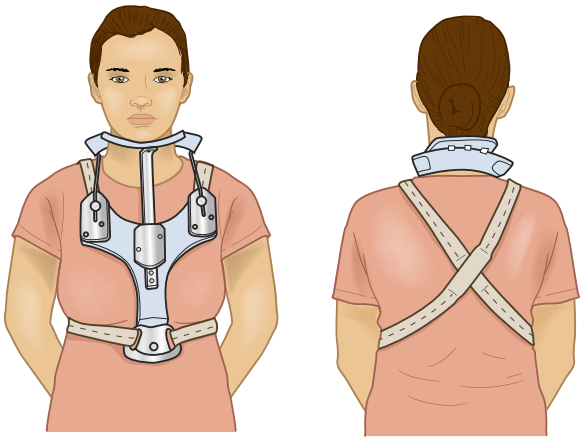

Fig. 65.7 Sternal-occipital-mandibular immobilizer brace.

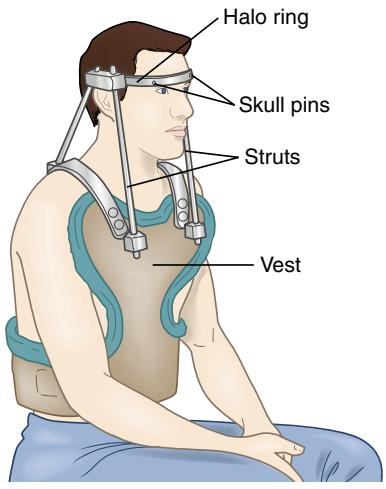

Fig. 65.8 Halo vest. The halo traction brace immobilizes the cervical spine, which allows the patient to ambulate and take part in self-care. (Modified from Urden LD, Stacy KM, Lough ME: *Priorities in critical care nursing*, ed 6, St Louis, 2012, Mosby.)

halo frame can be attached to a special vest (Halo vest) (Fig. 65.8). This allows the patient to move and ambulate while cervical bones fuse. Surgery is used instead of the halo if the patient has ligament instability from the injury; has severe cervical deformity; or is morbidly obese, older, cachectic, or noncompliant.

TABLE 65.6 PATIENT & CAREGIVER TEACHING

Halo Vest Care

Include the following instructions when teaching the patient and caregiver management of a halo vest:

1. Inspect the pins on the halo traction ring. Report to HCP if pins are loose or signs of infection are present, including redness, tenderness, swelling, or drainage at insertion sites.
2. Clean around pin sites carefully with chlorhexidine, water, or half-strength peroxide on a cotton swab as directed.
3. Apply antibiotic ointment as prescribed.
4. For skin care, have patient lie down with the head resting on a pillow to reduce pressure on the brace. Loosen 1 side of the vest. Gently wash the skin under the vest with soap and water, rinse area, and then dry it thoroughly. At the same time, check the skin for pressure points, redness, swelling, bruising, or chafing. Close the open side and repeat the procedure on the other side.
5. If the vest becomes wet or damp, carefully dry it with a blow dryer.
6. Encourage patient to use assistive device (e.g., cane, walker) to improve balance; encourage use of flat shoes.
7. Teach patient to turn the entire body, not just the head and neck, when trying to look sideways.
8. Keep a set of wrenches close to the halo vest in case they are needed for an emergency.
9. Mark the vest strap to maintain consistent buckling and fit.
10. Avoid grabbing bars or vest to help the patient.
11. Keep sheepskin pad under vest. Change and wash pad at least weekly.
12. If perspiration or itching is a problem, encourage patient to wear a cotton T-shirt under the sheepskin. The T-shirt can be modified with a Velcro seam closure on one side.

Infection at the tong or pin insertion sites is a potential problem. Preventive care is based on agency protocol. A common protocol involves cleansing sites twice a day with chlorhexidine. Antibiotic ointment is then applied to act as a mechanical barrier to the entrance of bacteria. Patient and caregiver teaching for a patient with a halo vest is outlined in Table 65.6.

Patients with stable thoracic or lumbar spine injuries may be immobilized with a custom thoracolumbar sacral orthosis (TLSO, body jacket). TLSO limits spinal flexion, extension, and rotation. A Jewett brace may be used instead to restrict forward flexion. Unstable injuries may require surgical decompression and fusion in addition to the TLSO or lumbosacral orthotic (LSO).

Skin care is vital because decreased sensation and circulation increase the risk for skin breakdown. Remove the patient's backboard as soon as possible. Replace it with other forms of immobilization to prevent skin breakdown in the coccygeal and occipital areas. Fit cervical collars properly. Carefully assess areas under any device used for immobilization.

Respiratory problems. Respiratory complications are the leading cause of morbidity and mortality in SCI.[6] Respiratory dysfunction is present in up to 65% of patients with cervical SCI. During the first 48 hours after injury, spinal cord edema may increase the level of dysfunction, and respiratory distress may occur. Injury at or above C4 affects the phrenic nerve. This leads to the diaphragm, and breathing can stop.

Monitor the patient for respiratory compromise. Be prepared for quick action if arrest occurs. Regularly assess (1) breath sounds, (2) arterial blood gases (ABGs), (3) tidal volume, (4) vital capacity, (5) skin color, (6) breathing patterns (especially use of accessory muscles), (7) subjective comments about the ability to breathe, and (8) amount and color of sputum. A PaO_2 greater than 60 mm Hg and a $PaCO_2$ less than 45 mm Hg are acceptable values in a patient with uncomplicated tetraplegia. A patient who is unable to count to 20 aloud without taking a breath needs immediate attention.

Provide measures to maintain ventilation. Apply O_2 and provide appropriate ventilatory support until ABGs stabilize. If the patient is exhausted from labored breathing or ABGs show inadequate oxygenation or ventilation, endotracheal intubation or tracheostomy, and mechanical ventilation is needed. Patients who have chest trauma or difficulty weaning from the ventilator may need a tracheostomy for airway management.

Clearing secretions is vital in reducing the risk for lung complications and possible respiratory failure.[6] Perform tracheal suctioning if crackles or coarse breath sounds are present. Chest physiotherapy and assisted (augmented) coughing can help. Perform assisted coughing either manually or mechanically with an insufflation-exsufflation device. Encourage the use of incentive spirometry.

The older adult has more difficulty responding to hypoxia and hypercapnia. Chest physiotherapy, adequate oxygenation, and proper pain management are needed to maximize respiratory function and gas exchange.

Cardiovascular instability. Heart rate is slowed, often to less than 60 beats/min, because of unopposed vagal response. Any increase in vagal stimulation, as occurs with turning or suctioning, can cause cardiac arrest. Loss of SNS tone in peripheral vessels results in chronic low BP with potential orthostatic hypotension. The lack of muscle tone to aid venous return can cause sluggish blood flow and predispose the patient to VTE. Dysrhythmias may occur.

Frequently assess vital signs. If bradycardia is symptomatic, give an anticholinergic drug, such as atropine. Some patients need a temporary or permanent pacemaker. Maintain SBP greater than 90 mm Hg and keep MAP between 85 and 90 mm Hg for the first 7 days after SCI.[6] Manage hypotension with fluid replacement and a vasopressor agent, such as phenylephrine or norepinephrine.

Maintain a normal blood volume. If blood loss has occurred from other injuries, monitor hemoglobin and hematocrit and give blood according to protocol. Assess the patient for signs of hypovolemic shock from hemorrhage.

Orthostatic hypotension is likely to occur in the patient with injury at T6 and above. The patient may have lightheadedness, dizziness, and nausea. Assess orthostatic BP when mobilizing the patient. Some lose consciousness when moved from the bed to a chair. For symptomatic patients, use an abdominal binder and graduated compression stockings to promote venous return. Drugs used to increase intravascular volume include salt tablets and fludrocortisone. Midodrine may be given to promote blood vessel contraction and increase venous return.

Use LMWH or low-dose heparin in combination with intermittent pneumatic compression devices or graduated

compression stockings to promote venous return and reduce the risk for VTE. Remove stockings every 8 hours for skin care. Assess thighs and calves every shift for signs of VTE. Regularly perform range-of-motion (ROM) exercises and stretching. Continue VTE prophylaxis for 3 months after injury.

Fluid and nutrition management. During the first 48 to 72 hours after the injury, the GI tract may stop functioning *(paralytic ileus)*. We may insert a nasogastric (NG) tube if severe ileus occurs. Because the patient cannot have oral intake, monitor fluid, and electrolyte status.

Nutrition should be started within the first 72 hours after injury. Specific solutions and additives are determined by individual requirements. Due to severe catabolism, a high-protein, high-calorie diet is needed for energy and tissue repair. If the patient cannot be fed through the GI system, either orally or through EN, PN should be started to reduce nitrogen losses that occur during the hypermetabolic state.

Once bowel sounds are present, or flatus is passed, and the patient is off mechanical ventilation, they have a formal swallow evaluation. If no risk for aspiration is identified, gradually introduce oral food and fluids. If the patient fails the swallow evaluation or is unable to eat due to an endotracheal tube or tracheostomy, a feeding tube may be placed in the stomach or jejunum (see Chapter 44).

CHECK YOUR PRACTICE

You are working in the spinal cord unit. Your 28-year-old male patient with SCI at T6 weighs 168 lb. When he was admitted 3 weeks ago, he weighed 196 lb. He asks you, "Well, what is my weight? Are you going to make me eat now? You know you can't do that."

- What assessment data do you need to obtain?
- What interventions would help him avoid further weight loss and regain lean body mass?

Patients may have anorexia due to depression, boredom with agency food, or discomfort at being fed (often by a hurried person). Some patients have a normally small appetite. Sometimes refusal to eat is a way of asserting control. If the patient is not eating adequately, assess the cause.

Based on assessment findings, make a contract with the patient with mutual goal setting for the diet. This contract gives the patient increased control and often results in improved intake. General measures also may be effective. For example, provide a pleasant eating environment and allow adequate time to eat (including any self-feeding the patient can achieve). Encourage the family to bring in special foods. Plan social rewards for eating.

Consult a dietitian to ensure evaluation of laboratory markers and develop the treatment plan. Keep a calorie count. Record daily weight to evaluate progress. If possible, have the patient take part in recording calorie intake. Diet supplements may be needed to meet nutrition goals. Increase dietary fiber to promote bowel function.

Bladder and bowel management. Immediately after the injury, urine retention occurs because of the loss of autonomic and reflex control of the bladder and sphincter *(neurogenic bladder)*. Because there is no sensation of fullness, overdistention of the bladder can result in reflux into the kidney and cause renal failure. Bladder overdistention may even result in rupture of the bladder. An indwelling catheter may be inserted soon after injury. Maintain patency of the catheter. Check the catheter to prevent kinking and ensure free flow of urine. Use strict aseptic technique for catheter care to prevent infection. While the catheter is in place, encourage a large fluid intake.

Catheter-acquired urinary tract infection (CAUTI) is a common problem. The best way to prevent CAUTI is regular and complete bladder drainage. Once the patient is stabilized, assess the best means of managing long-term urinary function. Clean intermittent catheterization (CIC) is the preferred method for emptying the bladder. CAUTI and CIC are discussed in Chapter 50.

CIC should be done 4 to 6 times daily to prevent bacterial overgrowth from urinary stasis. Keep urine residuals under 500 mL to prevent bladder distention. If the urine is cloudy or has a strong odor or if the patient develops symptoms of a urinary tract infection (UTI) (e.g., chills, fever, malaise), send a specimen for culture.

Consider age-related changes in renal function. The older adult is more likely to develop renal stones. Older men may have benign prostatic hyperplasia, which may interfere with urinary flow and complicate management of urinary problems. It can affect the ability to complete CIC.

Start a bowel program to combat constipation from neurogenic bowel. This involves inserting a rectal stimulant (suppository or small-volume enema) daily at a regular time, followed by gentle digital stimulation or manual evacuation until evacuation is complete. At first, the program may be done in bed with the patient in the side-lying position. However, as soon as the patient has resumed sitting, the patient should be in the upright position on a padded bedside commode chair. These programs typically take 30 to 60 minutes to complete. Measures to reduce constipation include adequate fluid intake, a diet high in fiber and vegetables, and increased activity and exercise as able.

Temperature control. Monitor the environment closely to maintain an appropriate temperature. Regularly assess the patient's temperature. Do not use excess covers or unduly expose the patient (e.g., during bathing). If an infection with fever develops, implement measures to control temperature (see Table 12.5).

Stress ulcers. Stress ulcers can occur because of the physiologic response to severe trauma and psychologic stress. Peak incidence of stress ulcers is 6 to 14 days after injury. Monitor the hematocrit for a slow drop. Histamine (H_2)-receptor blockers or proton pump inhibitors (e.g., pantoprazole, omeprazole) given prophylactically decrease the secretion of HCl acid and prevents ulcers.

Sensory deprivation. To prevent sensory deprivation, compensate for absent sensations by stimulating the patient above the level of injury. Conversation, music, and interesting foods can be a part of the care plan. If the head of the bed must stay flat, provide prism glasses to help the patient read and watch television.

Help the patient avoid withdrawing from the environment. Promote adequate rest and sleep. Assess for changes in mood. Depression is common.

Pain management. Musculoskeletal nociceptive pain can develop from injuries to bones, muscles, and ligaments. The pain is worse with movement or palpation. Antiinflammatory drugs, such as ibuprofen, may help with pain. Opioids may be used to manage nociceptive pain.

Visceral nociceptive pain is a dull, tender, or cramping pain in the thorax, abdomen, or pelvis. It may originate in the bladder or bowel. Assess bowel and bladder function to avoid bladder distention or constipation. Other causes of nociceptive pain include UTI and renal stones. Notify the HCP if the patient has persistent pain despite treatment. Diagnostic testing may be needed to determine the cause.

Neuropathic pain in the initial phase is usually at the level of SCI. It may occur on one or both sides of the body within the affected dermatome and up to 3 levels below. The patient will describe hot, burning, tingling, shooting, electric pain. Pregabalin (Lyrica) and Gabapentin (Neurontin) may be used to reduce symptoms.

Neuropathic pain can occur months or years after SCI, become chronic, and negatively affect sleep. Mood, sudden noise, constipation, and infection can affect the pain. Teach the patient and caregiver about possible pain triggers and offer relaxation therapy. Other treatments may include tricyclic antidepressants, intrathecal drugs, epidural stimulation, and destructive surgical intervention.

Skin care. The most common long-term complication in SCI is a pressure injury (PI). Healthy skin requires adequate blood circulation. Constant pressure in 1 position can compress blood vessels and limit blood supply, causing cell death and PI. Factors that increase risk for PI include duration of SCI, higher level of injury, smoking, being underweight, and comorbid medical conditions.[14]

Preventing PI requires diligent nursing care. Perform a risk assessment with a daily skin assessment. Areas most vulnerable to breakdown include the sacrum, ischia, trochanters, and heels. Assess surgical incisions for healing and skin integrity under collars and braces. Regularly assess nutrition status. Both weight loss and gain can contribute to skin breakdown. Teach the patient and caregiver about the causes and risk factors for PI development.[15]

A consult with the wound, ostomy, continence nurse (WOCN) can assist with prevention and management strategies (e.g., surface overlays).[15] Monitor incontinence. Implement appropriate neurogenic bowel and bladder management interventions. Apply skin barrier creams.

Carefully position and reposition the patient at least every 2 hours. Gradually increase the times between turns if no redness over bony prominences is seen when turning. While the patient is supine in bed, float the heels to reduce pressure. Consider prophylactic dressings to prevent sacral and heel injury. Move the patient carefully during turns and transfers to avoid stretching and folding of soft tissues *(shear)* or abrasion.

We often place patients on special beds (Fig. 65.9). Kinetic therapy involves continuous side-to-side rotation of a patient to 40 degrees or more to help prevent lung complications. This lateral rotation also redistributes pressure, helping prevent pressure injuries. We may use specialty mattresses.[15] When the patient is moved to a chair or wheelchair, use pressure-relieving cushions. Schedule pressure relief every 15 to 20 minutes when the patient is in a chair. It should last 30 to 60 seconds each time.

Fig. 65.9 The RotoRest Therapy System helps prevent and treat lung complications for immobile patients, including those with unstable cervical, thoracic, and lumbar fractures. Kinetic therapy, the continual side-to-side bilateral rotation of the patient, redistributes pulmonary blood flow and mobilizes secretions to improve ventilation and perfusion matching. The therapy system helps to prevent pressure injuries. (Courtesy Arjo Huntleigh, Addison, IL.)

Reflexes. Once spinal cord shock is resolved, return of reflexes may complicate rehabilitation. Lacking control from the higher brain centers, reflexes are often hyperactive and have exaggerated responses. Penile erection can occur from a variety of stimuli, causing embarrassment and discomfort. Spasms ranging from mild twitches to convulsive movements below the level of injury may occur. The patient or caregiver may interpret this reflex activity as a return of function. Tactfully explain the reason for the activity. Tell the patient the positive use of these reflexes in sexual, bowel, and bladder retraining. Antispasmodic drugs, such as baclofen (Lioresal), dantrolene (Dantrium), and tizanidine (Zanaflex), may help control spasms. Botulism toxin injections may be given to treat severe spasticity.

Autonomic dysreflexia. The return of reflexes after the resolution of spinal shock means patients with injury at T6 or higher may develop autonomic dysreflexia (AD). **Autonomic dysreflexia (AD)** is a massive, uncompensated cardiovascular reaction mediated by the SNS. It involves stimulation of sensory receptors below the level of the SCI. The intact SNS below the level of injury responds to the stimulation with a reflex arteriolar vasoconstriction that increases BP. The parasympathetic nervous system cannot directly counteract these responses via the injured spinal cord. Baroreceptors in the carotid sinus and aorta sense the hypertension and stimulate the parasympathetic system. This causes a decrease in heart rate. Visceral and peripheral vessels do not dilate because efferent impulses cannot pass through the injured spinal cord. It most often presents in the chronic phase after SCI.[16]

The most common precipitating cause is a distended bladder or rectum. However, any sensory stimulation, including contraction of the bladder or rectum, skin stimulation, or stimulation of pain receptors, can cause AD. AD is a life-threatening condition that requires immediate resolution. Proper identification and elimination of the inciting stimulus for AD can resolve the event. If uncorrected, it can lead to status epilepticus, stroke, myocardial infarction, and even death.

Manifestations include hypertension, throbbing headache, marked diaphoresis above the level of injury, bradycardia (30 to 40 beats/min), piloerection from pilomotor spasm, flushing of the skin above the level of injury, blurred vision or spots, nasal congestion, anxiety, and nausea. Measure BP when a patient with SCI reports a headache. Suspect AD in adults with SBP elevation of 20 to 40 mm Hg above baseline.[16]

Immediate interventions include elevating the head of the bed 45 degrees or sitting the patient upright (to lower the BP) and determining the cause (bowel impaction, urinary retention, UTI, PI, tight clothing). Notify the HCP. The most common cause is bladder irritation. Immediate catheterization to relieve bladder distention may be done. Instill lidocaine jelly in the urethra before catheterization. If a catheter is already in place, check it for kinks or folds. If it is plugged, perform small-volume irrigation slowly and gently to open the catheter or insert a new catheter.

Stool impaction can cause AD. Apply an anesthetic ointment to avoid increasing symptoms, and then perform a digital rectal examination (if trained). Remove all skin stimuli, such as constrictive clothing and tight shoes. Monitor BP often during the episode. If symptoms persist after the source has been relieved, give a rapid-onset and short-duration agent, such as nitroglycerin, nitroprusside, or hydralazine. Continue careful monitoring until vital signs stabilize.

Teach the patient and caregiver to recognize causes and symptoms of AD (Table 65.7). They must understand the life-threatening nature of AD, know how to relieve the cause, and activate the ERS, if needed.

TABLE 65.7 PATIENT & CAREGIVER TEACHING

Autonomic Dysreflexia

For a patient at risk for autonomic dysreflexia, include the following information in the teaching plan for the patient and caregiver:

1. Signs and symptoms
   - Sudden onset of acute headache.
   - Elevation in BP and/or reduction in pulse rate.
   - Flushed face and upper chest (above level of injury) and pale extremities (below level of injury).
   - Sweating above level of injury.
   - Nasal congestion.
   - Feeling of apprehension.
2. Immediate interventions.
   - Raise the person to a sitting position.
   - Remove the noxious stimulus (fecal impaction, kinked urinary catheter, tight clothing).
   - Call the HCP if above actions do not relieve the signs and symptoms.
3. Measures to decrease the incidence of autonomic dysreflexia
   - Maintain regular bowel function.
   - If manual rectal stimulation is used to promote bowel function, use a local anesthetic to prevent autonomic dysreflexia.
   - Monitor urine output.
   - Teach the patient to wear a Medic Alert bracelet indicating a history of risk for autonomic dysreflexia.

Rehabilitation and Home Care

Rehabilitation of the person with SCI is complex. With physical and psychologic care and intensive and specialized rehabilitation, the patient with SCI can learn to function at the highest level of wellness. All patients with a new SCI should receive comprehensive inpatient rehabilitation in a rehabilitation unit or center that specializes in SCI rehabilitation.[17] Rehabilitation is an interprofessional team effort. Team members include rehabilitation nurses, HCPs, physical therapists, occupational therapists, speech therapists, vocational counselors, psychologists, therapeutic recreation specialists, prosthetists, orthotists, case managers, social workers, and dietitians.

Many problems that begin in the acute period become chronic and continue throughout life. Rehabilitation focuses on retraining physiologic processes and extensive patient and caregiver teaching about how to manage the physiologic and life changes resulting from the injury (Fig. 65.10).

Rehabilitation care depends on the patient's goals and needs. The patient is expected to be involved in therapies and learn self-care for several hours each day. Such intensive work at a time when the patient is dealing with the sudden change in health and function can be stressful. Progress may be slow. The rehabilitation nurse has a key role in providing encouragement, specialized nursing care, and patient and caregiver teaching, and in helping to coordinate efforts of the rehabilitation team.

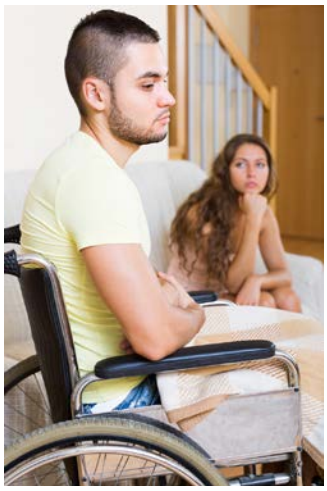

Fig. 65.10 SCI has a major effect on a person's physical, emotional, and psychologic health.

Respiratory rehabilitation. The patient with mechanical ventilation will need around-the-clock caregivers to provide respiratory hygiene and tracheostomy care. The rehabilitation nurse and respiratory therapist should teach patients and caregivers about home ventilator and tracheostomy care. The patient may need chest percussion or postural drainage to manage secretions to lower the risk for atelectasis and

TABLE 65.8 Types of Neurogenic Bladder

Type	Characteristics	Causes	Manifestations
Uninhibited bladder (spastic, overactive)	• No inhibitions influence time and place of voiding • Bladder empties in response to stretching of bladder wall	• Lesions above the pons • Seen in stroke, brain tumor, brain trauma	• Incontinence, frequency, urgency • Voiding is unpredictable and incomplete

Upper motor neuron bladder (flaccid, spastic/overactive)	• Mixed A type (most common):
	  • Bladder is flaccid and external sphincter is spastic, leading to urinary retention.
	• Mixed B type:
	  • Bladder is spastic with flaccid external sphincter leading to urinary incontinence.
		• Lesions between pons and sacral spinal cord
		• Seen in SCI or MS involving the cervicothoracic spinal cord
			• Detrusor-sphincter dyssynergia
			• Can lead to high bladder pressures and kidney damage from urinary reflex
			• Sensory function impaired

Lower motor neuron bladder (flaccid, underactive, areflexic)	• Bladder acts as if all motor functions were paralyzed • Bladder fills without emptying	• Lower motor neuron injury caused by trauma involving S2–4 or below • Lesions of cauda equina, pelvic nerves	• If sensory function intact, patient feels bladder distention and hesitancy • No control of micturition, resulting in urinary retention, over distention of bladder, overflow incontinence, and UTI

pneumonia. Refer to appropriate community agencies as needed.

Some patients with high cervical SCI have improved respiratory function with phrenic nerve stimulators or electronic diaphragmatic pacemakers.[18] These devices are not appropriate for all ventilator-dependent patients. They are safe and effective for those with an intact phrenic nerve. Some ventilators are portable, allowing ventilator-dependent patients with tetraplegia to be mobile and less dependent.

If the patient was weaned from the ventilator during hospitalization, downsizing (gradual decrease in size) and removal of the tracheostomy would be done during rehabilitation. Teach assisted coughing, regular use of incentive spirometry, and breathing exercises to the patient who is not ventilator dependent. They should limit exposure to persons with fever, cold, and cough. Adhering to swallowing precautions (e.g., proper positioning of head and neck) and diet recommendations can prevent aspiration.

Neurogenic bladder. Types of neurogenic bladder are described in Table 65.8. The type of bladder dysfunction determines management options. After the patient's overall condition is stable and assessment shows return of neurologic reflexes, urodynamic testing (see Table 49.11) and a urine culture may be done. Diagnostic and interprofessional care of neurogenic bladder is described in Table 65.9.

The patient with a neurogenic bladder needs a comprehensive program to manage bladder function. The goal is to improve quality of life and safety through preserving renal function, minimizing UTI and bladder stones, and developing a plan for urinary continence. Many factors are considered when selecting a bladder management strategy. These include patient preference, upper extremity function, and caregiver availability. For the selected strategy, teach the patient and caregiver successful self-management. Teach them about the various management techniques, how to obtain supplies, care of supplies and equipment, and when to seek health care.

TABLE 65.9 Interprofessional Care

Neurogenic Bladder

Diagnostic Assessment

- History and physical assessment, including neurologic and pelvic examinations
- Laboratory: Urinalysis, urine culture and sensitivity, blood urea nitrogen, serum creatinine, creatinine clearance
- Urodynamic testing (postvoid residual, cystometric testing, EMG, urethral pressure profile)

Management

- Patient teaching
- Voiding diary
- Bladder retraining: time voiding, manual expression, intermittent catheterization
- Fluid schedule: intake of 1800–2000 mL/day
- Indwelling urinary catheter

Drug Therapy

- Tricyclic antidepressants
- Anticholinergic drugs
- α-Adrenergic blockers
- Antispasmodics
- Botulinum toxin injection into bladder wall

Bladder and/or Urethral Surgical Therapy

- Bladder augmentation
- Sphincter resection or removal *(sphincterotomy)*
- Electrode placement for electrical stimulation
- Urinary diversion
- Urethral stents and balloon dilation
- Artificial urinary sphincter

Various drugs can be used to treat patients with a neurogenic bladder. Anticholinergic drugs (e.g., oxybutynin, tolterodine [Detrol]) may be used to suppress bladder contraction. α-Adrenergic blockers (e.g., terazosin, doxazosin [Cardura]) can relax the urethral sphincter. Antispasmodic drugs (e.g., baclofen)

may decrease spasticity of pelvic floor muscles. *Botulinum toxin* is an effective alternative in patients with neurogenic detrusor overactivity who cannot tolerate or have an inadequate response to anticholinergic drugs.[19]

Numerous drainage methods are possible. These include bladder reflex retraining (if partial voiding control remains), indwelling catheter, CIC, and external catheter (condom catheter). Evaluate long-term use of an indwelling catheter because of the associated high incidence of CAUTI, fistula formation, and diverticula. However, this is the best option for some patients. Patients with indwelling catheters need to have adequate fluid intake (at least 3 to 4 L/day). Regularly check the patency of the indwelling catheter. Frequency of routine catheter changes ranges widely depending on the type of catheter used and agency policy.

CIC is the first-line option for bladder management (see Chapter 50). Assessment is essential in selecting the time interval between catheterizations. At first, catheterization is done every 4 hours. Measure bladder volume before catheterization using bladder ultrasound. If less than 200 mL of urine is present, the time interval until catheterization may be extended. If more than 500 mL of urine is present, the time interval is shortened. CIC is usually done 4 to 6 times daily.

Suprapubic catheters are a safe option in select patients. Because of personal preference or the inability to catheterize due to neurologic dysfunction, 30% of patients with SCI use indwelling urethral or suprapubic catheters. The incidence of bacteriuria after catheter introduction is 5% to 10% per day.

Traditional bladder management options include *urinary diversion surgery* for the recurrent UTI patient with renal involvement or repeated stones. Surgical treatment of neurogenic bladder includes bladder neck revision (sphincterotomy), bladder augmentation (augmentation cystoplasty), perineal ureterostomy, cystotomy, vesicostomy, and anterior urethral transplantation. Placement of a sacral cord stimulator, penile prosthesis, or artificial sphincter is possible. Urinary diversion procedures are discussed in Chapter 50.

Neurogenic bowel. Management of bowel evacuation is necessary for the patient with SCI because voluntary control may be lost. Usual measures for preventing constipation include a high-fiber diet and adequate fluid intake (see Table 42.9). Patient and caregiver teaching is needed to promote successful independent bowel management. Guidelines related to bowel management are outlined in Table 65.10.

These measures may not be adequate to stimulate evacuation. Suppositories (e.g., bisacodyl) or small-volume enemas and digital stimulation (done 20 to 30 minutes after suppository insertion) by the nurse or patient may be needed. In the patient with an upper motor neuron injury, digital stimulation can relax the external sphincter to promote defecation. A stool softener can help regulate stool consistency. Oral stimulant laxatives should be used only if absolutely necessary and not on a regular basis.

Valsalva maneuver and manual stimulation are useful in patients with lower motor neuron injuries. Because the Valsalva maneuver requires intact abdominal muscles, it is used in patients with injuries below T12. In general, a bowel movement every other day is adequate. However, consider pre-injury bowel patterns. Fecal incontinence can result from too much stool softener or a fecal impaction.

Timing of defecation is important. Planning bowel evacuation for 30 to 60 minutes after the first meal of the day may enhance success by taking advantage of the gastrocolic reflex induced by eating. This reflex may also be stimulated by drinking a warm beverage right after the meal. Discuss timing of the bowel program so there are no interruptions when the patient is doing therapy (e.g., swimming pool therapy). Record all bowel movements, including amount, time, and consistency.

Spasticity. Spasticity can be both beneficial and undesirable. It aids with mobility, especially for the patient with incomplete SCI. Spasticity improves circulation by promoting venous return, decreasing orthostatic hypotension and the risk for VTE. Unfortunately, the patient with marked spasticity and tone may have difficulty with positioning and mobility from spasms. Spasms can cause significant pain and make activities of daily living (ADLs) difficult.

You can use the Ashworth and Modified Ashworth Scales to evaluate spasticity. Treatment includes ROM exercises to prevent muscle and joint tightness and reduce the risk for contracture. Antispasmodic drugs, such as baclofen or tizanidine, may be given. Botulinum toxin injection is useful for specific muscle involvement.

TABLE 65.10 PATIENT & CAREGIVER TEACHING

Bowel Management After SCI

For the patient with a SCI, include the following information about bowel management in the teaching plan for the patient and caregiver:

1. Optimal nutrition intake includes the following:
   - 3 well-balanced meals each day
   - 2 servings from the milk group
   - 2 or more servings from the meat group, including beef, pork, poultry, eggs, fish
   - 4 or more servings from the vegetable and fruit groups
   - 4 or more servings from the bread and cereal group
2. Fiber intake should be about 20–30 g/day. Increase the amount of fiber eaten gradually over 1–2 weeks.
3. Consume at least 2–3 L of fluid per day unless contraindicated. Drink water or fruit juices (fluid softens hard stools). Limit caffeinated beverages, such as coffee, tea, and cola (caffeine stimulates fluid loss through urination).
4. Avoid foods that produce gas (e.g., beans) or upper GI upset (e.g., spicy foods).
5. Timing: Follow a regular schedule for bowel elimination. A good time is 30 min after the first meal of the day.
6. Position: If possible, an upright position with feet flat on the floor or on a step stool enhances bowel evacuation. Staying on the toilet, commode, or bedpan for longer than 20–30 min may cause skin breakdown. Based on stability, someone may need to stay with the patient.
7. Activity: Exercise is important for bowel function. In addition to improving muscle tone, it increases appetite and GI transit time. Exercise muscles, including stretching, ROM, position changing, and functional movement.
8. Drug treatment: Suppositories may be needed to stimulate a bowel movement. Manual stimulation of the rectum may be helpful in starting defecation. Use stool softeners as needed to regulate stool consistency. Use oral laxatives only if necessary.

TABLE 65.11 PATIENT & CAREGIVER TEACHING

Skin Care After SCI

To prevent skin breakdown in a patient with SCI, include the following instructions when teaching the patient and caregiver:

Change Position Frequently
- If in a wheelchair, lift self and shift weight every 15–30 min.
- If in bed, change position with a regular turning schedule (at least every 2 h) that includes sides, back, and abdomen.
- Use pressure-reducing mattresses and wheelchair cushions (not eggcrate).
- Use pillows to protect bony prominences when in bed.

Monitor Skin Condition
- Inspect skin often for areas of redness, swelling, and breakdown.
- If a wound develops, follow standard wound care procedures.

Protect Skin
- Do not sit too close to fires, space heaters, or other sources of heat.
- Use sunscreen liberally when outdoors.
- Keep fingernails trimmed to avoid scratches and abrasions.
- Do not wear clothes that are too tight or too loose.
- Dress warmly in cold weather to prevent frostbite.
- Do not put hot food in your lap without protection.

Skin care. Prevention of PI is part of the lifelong treatment plan after SCI. Nurses in rehabilitation are responsible for teaching the patient and caregiver about daily skin care. PI may not be noticed until severe damage has occurred. Include information on the importance of adequate nutrition to skin condition. Provide anticipatory guidance about potential risks. Patient and caregiver teaching about skin care is outlined in Table 65.11.

Pain management. The acute pain of the initial injury may persist during the first few weeks of rehabilitation. Chronic pain can result from overuse of muscles in the shoulders and arms for movement and repositioning. Pain often disrupts sleep. Assess, evaluate, and treat pain routinely. Use analgesics and interventions, such as massage and repositioning, to help the patient during therapy. Patients may benefit from referral to a pain management specialist.

Sexuality. Sexuality is an important issue regardless of the patient's age or gender. Open discussion with the patient about sexual rehabilitation is essential. A nurse or other rehabilitation professional trained in sexual counseling should provide support for the patient and the partner. Alternative methods of obtaining sexual satisfaction, such as oral-genital sex, may be options. Explicit films may help, such as a film showing sexual activities of a patient with paraplegia and a nondisabled partner. Use graphics cautiously because they may focus too much on the mechanics of sex rather than on the relationship.

We need to know the level and completeness of injury to understand the male patient's potential for orgasm, erection, fertility, and capacity for sexual satisfaction. Men normally have 2 types of erections: psychogenic and reflex. The process of *psychogenic erection* begins in the brain with sexual thoughts. Signals from the brain are sent through the nerves of the spinal cord to the T10–L2 levels. The signals are then relayed to the penis and trigger an erection. Men with low-level incomplete injuries are more likely to have psychogenic erection than men with higher level incomplete injuries. Men with complete injuries are less likely to have psychogenic erection.[20]

A *reflex erection* occurs with direct physical contact to the penis or other erotic areas. This short-lived, uncontrolled erection is involuntary. It does not require sexually stimulating thoughts. Most men with SCI can have a reflex erection with physical stimulation if the S2–S4 nerve pathways are not damaged.

Treatment for erectile dysfunction includes drugs, vacuum devices, and surgery. Phosphodiesterase inhibitors (e.g., sildenafil [Viagra]) are the first-line treatment in men with SCI between T6 and L5. Sexual stimulation is needed to get an erection after taking the medication. Penile injection of vasoactive substances (papaverine, alprostadil, or a combination) is another treatment. Risks include scarring, bruising, and infection. Use may lead to priapism. Vacuum suction devices use negative pressure to encourage blood flow into the penis. A constriction band placed at the base of the penis maintains the erection. The main surgical option is implantation of a penile prosthesis.[24] Erectile dysfunction is discussed in Chapter 59.

SCI affects male fertility, causing poor sperm motility and ejaculatory dysfunction. Sperm retrieval methods include penile vibratory stimulation and rectal probe electroejaculation. Surgical removal of sperm is a last resort for sperm retrieval. Once retrieved, sperm can be directly injected into an egg via intracytoplasmic sperm injection (ICSI). These techniques have changed the prognosis for men with SCI to father children from unlikely to a reasonable chance of successful outcomes.[20]

The effect of SCI on female sexual response is less clear. A woman of childbearing age with SCI usually stays fertile. The injury does not affect the ability to become pregnant or deliver normally through the birth canal. Menses may cease for as long as 6 months after injury. If sexual activity is resumed, discuss protection against unplanned pregnancy. Pregnancy increases the risk for diabetes and UTI and higher rates of AD, PI, increased spasticity, and catheter-related issues. Labor and delivery have high rates of complications.[21]

Care must be taken not to dislodge an indwelling catheter during sexual activity. A patient with an external catheter should refrain from fluids and remove the catheter before sexual activity. Teach patients about the risk for AD. The bowel program should include evacuation on the morning of sexual activity. Encourage the patient to tell the partner that incontinence is always possible. The woman may need a water-soluble lubricant to supplement decreased vaginal secretions and ease vaginal penetration. Women with some residual pelvic innervation can achieve normal orgasm. Use of the Eros device may help with orgasmic dysfunction.[21]

Grief and depression. Depression after SCI is common and disabling. Patients with SCI may feel an overwhelming sense of loss. They may temporarily lose control over everyday activities as they depend on others for ADLs and for life-sustaining measures. Patients may feel they are useless and burdens to their families. At a life stage when independence is of great importance, they may be totally dependent on others.

TABLE 65.12 Grief Response in SCI

Patient Behavior	Nursing Intervention
Shock and Denial	
Struggle for survival, complete dependence, excessive sleep, withdrawal, fantasies, unrealistic expectations	• Provide honest information. • Use simple diagrams to explain injury. • Encourage patient to begin road to recovery. • Establish agreement to use and improve all current abilities while not denying the possibility of future improvement.
Anger	
Refusal to discuss paralysis, ↓ self-esteem, manipulation, hostile and abusive language	• Coordinate care with patient and encourage self-care. • Support family members. • Use humor appropriately. • Allow patient outbursts of emotions. • Do not allow fixation on injury.
Depression	
Sadness, pessimism, anorexia, nightmares, insomnia, agitation, "blues," suicidal preoccupation, refusal to take part in any self-care activities	• Encourage family involvement and use of community resources. • Plan graded steps in rehabilitation to give success with minimal opportunity for frustration. • Give cheerful and willing assistance with ADLs. • Avoid sympathy. • Use firm kindness.
Adjustment and Acceptance	
Planning for future, actively taking part in therapy, finding personal meaning in experience and continuation of growth, returning to premorbid personality	• Remember patients have unique personalities. • Balance support systems to encourage independence. • Set goals with patient input. • Emphasize potential.

BOX 65.1 ETHICAL/LEGAL DILEMMAS

Right to Refuse Treatment

Situation

R.D., a 25-year-old man, had a SCI to C7-8 after a motorcycle accident. He was diagnosed with anterior cord syndrome and has motor paralysis. He has become very depressed and no longer wishes to live. Because of his emotional state, R.D. is now refusing to eat. Can we force him to receive EN?

Ethical/Legal Points for Consideration

- Withholding treatment in a newly injured but otherwise healthy young adult may present an ethical dilemma for some nurses. They may consider it assisted suicide and believe that it violates the ethical principles of beneficence and nonmaleficence.
- A competent adult has the right to consent to or refuse medical treatment under the right to privacy, the Fourteenth Amendment of the Constitution, and case law (*Cruzan v. Director, Missouri Department of Health,* 497 U.S. 261, 1990. Retrieved from www.supreme.justia.com/cases/federal/us/497/261). Case law has supported the concept that forced treatment is battery (unlawful use of force on somebody). A mentally competent, physically incapacitated adult can refuse EN. The health agency must follow the patient's wishes (*Bouvia v. Superior Court,* 1986. Retrieved from http://law.justia.com/cases/california/calapp3d/179/1127.html).
- To be competent to take part in informed consent or refusal, an adult must be able to understand the information provided about the procedure or treatment, consider choices among available alternatives, and make a choice based on his values and preferences. Depression may not be a factor in determining competency to make informed treatment choices.
- If, after adequate evaluation and treatment for pain, depression, or other medical conditions, the patient persists in his refusal, his wishes must be respected.
- Refusal to eat or drink has never been upheld as illegal, and the alternative—forced eating and drinking—is clearly a violation of patient rights and the criminal act of battery.

Discussion Questions

1. What are your feelings about requests to withhold treatment in a young person with a newly acquired disability?
2. What resources are available to help R.D., his family, and nursing staff deal with this emotionally charged and ethically complex situation?

Working through grief is a hard, lifelong process for which the patient needs support and encouragement. Table 65.12 outlines the grief response to SCI and appropriate nursing interventions. Your role in grief work is to support the patient and family and to allow mourning as part of the rehabilitation process. Maintaining hope is important during the grieving process. It should not be viewed as denial. With recent advances in rehabilitation, the patient is often independent physically and discharged from the rehabilitation center before completing the grief process.

The goal of recovery is related more to adjustment than to acceptance. *Adjustment* implies the ability to go on with living with certain limitations. Problem-based strategies are effective in supporting positive adjustment. When the patient accepts the current new normal, levels of coping and adjustment are improved. Nonacceptance is more predictive of psychologic distress, disengagement, denial, fantasy, and drug, and alcohol use.

Include and encourage the patient to participate in care planning. A primary nurse relationship is helpful. To adjust, the patient needs continual support throughout the rehabilitation process in the form of acceptance, affection, and caring. Be attentive when the patient needs to talk and sensitive to needs at various stages of the grief process.

Although depression during the grief process usually lasts days to weeks, some patients become clinically depressed and need treatment for depression. Evaluation by a psychiatric nurse or psychiatrist is recommended. Treatment may include drugs and therapy. Treatment is maximized when the patient's personal preferences are identified, and care is tailored to patient needs (Box 65.1).

Caregivers need counseling to avoid promoting dependency in the patient through guilt or misplaced sympathy. A support group of family members and friends of patients with SCI can help them increase their participation and knowledge of the grieving process, physical problems, rehabilitation plan, and meaning of the disability.

Fig. 65.11 An increasing number of older adults are living with chronic SCI. (© WavebreakmediaLtd/WavebreakMedia/Thinkstock.)

Evaluation

Expected outcomes are that the patient with SCI will:

- Maintain adequate ventilation and have no signs of respiratory distress
- Maintain adequate circulation and BP
- Maintain intact skin over bony prominences
- Maintain adequate nutrition
- Establish a bowel and bladder management program
- Have no episodes of AD

Gerontologic Considerations: SCI

Because of increased work and recreational activities among older adults, more of them have SCI (Fig. 65.11). Falls are the leading cause of SCI for people age 65 and older. Older adults with traumatic injuries have more complications, are hospitalized longer, and have higher mortality rates.

Chronic illnesses can have a serious impact on older adults living with SCI. As patients with SCI age, both aging changes and length of time since injury can affect functional ability. For example, bowel and bladder dysfunction can increase with the duration and severity of SCI.

Health promotion and screening are important for the older patient with SCI. Daily skin inspections and UTI prevention measures are critical. Regular breast examinations for women and prostate cancer screening for men are recommended. Heart disease is the most common cause of morbidity and mortality among older adults with SCI. The lack of sensation, including chest pain, in persons with high-level injuries may mask acute myocardial ischemia. Altered autonomic nervous system function and decreases in physical activity can place patients at risk for heart problems, including hypertension.

Rehabilitation may take longer because of preexisting conditions and poorer health status at the time of initial injury. An interprofessional approach to rehabilitation is needed to prevent secondary complications.

SPINAL CORD TUMORS

Spinal cord tumors can have a devastating impact due to spinal compression and neurologic dysfunction. We classify tumors as *primary* (arising from some part of spinal cord, dura, nerves, or vessels) or *secondary* (from primary growths in other places in the body that have metastasized to the spinal cord).

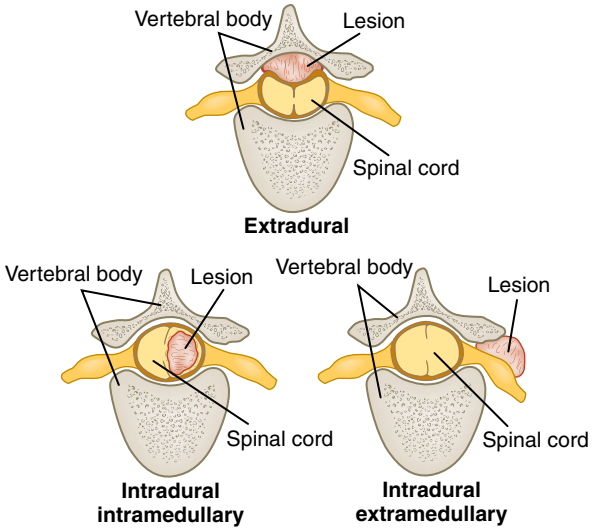

Fig. 65.12 Types of spinal cord tumors.

Etiology and Pathophysiology

Spinal cord tumors are either *extradural* (outside the dura), *intradural-extramedullary* (between the spinal cord and dura), and *intramedullary* (within the substance of spinal cord itself) (Fig. 65.12 and Table 65.13).

Extradural tumors include metastatic cancer and benign schwannomas. Many patients with cancer will have metastasis to the spine. Metastatic lesions can invade intradurally and compress the spinal cord. Tumors that often metastasize to the spinal epidural space are those that spread to bone, such as prostate, breast, lung, and kidney cancer. Intradural-extramedullary lesions include meningiomas that develop in the arachnoid membrane, schwannomas and neurofibromas that extend from the nerve root, and ependymomas found at the end of the spinal cord. Intramedullary tumors arise from glial or ependymal cells found throughout the entire spinal cord. The most common lesions are astrocytes and ependymomas.[22]

Many spinal cord tumors are slow growing. Their symptoms are due to the mechanical effects of slow compression and irritation of nerve roots, spinal cord displacement, or gradual obstruction of the blood supply. The slowness of growth does not cause secondary injury as in traumatic SCI. Thus, complete functional restoration may be possible when the tumor is removed.

Clinical Manifestations

Both sensory and motor problems may result. The location and extent of the tumor determine the severity and extent of the problem. The most common early symptom of a spinal cord tumor is back pain or pain radiating along the compressed nerve route.[23] Location of the pain depends on the level of compression. Pain may worsen with activity, coughing, straining, and/or lying down. There may be slowly increasing clumsiness, weakness, and spasticity. Paralysis can develop. Sensory disruption occurs

TABLE 65.13 Classification of Spinal Cord Tumors

Type	Incidence	Treatment	Prognosis
Extradural			
Outside spinal cord in extradural space	Metastatic lesions. Benign schwannomas	Relief of cord pressure by surgical laminectomy, radiation, chemotherapy, or combination approach	*Benign:* Excellent with resection *Metastatic:* Poor, treatment usually palliative
Intradural Extramedullary			
Within dura mater but outside spinal cord	Mostly benign. Meningiomas, neurofibromas, schwannomas	Complete surgical removal of tumor (if possible) Partial removal followed by radiation	Usually very good if no damage to cord from compression
Intramedullary			
Within spinal cord	Mostly benign. Astrocytomas, ependymomas	Complete surgical removal of tumor (if possible) Partial removal followed by radiation	Usually very good if no damage to cord from compression Complete surgical resection of astrocytomas difficult

as coldness, numbness, and tingling in 1 or more extremities. Neurogenic bowel and bladder are marked by incontinence, constipation, and urgency with difficulty in starting the flow, progressing to retention with overflow incontinence.

Interprofessional and Nursing Care

Extradural tumors can be seen on routine spinal x-rays. Intradural extramedullary and intramedullary tumors require MRI, CT scan, or CT myelogram for detection. Cerebrospinal fluid (CSF) analysis may reveal tumor cells. Patients with tumors suspicious for metastatic disease need an oncology referral and further diagnostic testing to identify the primary cancer.[22]

Spinal cord compression is an emergency. Relief of ischemia related to the compression is the goal of therapy. Indications for surgery depend on the type of tumor and neurologic deficit. Emergency surgery may be needed to decompress the spinal cord, obtain tissue for biopsy, and help to determine treatment.[22] Primary spinal tumors may be removed with the goal of cure. In patients with metastatic tumors, treatment is mainly palliative. The goal is to restore or preserve neurologic function, stabilize the spine, and alleviate pain.

Radiation and/or chemotherapy are other treatment options. Surgery and radiation therapy may cause more inflammation. Corticosteroids (e.g., dexamethasone) may be used to relieve tumor-related edema.[24]

Relieving pain and maximizing neurologic function are the goals of treatment. Assess neurologic status before and after treatment. Giving analgesia as needed is an important nursing responsibility. Depending on the amount of neurologic dysfunction, care of the patient may be similar to that of a patient recovering from SCI.

CRANIAL NERVE DISORDERS

Cranial nerve disorders are often classified as peripheral neuropathies. The 12 pairs of cranial nerves are considered the peripheral nerves of the brain. The disorders usually involve the motor and/or sensory branches of a single nerve *(mononeuropathies)*. Causes of cranial nerve problems include tumors, trauma, infection, inflammatory processes, and idiopathic (unknown) causes. The 2 cranial nerve disorders discussed here are trigeminal neuralgia (TN) and Bell's palsy.

TRIGEMINAL NEURALGIA

Trigeminal neuralgia (TN) *(tic douloureux)* is characterized by sudden, usually unilateral, severe, brief, stabbing, recurrent episodes of pain in the distribution of the trigeminal nerve. It occurs in about 12 per 100,000 Americans each year. TN affects more women. It occurs most often in people over age 50.

We classify TN as *classic* (TN 1) or *atypical* (TN 2). Patients may have both types. The pain intensity and lifestyle disruption that accompany TN can cause marked physical and psychologic dysfunction.

Etiology and Pathophysiology

The trigeminal nerve, the 5th cranial nerve (CN V), has both motor and sensory branches. TN most often affects the sensory (afferent) branches of the second and third divisions (maxillary and mandibular branches) of CN V (Fig. 65.13).

Most cases result from vascular compression of the trigeminal nerve root by an abnormal loop of the superior cerebellar artery. This artery compresses the nerve as it exits the brainstem. Constant compression appears to lead to chronic injury, causing flattening and atrophy of the nerve and damage to the myelin sheath.[25] In some cases, TN may be related to underlying pathology, such as multiple sclerosis (MS), shingles, or masses in the cerebellum or brainstem.

Clinical Manifestations

The first episode of TN is sudden, with a memorable onset. In TN 1, the patient has an abrupt onset of waves of excruciating pain. It is described as a burning, knifelike, or lightning-like shock in the lips, upper or lower gums, cheek, forehead, or side of the nose.[25] Facial twitching, grimacing, and frequent blinking and tearing of the eye can occur during the acute attack (giving rise to the term *tic douloureux*). Some patients may have facial sensory loss. Attacks are usually brief, lasting only seconds to 2 or 3 minutes. Frequency ranges from 1 to over 50 times a day.[26]

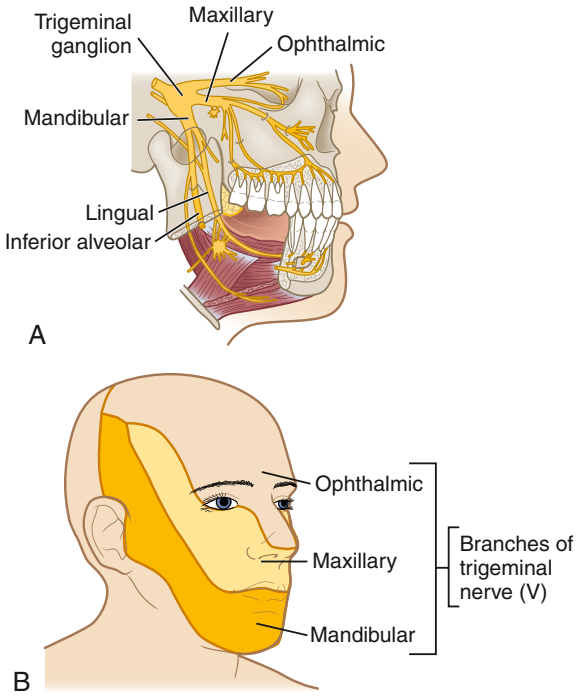

Fig. 65.13 (A) Trigeminal (fifth cranial) nerve and its 3 main divisions: ophthalmic, maxillary, and mandibular nerves. (B) Cutaneous innervation of the head. (Modified from Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.)

Pain episodes are usually started by a triggering mechanism of light touch at a specific point *(trigger zone)* along the distribution of the nerve branches. Precipitating stimuli include chewing, brushing the teeth, feeling a hot or cold blast of air on the face, washing the face, yawning, or even talking. As a result, the patient may eat improperly, neglect hygienic practices, wear a cloth over the face, and withdraw from interaction with others. The patient may sleep to cope with pain.

TN 2 manifests as constant aching, burning, crushing, or stabbing pain. The pain has a lower intensity and does not subside completely.[25] The distinct attacks of TN 1 do not occur in TN 2.

Diagnostic Studies

Diagnosis is based almost entirely on history and results from physical and neurologic assessments. Other disorders that cause facial pain are ruled out before TN is diagnosed. MRI can rule out sinusitis, cancer, MS, or masses in the cerebellopontine angle. 3D reconstruction and angiography MRI are helpful with seeing the specific brain anatomy, nerve roots, and vasculature involved. Other specialists, such as neuroradiology, neurosurgery, dentistry, maxillofacial surgery, and pain management, may be involved.

Interprofessional Care

Once a diagnosis is made, the goal is to relieve pain with either medical or surgical treatment (Tables 65.14 and 65.15). Electrical nerve stimulation and nerve blocks with local anesthetics or botulinum toxin are options.

Antiseizure drug therapy may reduce pain by stabilizing the neuronal membrane and blocking nerve firing. These drugs are usually effective in treating TN 1 but less effective in TN 2. First-line drugs include carbamazepine (Tegretol) and oxcarbazepine (Trileptal). Topiramate (Topamax), clonazepam (Klonopin), phenytoin, lamotrigine (Lamictal), gabapentin, and valproic acid are other options.[25]

Tricyclic antidepressants, such as amitriptyline or nortriptyline, can help treat the constant burning or aching pain. Analgesics or opioids are usually not effective in controlling pain in TN 1. They may help with pain in TN 2.[25]

If a conservative approach is ineffective or the patient cannot tolerate drug therapy, surgical therapy is available (Table 65.15 and Fig. 65.14). In percutaneous procedures, affected nerve fibers are damaged to eliminate pain. Although most patients are pain-free after any procedures, pain relief lasts the longest with microvascular decompression. About half of treated patients develop recurrent pain within 12 to 15 years.[25]

Trigeminal Neuralgia

Diagnostic Assessment

- History and physical assessment, including neurologic examination
- MRI

Management

- Drug therapy
  - Antiseizure drugs (e.g., carbamazepine, oxcarbazepine, gabapentin [Neurontin])
  - Tricyclic antidepressants (e.g., amitriptyline)
- Local nerve block
- Surgical therapy (Table 65.15)

❖ NURSING MANAGEMENT: TRIGEMINAL NEURALGIA

Patients usually receive outpatient treatment. Assess the attacks in detail, including triggering factors, characteristics, frequency, and pain management techniques. This information helps you to plan care. Evaluate the degree of pain and its effects on the patient's lifestyle, drug use, emotional state, and suicidal tendencies. Note behavior, including withdrawal.

Monitor the patient's response to drug therapy. Note any side effects. Discuss complementary pain management measures, such as acupuncture, biofeedback, and yoga. Environmental assessment is essential during an acute period to decrease triggering stimuli. The room should be kept at an even, moderate temperature and free of drafts. The patient may prefer to complete all self-care activities, fearing someone else will inadvertently cause injury.

Assess nutrition status and hygiene, especially oral. Teach the patient the importance of nutrition, hygiene, and oral care. Convey understanding if oral neglect is apparent. A small, soft-bristled toothbrush or a warm mouthwash helps promote oral care. Hygiene activities are best done when analgesia is at its peak.

Encourage food that is high in protein and calories and easy to chew. Serve food lukewarm. Encourage small, frequent meals.

TABLE 65.15 Therapies for Trigeminal Neuralgia

Procedure	Description
Percutaneous Procedures	
Balloon compression	• Cannula is inserted through cheek and guided to a natural opening in the base of skull. • Soft catheter with a balloon tip is threaded through cannula. • Balloon is inflated and mechanical compression damages trigeminal nerve.
Glycerol rhizotomy (injection into 1 or more branches of trigeminal nerve) (Fig. 65.14)	• Thin needle inserted through puncture in cheek and guided through natural opening in base of skull. • Glycerol is injected into trigeminal ganglion. • Procedure can be repeated multiple times.
Radiofrequency thermal lesioning	• Needle is passed through cheek thorough a natural opening in base of skull. • Patient is awakened, and then a small electric current is passed through the needle, causing tingling. • When the needle is positioned so the tingling occurs in the same area of pain, patient is sedated again, then radiofrequency current is used to destroy part of the nerve. • Can result in facial numbness (although some degree of sensation may be retained), corneal anesthesia, and trigeminal motor weakness
Surgical Procedures	
Microvascular decompression, with or without neurectomy	• Small craniotomy done behind the ear (suboccipital craniotomy). • Blood vessels that appear to be compressing the nerve at the root entry zone where it exits the pons are then displaced and repositioned. • If there is no compression, cutting of the nerve (neurectomy) may be done.
Stereotactic radiosurgery (gamma knife, cyber knife)	• Uses stereotactic localization to focus high doses of radiation to area where trigeminal nerve exits the brainstem. • Radiation causes slow formation of a lesion on nerve and disrupts transmission of pain signals to brain. • Pain relief may take several months.

If oral intake is sharply reduced and the patient is nutritionally compromised, an NG tube can be inserted on the unaffected side for EN.

Appropriate teaching related to surgery depends on the type of procedure planned (e.g., percutaneous). The patient needs to know they will be awake during local procedures to cooperate when corneal and ciliary reflexes and facial sensations are checked. After the procedure, compare the patient's pain with the preoperative intensity. Evaluate the corneal reflex, extraocular muscles, hearing, sensation, and facial nerve function often (see Chapter 60). If the corneal reflex is impaired, take special

Fig. 65.14 Glycerol rhizotomy for the treatment of trigeminal neuralgia. (A) Patient with trigeminal neuralgia having needle placed. (B) HCP injecting glycerol. (Courtesy Joe Rothrock, Media, PA.)

care to protect the eyes. This includes using artificial tears or eye shields.

After a percutaneous radiofrequency procedure, apply an ice pack to the jaw on the operative side for 3 to 5 hours. To avoid injuring the mouth, the patient should not chew on the operative side until sensation has returned. If intracranial surgery was done, general postoperative nursing care after a craniotomy is appropriate. Nursing care related to craniotomy is discussed in Chapter 61.

Plan for regular follow-up care. Teach the patient about drug therapy. Encourage the patient to keep environmental stimuli to a moderate level and use stress management techniques. Long-term management after surgery depends on residual effects of the procedure. If anesthesia is present or the corneal reflex is altered, teach the patient to (1) chew on the unaffected side; (2) avoid hot foods or beverages, which can burn the mucous membranes; (3) check the oral cavity after meals to remove food particles; (4) practice meticulous oral hygiene and continue with semiannual dental visits; (5) protect the face against temperature extremes; (6) use an electric razor; (7) wear a protective eye shield and avoid rubbing eyes; and (8) examine eye regularly for symptoms of infection or irritation.

BELL'S PALSY

Bell's palsy is an acute, usually temporary, facial paresis (or palsy) resulting from damage or trauma of the facial nerve (CN VII). It usually affects only 1 side of the face, but both sides can be affected.

Bell's palsy is the most common facial nerve disorder.[27] Each year, about 40,000 Americans are diagnosed with Bell's palsy.

Fig. 65.15 Facial characteristics of a person with Bell's palsy. (© Jo Ann Snover/123RF Stock Photo/123rf.com.)

It occurs equally between men and women and affects any age group. The peak incidence is between ages 15 and 60 years. There is a high incidence during pregnancy and in persons with upper respiratory tract conditions (e.g., flu, colds). Risk factors include obesity, diabetes, and hypertension.[27]

Etiology and Pathophysiology

We do not know the exact cause. Several theories exist. Some think it is a reactivation of herpes simplex virus isoform (HSV-1) and/or herpes zoster virus (HZV). The viral infection causes inflammation, leading to nerve compression and the subsequent clinical features (Fig. 65.15). Another cause may be acute demyelination, similar to what happens in Guillain-Barré syndrome (GBS).

The prognosis is often very good. The extent of nerve damage determines the extent of recovery. Most begin to get better within 2 weeks after the onset and recover some or all facial function within 6 months. There may be residual effects in some cases, including facial asymmetry or abnormal facial movements.

Clinical Manifestations

CN VII is a mixed cranial nerve with motor, sensory, and autonomic function, which accounts for the manifestations. The key feature is the acute onset of unilateral lower motor facial weakness. 50% to 60% have pain around and behind the ear and neck. Other manifestations include drooping of the eyelid and corner of the mouth, drooling, facial twitching, dryness of the eye or mouth, facial numbness, altered taste, hearing loss, and excessive tearing in 1 eye.[27] Most often, these symptoms begin suddenly. They reach their peak within 48 to 72 hours.

Quality of life is often decreased due to eating, swallowing, speech, and taste problems. Patients may have psychologic withdrawal because of changes in appearance, muscle stretching, and facial spasms and contractures. They may have malnutrition, dehydration, mucous membrane trauma, or corneal abrasions.

Diagnostic Studies

Bell's palsy is a clinical diagnosis. No definitive diagnostic test exists. The assessment and typical pattern of onset guide the diagnosis and prognosis. Patients should be referred to a neurologist or otolaryngologist as soon as possible to exclude other neurologic conditions. If indicated, MRI and CT can eliminate other causes for facial paralysis. Blood tests can diagnose infections or other diseases. Electromyography (EMG) can confirm the presence of nerve damage.

Interprofessional Care

Care focuses on relieving symptoms, preventing complications, and protecting the eye on the affected side. Early treatment improves the chance of a complete recovery. Oral corticosteroid therapy to reduce inflammation and swelling should be started within 72 hours of onset.[28] Some patients should also receive an antiviral agent, such as acyclovir (Zovirax). Surgical decompression of the facial nerve is controversial but an option in refractory cases.

❖ NURSING MANAGEMENT: BELL'S PALSY

Mild analgesics can relieve pain. Moist heat can reduce discomfort and aid circulation. Electrical stimulation of the nerve, facial massage, and physical therapy help maintain muscle tone and ease pain. A facial sling may be helpful to support affected muscles, improve lip alignment, and facilitate eating. The facial sling is usually made and fitted by a physical or occupational therapist. When function begins to return, active facial muscle exercises are done several times a day. Tell the patient to protect the face from cold and drafts because trigeminal *hyperesthesia* (extreme sensitivity to pain or touch) may occur.

CHECK YOUR PRACTICE

You are working in the outpatient neurology clinic. Your patient is a 68-year-old woman with Bell's palsy. Her main problem today is dry eyes. When you are doing an assessment, she tells you, "I hate the way I look. I cannot go anywhere, and I am afraid to leave the house. I am so ugly."

- How can you help her cope?
- What can you suggest to increase moisture in the affected eye?

Eye protection is important. The patient may wear dark glasses for protective and cosmetic reasons. Frequent use of artificial tears (methylcellulose) during the day can prevent drying of the cornea. Ointment and an impermeable eye shield can be used at night to retain moisture. Some patients may need to tape the lids closed at night. Teach the patient to report eye pain, drainage, or discharge.

Maintaining good nutrition is important. Teach the patient to chew on the unaffected side of the mouth to avoid trapping food and enjoy the taste of food. After each meal, thorough oral hygiene helps prevent parotitis, caries, and periodontal disease from accumulated residual food.

The change in physical appearance from Bell's palsy can be devastating. Reassure the patient that chances for a full recovery are good. Enlisting support from family and friends is important. Tell the patient most people recover within 3 to 6 months after onset of symptoms.

POLYNEUROPATHIES

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome (GBS) is an autoimmune process that occurs a few days or weeks after a viral or bacterial infection. GBS is rare, affecting about 1 person in every 100,000.[29] It can occur at any age, but those over age 50 are at greatest risk.[30] The most common type of GBS is *acute inflammatory demyelinating polyneuropathy (AIDP)*. Other types include acute motor axonal neuropathy (AMAN) and acute motor-sensory axonal neuropathy (AMSAN). AMAN is more common in children.

Etiology and Pathophysiology

The cause of GBS is unknown. Both cellular and humoral immune responses likely play a role in AIDP. Humoral responses appear to cause AMAN.[30] After an infection, immune responses cause injury to either the myelin sheath (AIDP) or the nerve axon itself (AMAN). There is edema and inflammation of affected nerves. The result is segmental loss of the myelin sheath with exposed nerve membranes in nerve terminals and the nodes of Ranvier. Transmission of nerve impulses is stopped or slowed. This leads to flaccid paralysis with muscle denervation and atrophy. In the recovery phase, remyelination occurs slowly. Neurologic function returns in a proximal-to-distal pattern.

Most GBS cases follow a viral or bacterial infection of the GI or upper respiratory tract. Cytomegalovirus is the most common viral cause. *Campylobacter jejuni* gastroenteritis is the most common bacterial cause, especially for AMAN. Other related infections include Epstein-Barr virus, *Mycoplasma pneumoniae, Haemophilus influenza,* hepatitis (A, B, E), and Zika virus.[29] Surgery and trauma may trigger GBS.

Clinical Manifestations and Complications

The main features of GBS include acute, ascending, rapidly progressive, symmetric weakness of the limbs. The first symptoms are weakness, *paresthesia* (numbness and tingling), and *hypotonia* (reduced muscle tone) of the limbs. Reflexes in the affected limbs are weak or absent. Maximal weakness is reached in 4 weeks.

Autonomic nervous system dysfunction occurs with AIDP and AMSAN, causing orthostatic hypotension, hypertension, and abnormal vagal responses (bradycardia, heart block, asystole). Other autonomic dysfunction effects include bowel and bladder dysfunction, facial flushing, and diaphoresis. Cranial nerve involvement manifests as facial weakness and paresthesia, extraocular eye movement problems, and dysphagia.

Pain is common. It can include paresthesia, muscular aches and cramps, and hyperesthesia. It is often worse at night. Pain may contribute to decreased appetite and interfere with sleep.

The most serious complication is respiratory failure. It occurs if the paralysis progresses to nerves that innervate the thoracic area. Assess the respiratory system by checking respiratory rate and depth to determine the need for immediate intervention, including intubation and mechanical ventilation. Respiratory infection or UTI may occur. Immobility from paralysis can cause paralytic ileus, muscle atrophy, VTE, PIs, orthostatic hypotension, and nutrition deficiencies.[31]

Diagnostic Studies

Diagnosis is based mainly on history and assessment. Clinical features required for diagnosis include progressive weakness of more than 1 limb and decreased or absent reflexes. Electrolyte levels, liver function tests, creatinine phosphokinase, and erythrocyte sedimentation rates are evaluated. CSF analysis helps exclude other causes. In GBS, the CSF has more protein than normal.[31] Results of EMG and nerve conduction studies (NCS) are used after 2 weeks to confirm the diagnosis. NCS allows the HCP to diagnose the subtype. NCS in AIDP show demyelination. These studies aid in diagnosis and selecting treatment.

Interprofessional and Nursing Care

The management of GBS is supportive. Ventilatory support is critical during the acute phase. Patients may be in ICU for hemodynamic monitoring. Immunomodulating treatments, such as plasma exchange (PE) *(plasmapheresis)* or high-dose IV immunoglobulin (IVIG), are most effective if used within the first 2 weeks of symptom onset. They are equally effective. PE removes antibodies and other immune factors. It is used 5 times, either daily or every other day in the first 2 weeks (see Chapter 14). IVIG interferes with antigen presentation. It is given over 5 days. It is readily available and is the preferred treatment in many centers.[31] After 4 weeks past disease onset, PE and IVIG therapies have little value.

Assessment is important during the acute phase. During the neurologic assessment, evaluate motor and sensory function. Report changes in motor function (e.g., ascending paralysis), reflexes, cranial nerve function (gag, cornea, swallow), and level of consciousness.

Assess respiratory and cardiac function. Monitor ABGs and vital capacity. Closely monitor BP and cardiac rate and rhythm during the acute phase because dysrhythmias, orthostatic hypotension, and increased or decreased BP and heart rate may occur. Vasopressor agents and volume expanders may be needed to treat the low BP. If fever develops, obtain sputum and blood cultures to identify the pathogen. Appropriate antibiotic therapy is then started.

Nutrition needs must be met despite possible delayed gastric emptying, paralytic ileus, and potential for aspiration if the gag reflex is lost. In addition to testing for the gag reflex, note drooling and other problems with secretions that may indicate an inadequate gag reflex. EN or PN may be used to ensure adequate caloric intake.

Throughout the course of the illness, provide support and encouragement to the patient and caregivers. Coordinate early referrals for physical, occupational, and speech therapy. Counseling may help the patient adjust to the sudden disabling syndrome and dependence on others.

Most patients with GBS will start to recover spontaneously at about 28 days. 80% of patients walk independently at 6 months, with 60% making a full recovery in 1 year. GBS patients who

have a GI infection, are older in age, have poor upper extremity motor strength, or need mechanical ventilation have a poorer prognosis.[31]

CHRONIC INFLAMMATORY DEMYELINATING POLYNEUROPATHY

Chronic inflammatory demyelinating polyneuropathy (CIDP) is a motor and sensory neuropathy. CIDP is a rare autoimmune disorder affecting 1 to 2 persons per 100,000. CIDP is more common in men and those in their 50s and 60s.

Like GBS, there are different types of CIDP. CIDP differs from GBS in that symptoms gradually occur over 8 weeks, and there is no acute onset. CIDP is not self-limiting (with an end to the acute phase). Early recognition and treatment can help the patient avoid significant disability.

Etiology and Pathophysiology

We do not know the exact cause of CIDP. Evidence supports an autoimmune basis. CIDP seems to be associated with infection, HIV, hepatitis C, Sjögren syndrome, inflammatory bowel disease, melanoma, lymphoma, and diabetes.

Clinical Manifestations and Diagnostic Studies

It is important to recognize the differences between CIPD and GBS to prevent incorrect or delayed treatment. The classic presentation of patients with CIPD includes progressive symptoms lasting over 2 months, more weakness than sensory deficits, symmetric weakness in the arms and legs, impaired sensation (from distal to proximal), paresthesia and dysesthesia, and absent or decreased reflexes in all extremities. Tremors, facial weakness, and papilledema may be present. Sensory ataxia and impaired vibration and pinprick sensation occur more often in CIDP.

CIDP diagnostic tests are similar to those for GBS. CSF shows high protein levels. MRI may show changes. Key identifying features of CIDP include nerve conduction block and slowed conduction velocity, possibly due to demyelination. Nerve biopsy is done when other studies do not confirm a diagnosis.

Interprofessional and Nursing Care

Early recognition and diagnosis of CIDP are key to reducing permanent disability. The goal of treatment is to halt the immune response and stop nerve inflammation and demyelination. Use of IVIG, high-dose corticosteroids, or PE are all effective treatments.

Patients continue therapy until maximum clinical improvement is achieved or until they reach a plateau. Patients need maintenance therapy to prevent relapse or progression. Coordinate appropriate referrals to rehabilitation to promote maximum recovery. Therapy may improve muscle strength, function, and mobility while minimizing muscle atrophy and joint distortion.

TETANUS

Tetanus (lockjaw) is a severe nervous system infection affecting spinal and cranial nerves. In the United States, because of widespread immunization and careful wound care, there are only about 40 to 50 cases per year.[32] The annual worldwide incidence is between 500,000 and 1 million cases.[33]

Tetanus results from the effects of a potent neurotoxin (tetanospasmin) released by the anaerobic bacillus *Clostridium tetani*. The spores of the bacillus are present in soil, garden mold, and manure. Tetanospasmin binds to motor nerves and enters the axons. From there, it can travel to the brain and spinal cord and stop the release of inhibitory neurotransmitters. This causes sustained muscle contraction. Many different muscles can be affected if the toxin reaches the blood or lymph system.[32]

C. tetani enters the body through a wound that provides an appropriate low-O_2 environment for the organisms to mature and make toxin. Examples of such wounds include IV drug use injection sites, human and animal bites, puncture wounds from stepping on a nail, gardening injuries, burns, frostbite, open fractures, and gunshot wounds. The incubation period is typically 4 to 14 days. The shorter the period, the more severe the symptoms.

The hallmark feature of generalized tetanus is muscle rigidity and spasms. Patients may have muscle soreness, cramping, or difficulty swallowing. Facial muscles are affected first with stiffness in the jaw *(trismus)*. They may have a sardonic smile *(risus sardonicus)* from facial muscle contractions. The neck muscles, back, abdomen, and extremities become increasingly rigid as the disease progresses. In severe forms, continuous tonic seizures may occur with *opisthotonos* (extreme arching of the back and retraction of the head). Laryngeal and respiratory spasms cause apnea and anoxia. The slightest noise, jarring motion, or bright light can set off a painful seizure.

Tetanus prevention and immunizations are the most important factors influencing incidence. Adults should receive a tetanus and diphtheria toxoid booster every 10 years.[32] Teach the patient that immediate, thorough cleansing of all wounds with soap and water is important to prevent tetanus. If an open wound occurs and the patient has not been immunized within 5 years, contact the HCP so they can get a tetanus booster.

Tetanus is a medical emergency that requires hospitalization. Patients receive tetanus immune globulin (TIG). It provides temporary immunity by directly providing antitoxin.[32] Drugs to control spasms are essential. Diazepam or barbiturates are given to promote sedation and skeletal muscle relaxation. In severe cases, neuromuscular blocking agents (e.g., vecuronium) are given to paralyze skeletal muscles. Opioid analgesics are used for pain management. A 10- to 14-day course of penicillin, metronidazole, tetracycline, or doxycycline inhibits further growth of *C. tetani*.

Because of laryngospasm and the potential need for neuromuscular blocking drugs, the patient is placed on mechanical ventilation. Sedative agents and opioid analgesics are given to all patients who are pharmacologically paralyzed. IV fluids are needed for proper hydration due to sustained muscle contraction. Any wound should be debrided or abscess drained. Antibiotics may be given to prevent secondary infections.

Case Study

SCI

(© Comstock Images/Stockbyte/Thinkstock.)

Patient Profile

Acute Phase

S.W., an 18-year-old woman, is admitted to the ED with a cervical SCI. S.W. was swimming at a neighbor's backyard pool. She dove into the shallow end, striking her head on the bottom of the pool. Her friends noticed she did not resurface. They rescued her and brought her to the side of the pool. They maintained neck immobilization until emergency personnel arrived.

Subjective Data

- Awake and alert
- Reporting neck pain
- Anxious and asking why she cannot move her legs
- Asking to see her family

Objective Data

- Weak elbow flexion (biceps) movement bilaterally
- No triceps movement bilaterally
- Gross shoulder movement present bilaterally
- No movement in bilateral lower extremities
- Decreased sensation from the shoulders down
- No bladder or bowel control
- BP 85/50 mm Hg; pulse 56 beats/min; respirations 32 breaths/min and labored

Diagnostic Studies

- CT C-spine shows C5 subluxation and compression fracture
- MRI C-spine shows severe spinal cord compression at C5-6

Interprofessional Care

- Intubated started on mechanical ventilation
- Placed in tongs and traction on arrival to ICU

Discussion Questions

1. ***Recognize:*** What signs and symptoms would indicate respiratory distress? What physiologic problem would cause respiratory distress in S.W.'s injury state?
2. ***Analyze:*** What physiologic problems are causing S.W. to have hypotension and bradycardia?
3. ***Plan***: What would be the initial treatment for S.W.'s hypotension and bradycardia?
4. ***Prioritize:*** What nursing activities would be a priority on S.W.'s arrival in the ICU?
5. ***Act***: What interventions can decrease S.W.'s anxiety?

Patient Profile

Rehabilitation Phase

S.W. is now 1-month post injury and has been transferred to a local inpatient SCI rehabilitation center. She is extubated and using a wheelchair to mobilize. She eats 3 meals a day with help and is on a strict bowel and bladder program.

Subjective Data

- Awake and alert but anxious
- Reporting a severe headache, blurred vision, and nausea

Objective Data

- Flushed and diaphoretic above the level of injury
- No bowel movement for 2 days
- BP 235/106 mm Hg, pulse 32 beats/min, respirations 30 breaths/min, and labored

Discussion Questions

1. ***Analyze:*** What physiologic problem is causing S.W.'s hypertension and bradycardia?
2. ***Prioritize:*** What initial priority nursing interventions would be appropriate?
3. ***Plan***: Once you notify the HCP, what other interventions would be appropriate?
4. ***Act:*** Patient and caregiver involvement in rehabilitation is vital. What teaching will you provide about bowel management?
5. ***Act:*** S.W. and her family are concerned about the risk for autonomic dysreflexia. What effective strategies to prevent autonomic dysreflexia would you discuss with them?
6. ***Evaluation:*** What outcomes would indicate that nursing interventions were successful?

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. During rehabilitation, a patient with spinal cord injury begins to ambulate with long leg braces. Which level of injury does the nurse associate with this degree of recovery?
   a. L1-2
   b. T6-7
   c. T1-2
   d. C7-8
2. A patient with a T4 spinal cord injury has neurogenic shock due to sympathetic nervous system dysfunction. What would the nurse recognize as characteristic of this condition?
   a. Tachycardia
   b. Hypotension
   c. Increased cardiac output
   d. Peripheral vasoconstriction
3. A patient with spinal cord injury has severe neurologic deficits. What is the *most* likely mechanism of injury for this patient?
   a. Compression
   b. Hyperextension
   c. Flexion-rotation
   d. Extension-rotation
4. A patient undergoing rehabilitation for a C7 spinal cord injury tells the nurse he must have the flu because he has a bad headache and nausea. The nurse's *first priority* is to
   a. call the health care provider.
   b. check the patient's temperature.

c. measure the patient's blood pressure.
d. elevate the head of the bed to 90 degrees.

5. The most common early symptom of a spinal cord tumor is
a. urinary incontinence.
b. back pain that worsens with activity.
c. paralysis below the level of involvement.
d. impaired sensation of pain, temperature, and light touch.

6. During assessment of the patient with trigeminal neuralgia, the nurse should *(select all that apply)*
a. inspect all aspects of the mouth and teeth.
b. assess the gag reflex and respiratory rate and depth.
c. lightly palpate the affected side of the face for edema.
d. test for temperature and sensation perception on the face.
e. ask the patient to describe factors that initiate an episode.

7. During routine assessment of a patient with Guillain-Barré syndrome, the nurse finds the patient is short of breath. The patient's respiratory distress is caused by
a. elevated protein levels in the CSF.
b. immobility resulting from ascending paralysis.
c. degeneration of motor neurons in the brainstem and spinal cord.
d. paralysis ascending to the nerves that stimulate the thoracic area.

1. a; 2. b; 3. c; 4. c; 5. b; 6. a, d, e; 7. d.

Assessment: Musculoskeletal System

Colleen Walsh

http://evolve.elsevier.com/Lewis/medsurg/

CONCEPTUAL FOCUS

Functional Ability
Mobility
Safety

LEARNING OUTCOMES

1. Describe the gross and microscopic anatomy of bone.
2. Explain the classification system for joints and movements at synovial joints.
3. Describe the functions of cartilage, muscles, ligaments, tendons, fascia, and bursae.
4. Link age-related changes in the musculoskeletal system to the differences in assessment findings.
5. Obtain significant subjective and objective assessment data related to the musculoskeletal system from a patient.
6. Perform a physical assessment of the musculoskeletal system using appropriate techniques.
7. Distinguish normal from abnormal findings of a physical assessment of the musculoskeletal system.
8. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the musculoskeletal system.

The musculoskeletal system is composed of voluntary muscle and 6 types of connective tissue: bone, cartilage, ligaments, tendons, fascia, and bursae. The purpose of the musculoskeletal system is to protect body organs, provide support and stability for the body, store minerals, and allow coordinated movement. This chapter reviews the structure and function of the musculoskeletal system to enable nursing assessment and evaluation of assessment findings.

STRUCTURES AND FUNCTIONS OF MUSCULOSKELETAL SYSTEM

Bone

Function

The main functions of bone are support, protection of internal organs, voluntary movement, blood cell production, and mineral storage. Bones provide the supporting framework that keeps the body from collapsing. It allows the body to bear weight. Bones protect underlying vital organs and tissues. For example, the skull encloses the brain and vertebrae surround the spinal cord. The rib cage protects the lungs and heart.

Bones serve as a point of attachment for muscles and ligaments. Muscles are connected to bones by tendons. Bones act as a lever for muscles. Movement occurs because of muscle contractions applied to these levers. Ligaments provide stability to joints. Bone marrow contains the tissues responsible for making red and white blood cells. Bones serve as a storage site for inorganic minerals, including calcium and phosphorus.[1]

Bone is a dynamic tissue that continuously changes form and composition. It contains both organic material (collagen) and inorganic material (calcium, phosphate). The internal and

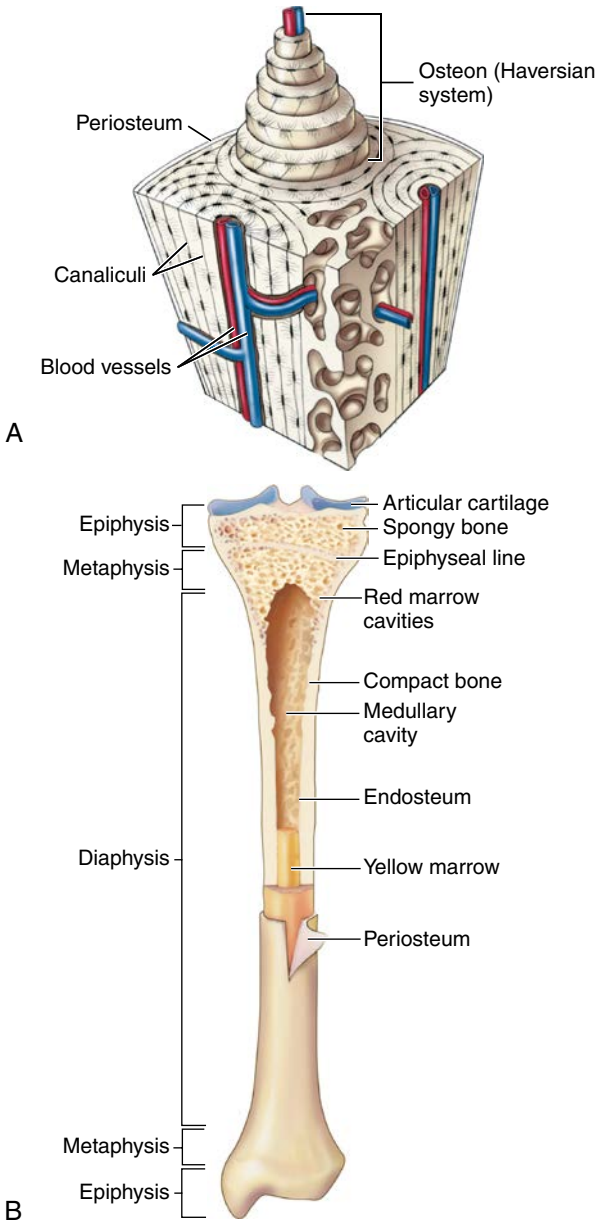

Fig. 66.1 Bone structure. (A) Cortical bone showing numerous structural units called osteons. (B) Anatomy of a long bone (tibia) showing cancellous and compact bone. (A, From Patton KT, Thibodeau GA: *Anatomy and physiology*, ed 9, St Louis, 2016, Mosby. B, From Patton KT, Thibodeau GA: *The human body in health and disease*, ed 7, St Louis, 2018, Mosby.)

external growth and remodeling of bone are ongoing processes that vary throughout the life span.

Microscopic Structure

We classify bone according to structure as *cortical* (compact and dense) or *cancellous* (spongy). In *cortical bone,* cylindrical structural units called *osteons (Haversian systems)* fit closely together to create a dense bone structure (Fig. 66.1A). Within the systems, the Haversian canals run parallel to the bone's long axis. They contain the blood vessels that travel to the bone's interior from the periosteum. Surrounding each osteon are concentric rings called *lamellae,* which indicate mature bone. Smaller canals *(canaliculi)* extend from the Haversian canals to the *lacunae*, where mature bone cells are embedded.

Cancellous bone has a different structure. The lamellae occur along the lines of maximum stress placed on the bone. Cancellous bone is filled with red or yellow marrow. Blood reaches the bone cells by passing through spaces in the marrow.

The 3 types of bone cells are osteoblasts, osteocytes, and osteoclasts.[2] Osteoblasts make organic bone matrix (collagen). They are the basic bone-forming cells. Osteocytes are mature bone cells. Osteoclasts take part in bone remodeling by helping breakdown bone tissue. **Bone remodeling** is the removal of old bone by osteoclasts (resorption) and the deposit of new bone by osteoblasts (ossification). The inner layer of bone is made mostly of osteoblasts with a few osteoclasts.

Gross Structure

The anatomic structure of bone is best represented by a typical long bone, such as the tibia (Fig. 66.1B). Each long bone consists of the epiphysis, diaphysis, and metaphysis. The *epiphysis*, the widened area at each end of a long bone, is made mostly of cancellous bone. The wide epiphysis allows greater weight distribution and provides stability for the joint. The epiphysis is a main location for muscle attachment. Articular cartilage covers the ends of the epiphysis. It provides a smooth, low-friction surface for joint movement.

The *diaphysis* is the main shaft of the long bone. It provides structural support and is composed of cortical bone. The tubular structure of the diaphysis allows it to withstand bending and twisting forces more easily. The *metaphysis* is the flared area between the epiphysis and diaphysis. It is composed of cancellous bone.

The *epiphyseal plate* (physis or growth plate) is the cartilaginous area between the epiphysis and metaphysis. In skeletally immature children who still have open growth plates, the epiphyseal plate actively makes chondrocytes that become mature bone. Chondrocyte division causes longitudinal bone growth in children. Injury to the epiphyseal plate in a growing child can cause the formation of new bone to stop at the growth plate. This leads to a shorter extremity and may contribute to major functional problems. In the adult, the metaphysis and epiphysis become joined when chondrocyte formation at the growth plate stops and bone formation is complete.

The *periosteum* is composed of fibrous connective tissue that covers the bone. Tiny blood vessels penetrate the periosteum to bring nutrition to underlying bone. Musculotendinous fibers attach to the outer layer of the periosteum. Collagen bundles attach the inner layer of the periosteum to the bone. There is no periosteum on the articular surfaces of long bones. These bone ends are covered by articular cartilage.[3]

The medullary *(marrow)* cavity in the center of the diaphysis contains either red or yellow bone marrow.[2] In adults, red marrow is found mainly in the flat bones, such as the pelvis, sternum, and scapula, and cancellous bone at the epiphyseal ends of long bones, such as the femur and humerus. Red bone marrow is involved in blood cell production (hematopoiesis). In the adult, the medullary cavity of long bones contains yellow

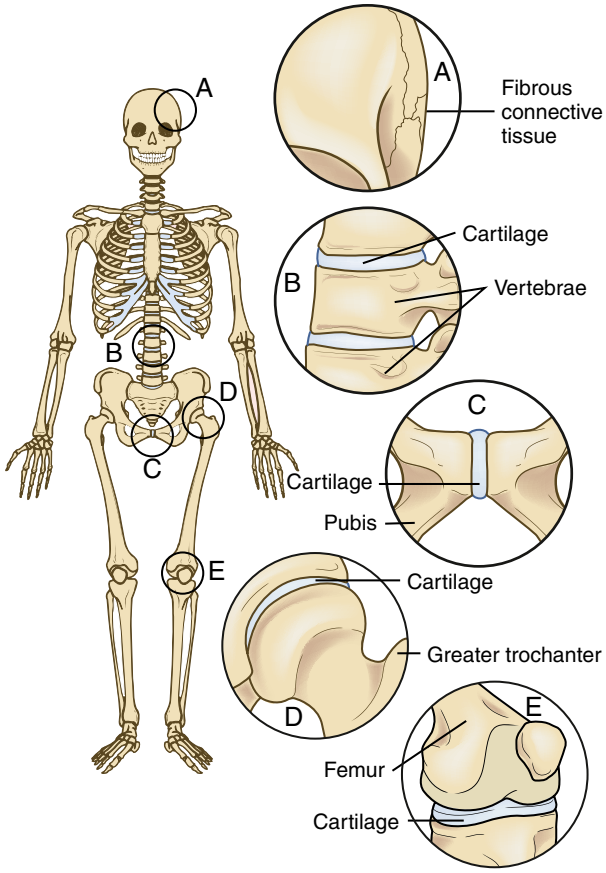

Fig. 66.2 Classification of joints. (A–C) Synarthrotic (immovable) and amphiarthrotic (slightly movable) joints. (D and E) Diarthrodial (freely movable) joints.

bone marrow (mainly adipose tissue). It serves as a storage site for triglycerides.[4] Yellow marrow is involved in hematopoiesis in times of great blood cell need.

Types

The skeleton consists of 206 bones. We classify bones by shape as long, short, flat, irregular, or seismoid.

Long bones have a central shaft (diaphysis) and 2 widened ends (epiphyses) (Fig. 66.1B). Examples include the femur, humerus, and tibia. Short bones are composed of cancellous bone covered by a thin layer of compact bone. Examples include the carpals in the hand and tarsals in the foot.

Flat bones have 2 layers of compact bone separated by a layer of cancellous bone. Flat bones include the pelvis, skull, sternum, ribs, vertebrae, and scapula. The spaces in the cancellous bone contain bone marrow. Irregular bones appear in a variety of shapes and sizes. Examples include the sacrum, mandible, and ear ossicles. *Sesamoid bones* are round or oval bones (such as the patella), which develop in tendons.[3]

Joints

A *joint* (articulation) is a place where the ends of 2 bones are close and move in relation to each other. Joints are classified by the degree of movement that they allow (Fig. 66.2).

The most common joint is the freely movable *diarthrodial* (synovial) type. Each joint is enclosed in a capsule of fibrous

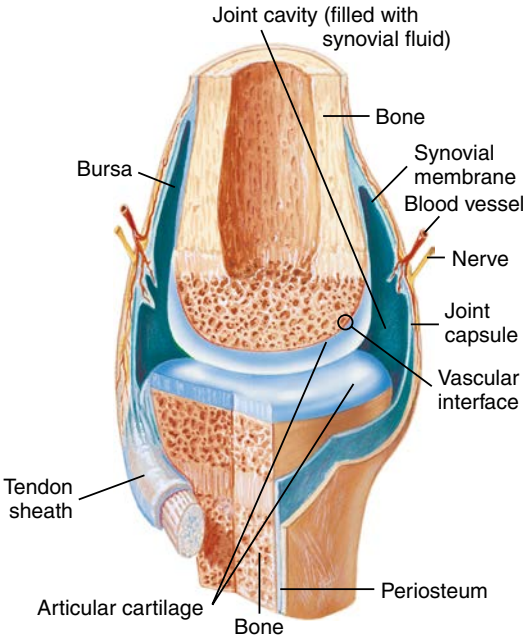

Fig. 66.3 Structure of diarthrodial (synovial) joint.

connective tissue, which joins the 2 bones together to form a cavity (Fig. 66.3). The capsule is lined by a synovial membrane, which secretes thick synovial fluid. This fluid lubricates the joint, reduces friction, and allows opposing surfaces to slide smoothly over each other. It supplies oxygen and nutrients to and removes carbon dioxide and metabolic wastes from the chondrocytes within articular cartilage. The end of each bone is covered with articular (hyaline) cartilage. Supporting structures (e.g., ligaments, tendons) reinforce the joint capsule. They provide limits and stability to joint movement. Types of diarthrodial joints are shown in Fig. 66.4.

Cartilage

The 3 types of *cartilage* are hyaline, elastic, and fibrous. *Hyaline cartilage* is the most common. It has a moderate amount of collagen fibers. It is found in the trachea, bronchi, nose, epiphyseal plate, and articular surfaces of bones.

Elastic cartilage, which has both collagen and elastic fibers, is more flexible than hyaline cartilage. It is found in the ear, epiglottis, and larynx.

Fibrous cartilage (fibrocartilage) consists mostly of collagen fibers. It is a tough tissue that often functions as a shock absorber. Fibrous cartilage is found between the vertebral discs. It forms a protective cushion between the bones of the pelvic girdle, knee, and shoulder.

Cartilage in synovial joints serves as a support for soft tissue and provides the articular surface for joint movement. It protects underlying tissues. Because articular cartilage is avascular, it must receive nourishment by the diffusion of material from the synovial fluid. The lack of a direct blood supply contributes to the slow metabolism of cartilage cells and explains why healing and repair of cartilage tissue occur slowly. The cartilage in the epiphyseal plate is involved in the growth of long bones before reaching physical maturity.[5]

Joint	Movement	Examples	Illustration
Hinge joint	Flexion, extension	Elbow joint (shown), interphalangeal joints, knee joint	Ball and socket (spheroidal)	Flexion, extension; adduction, abduction; circumduction	Shoulder (shown), hip	Pivot (rotary)	Rotation	Atlas-axis, proximal radioulnar joint (shown)	Condyloid	Flexion, extension; abduction, adduction; circumduction	Wrist joint (between radial and carpals) (shown)	
Saddle	Flexion, extension; abduction, adduction; circumduction, thumb-finger opposition	Carpometacarpal joint of thumb (shown)	
Gliding	One surface moves over another surface	Between tarsal bones, sacroiliac joint, between articular processes of vertebrae, between carpal bones (shown)	
Fig. 66.4 Types of diarthrodial (synovial) joints.

Muscle

Types

The 3 types of muscle tissue are cardiac (striated, involuntary), smooth (nonstriated, involuntary), and skeletal (striated, voluntary) muscle. *Cardiac muscle* is found only in the heart. Its contractions are spontaneous. *Smooth muscle* is found in the walls of hollow structures, such as airways, arteries, gastrointestinal (GI) tract, urinary bladder, and uterus. Smooth muscle contraction is controlled by neuronal and hormonal influences. *Skeletal muscle* requires neuronal stimulation for contraction. It accounts for about half of a human's body weight. We focus on skeletal muscle in the following discussion.

Structure

The skeletal muscle is enclosed by the *epimysium*, a continuous layer of deep fascia. The epimysium helps muscles slide over nearby structures. Connective tissue surrounding and extending into the muscle can be subdivided into fiber bundles *(fasciculi)*. These bundles are covered by *perimysium* and an innermost connective tissue layer called the *endomysium* that surrounds each fiber (Fig. 66.5).[6]

The structural unit of skeletal muscle is the muscle cell or muscle fiber. It is highly specialized for contraction. Skeletal muscle fibers are long, multinucleated cylinders that contain many mitochondria to support their high metabolic activity. Muscle fibers are composed of myofibrils, which in turn are made up of protein contractile filaments. The *sarcomere* is the contractile unit of a myofibril. Each sarcomere consists of *myosin* (thick) filaments and *actin* (thin) filaments. The arrangement of the thin and thick filaments causes the characteristic banding of muscle seen under a microscope. Muscle contraction occurs as thick and thin filaments slide past each other, causing the sarcomeres to shorten.[6]

Contractions

Skeletal muscle contractions allow posture maintenance, body movement, and facial expressions. **Isometric contractions** increase the tension within a muscle but do not produce movement. **Isotonic contractions** shorten a muscle to produce movement. Most contractions are a combination of tension *(isometric)* and shortening *(isotonic)*. Repeated isometric and/or isotonic contractions provide stress to stimulate muscle growth.

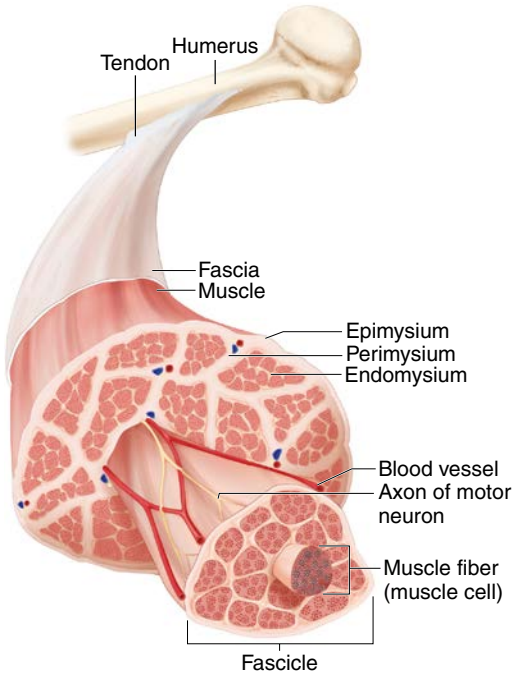

Fig. 66.5 Myofibrils of a skeletal muscle fiber and overall organization of skeletal muscle. (From Patton KT, Thibodeau GA, Douglas M: *Anatomy and physiology*, ed 9, St Louis, 2016, Mosby.)

Muscular *atrophy* (decrease in size) occurs with the absence of contractions. Atrophy can result from immobility or decreased neuronal stimulation. Increased muscular activity leads to *hypertrophy* (increase in size).

Skeletal muscle fibers are divided into 2 groups based on the type of activity they show. *Slow-twitch muscle fibers* support prolonged muscle activity, such as marathon running. Because they support the body against gravity, they help maintain posture. *Fast-twitch muscle fibers* are used for rapid muscle contraction needed for activities, such as blinking the eye, jumping, or sprinting. Fast-twitch fibers tire more quickly than slow-twitch fibers.

Neuromuscular Junction

Skeletal muscle fibers require a nerve impulse to contract. A nerve fiber and the skeletal muscle fibers it stimulates are called a *motor endplate*. The junction between the axon of the nerve cell and the adjacent muscle cell is called the *myoneural* or *neuromuscular junction* (Fig. 66.6).[7]

Presynaptic neurons release acetylcholine. It diffuses across the neuromuscular junction to bind with receptors on the motor endplate of the muscle. In response to this stimulation, the sarcoplasmic reticulum releases calcium into the cytoplasm. The presence of calcium triggers contraction in the myofibrils. When calcium is low, *tetany* (involuntary skeletal muscle contractions) can occur.

Energy Source

The direct energy source for muscle contractions is adenosine triphosphate (ATP). ATP is synthesized through cellular oxidative metabolism in the numerous mitochondria found close to the myofibrils. It is rapidly depleted through conversion to adenosine diphosphate (ADP) and must be rephosphorylated. Phosphocreatine provides a rapid source for the resynthesis

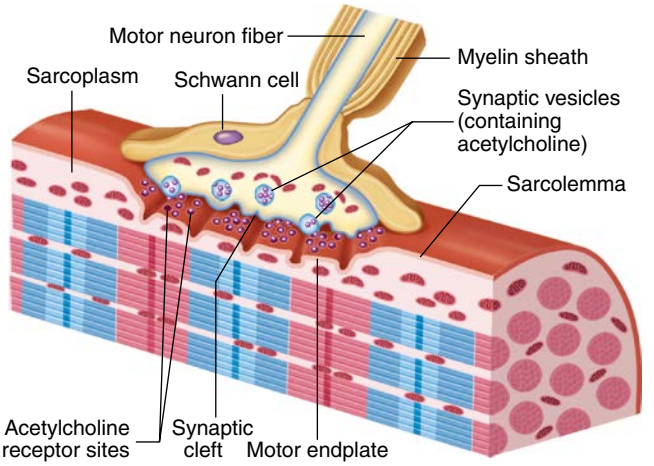

Fig. 66.6 Motor units of a muscle. (From McCance KL, Huether SE: *Pathophysiology: the biological basis for disease in adults and children*, ed 8, St. Louis, 2019, Elsevier.)

of ATP, but it is, in turn, converted to creatine. Glycolysis can serve as a source of ATP when the O_2 supply is inadequate for metabolic needs of the muscle tissue. In this process, 1 glucose molecule is broken down to 2 ATP molecules.

Ligaments and Tendons

Ligaments and tendons are composed of dense, fibrous connective tissue with bundles of closely packed collagen fibers arranged in the same plane for additional strength. *Tendons* attach muscles to bones as an extension of the muscle sheath that adheres to the periosteum. *Ligaments* connect bones to bones (e.g., tibia to femur at knee joint). They have a higher elastic content than tendons.[8] Ligaments provide stability while allowing controlled movement at joints.

Ligaments and tendons have a poor blood supply. This can make their repair after injury a slow process. For example, the stretching or tearing of ligaments that occurs with a sprain may require a long time to mend.

Fascia

Fascia refers to layers of connective tissue with intermeshed fibers that can withstand limited stretching. Superficial fascia lies right under the skin. Deep fascia is a dense, fibrous tissue that surrounds muscle bundles, nerves, and blood vessels. It encloses individual muscles, allowing them to act independently and glide over each other during contraction. Fascia provides strength to muscle tissues.

Bursae

Bursae are small sacs of connective tissue lined with synovial membrane and containing viscous synovial fluid. They are found at bony prominences or joints to relieve pressure and decrease friction between moving parts.[9] Bursae are found between the (1) patella and skin (prepatellar bursae), (2) olecranon process of the elbow and skin (olecranon bursae), (3) head of the humerus and acromion process of the scapula (subacromial bursae), and (4) greater trochanter of the proximal femur and skin (trochanteric bursae). *Bursitis* is an inflammation of a bursa sac. The inflammation may be acute or chronic.

Gerontologic Considerations: Effects of Aging on Musculoskeletal System

Many functional problems experienced by the older adult are related to changes in the musculoskeletal system. Although some changes begin in early adulthood, obvious signs of musculoskeletal impairment may not appear until later adult years. Changes may affect the older adult's ability to complete self-care tasks and pursue usual activities. Effects of musculoskeletal changes may range from mild discomfort and decreased ability to perform ADLs to severe, chronic pain and immobility.

The bone remodeling process changes in the aging adult. Increased bone resorption and decreased bone formation cause a loss of bone density. This contributes to osteopenia and osteoporosis (see Chapter 68). Muscle mass and strength decrease. Almost 30% of muscle mass is lost by age 70. A loss of motor neurons can cause problems with skeletal muscle movement. Tendons and ligaments become less flexible, making movement more rigid.

Osteoarthritis is more likely to affect joints in the aging adult (see Chapter 69). Metabolic bone diseases involve bone tissue deterioration (osteoporosis) and cartilage destruction (osteoarthritis). Carefully distinguish between expected changes and the effects of disease in the aging adult. Symptoms of disease can be treated in many cases, helping the older adult to return to a higher functional level. Table 66.1 outlines age-related changes in the musculoskeletal system and differences in assessment findings.

Assess the impact of age-related changes on functional status. Ask about changes in self-care habits and ability to be independent in the home environment. Functional limitations that are accepted by the older adult as a normal part of aging can often be addressed with preventive strategies.

The risk for falls increases due in part to loss of strength. Aging can also bring changes in the patient's balance, making the person unsteady. *Proprioception* (awareness of self in relation to the environment) may be altered. Identify any musculoskeletal changes that increase the patient's risk for falls. Discuss fall prevention strategies.

TABLE 66.1 GERONTOLOGIC ASSESSMENT DIFFERENCES

Musculoskeletal System

Changes	Differences in Assessment Findings
Bone	
• ↓ Bone density and strength • Slowed remodeling process	• Loss of height and deformity, such as dowager's hump (kyphosis), from vertebral compression and degeneration • Back pain, stiffness • Bony prominences more pronounced • ↑ Risk for osteopenia and osteoporosis
Joints	
• ↑ Risk for cartilage erosion that leads to direct contact between bone ends and overgrowth of bone around joint margins • Loss of water from discs between vertebrae, ↓ height of intervertebral spaces	• Joint stiffness, ↓ mobility, limited ROM, possible crepitation on movement • Pain with motion and/or weight bearing • Loss of height and shortening of trunk from disc compression. Posture change
Muscles	
• ↓ Number and diameter of muscle cells. Replacement of muscle cells by fibrous connective tissue • Loss of elasticity and deterioration of cartilage • ↓ Ability to store glycogen. ↓ Ability to release glycogen as quick energy during stress • ↓ Basal metabolic rate	• ↓ Muscle strength and mass • Abdominal protrusion • ↑ Rigidity in neck, shoulders, back, hips, and knees • ↓ Fine motor dexterity, ↓ agility • Slowed reaction times and reflexes from slowed conduction of nerve impulses along motor units • Earlier fatigue with activity

ASSESSMENT OF MUSCULOSKELETAL SYSTEM

Subjective Data

Important Health Information

Health history. The most common manifestations of musculoskeletal impairment include pain, weakness, deformity, limitation of movement, stiffness, and joint crepitation (crackling sound). Ask the patient about changes in sensation or in the size of a muscle.

Focus questions on symptoms of arthritic and connective tissue diseases (e.g., gout, psoriatic arthritis, systemic lupus erythematosus [SLE]), osteomalacia, osteomyelitis, and fungal infection of bones or joints. Ask the patient about sources of a secondary bacterial infection, such as ears, tonsils, teeth, sinuses, lungs, or genitourinary tract. These infections can enter the bones via the blood, resulting in osteomyelitis or joint destruction. Get a detailed account of the course and treatment of any of these problems.

Certain illnesses are known to affect the musculoskeletal system directly or indirectly. Ask the patient about problems such as tuberculosis, polio, diabetes, parathyroid problems,

Case Study

Patient Introduction

(© pixelhead-photo/iStock/Thinkstock.)

G.A. is a 58-year-old woman whose husband brought her to the emergency department (ED) this morning after she awoke with a sudden onset of excruciating pain in her left great toe. She denies any injury to her foot. She says she has never had this type of pain before.

Discussion Questions

1. What are the possible causes for G.A.'s acute pain in her great toe?
2. Is this condition stable or an emergency?
3. What type of assessment would be most appropriate for G.A.: comprehensive, focused, or emergency? What is the basis for your decision?
4. What assessment questions will you ask G.A.?

You will learn more about how to assess G.A.'s condition as you read this chapter.

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

hemophilia, rickets, soft tissue infection, and neuromuscular disability.

Trauma to the musculoskeletal system is a common reason for seeking medical care. The patient who is a good historian can recount minor and major injuries of the musculoskeletal system. Record information chronologically and include:

- Mechanism and circumstances of the injury (e.g., twist, crush, stretch)
- Methods and duration of treatment
- Current status of the injury
- Need for assistive devices
- Interference with ADLs

Medications. Obtain a complete medication history. Ask about the use of skeletal muscle relaxants, opioids, nonsteroidal antiinflammatory drugs, corticosteroids, and calcium and vitamin D supplements. Review the use of drugs that can have detrimental effects on the musculoskeletal system. Some of these and their potential side effects include antiseizure drugs (osteomalacia), phenothiazines (gait changes), corticosteroids (avascular necrosis, decreased bone and muscle mass), and potassium-depleting diuretics (muscle cramps and weakness). Ask postmenopausal women about the use of hormone therapy.

Surgery or other treatments. Ask about any hospitalizations due to a musculoskeletal problem. Document the reason for hospitalization; the date and duration; and the treatment, including ongoing rehabilitation. Record details of emergency treatment for musculoskeletal injuries. Get specific information about any surgeries, postoperative course, and complications. Ask the patient about total knee or total hip replacements. If the patient had a period of prolonged immobilization, consider the possibility of disuse osteoporosis and muscle atrophy.

Functional Health Patterns

Past or developing musculoskeletal problems can affect the patient's overall health. Use functional health patterns to organize assessment data. Table 66.2 outlines specific questions to ask in relation to functional health patterns.

Health perception–health management pattern. Ask about health practices related to the musculoskeletal system. This includes maintaining normal body weight, avoiding excessive stress on muscles and joints, and using proper body mechanics when lifting objects. Ask the patient about tetanus, pertussis, and polio immunizations.

Safety practices can affect the predisposition for certain injuries and illnesses. Ask about safety practices related to the work environment, home life, recreation, and exercise. For example, if the patient works with computers, do they use ergonomic adaptations that decrease the risk for carpal tunnel syndrome or low back pain? Identifying problems in this area will direct your patient teaching.

Is there a family history of rheumatoid arthritis, SLE, ankylosing spondylitis, osteoarthritis, gout, osteoporosis, and scoliosis (Box 66.1)? A patient may have a genetic predisposition to these or other musculoskeletal problems.

Nutritional-metabolic pattern. The patient's description of a typical day's diet gives clues to areas of nutrition concern that can affect the musculoskeletal system. Adequate intake of vitamins C and D, calcium, and protein is essential for a healthy musculoskeletal system. Nutrition problems can contribute to osteomalacia and osteoporosis. Maintaining normal weight is an important goal. Obesity places added stress on weight-bearing joints, such as the knees, hips, and spine. This increases the risk for cartilage deterioration and ligament instability.

Elimination pattern. Questions about the patient's mobility may reveal problems with ambulating to the toilet. Ask the patient if an assistive device, such as an elevated toilet seat or a grab bar, is needed to manage toileting. Decreased mobility can lead to constipation. Musculoskeletal problems can contribute to bowel or bladder incontinence when ambulation is a problem.

Activity-exercise pattern. Many musculoskeletal problems can affect the patient's activity-exercise pattern. Get a detailed account of the type, duration, and frequency of exercise and recreational activities. What are their warm-up activities? Compare daily, weekend, and seasonal patterns because occasional exercise can be more of a problem than regular exercise. Ask the patient about clumsiness or limitations in movement, pain, weakness, crepitus, or any change in bones or joints that interferes with daily activities.

Occupational activity can affect the musculoskeletal system. For example, a desk job can negatively affect muscle flexibility and strength. Jobs that require heavy lifting or pushing can lead to damage of joints and supporting structures. Ask the patient about work-related musculoskeletal injuries, including treatment and time lost from work.

Sleep-rest pattern. Discomfort from a musculoskeletal problem can interfere with sleep and lead to fatigue. Ask the patient about any changes in sleep patterns. If the patient describes poor sleep because of a musculoskeletal problem, ask about the type of bedding and pillows used, bedtime routine, sleeping partner, and sleeping positions.

Cognitive-perceptual pattern. Fully discuss any reports of pain reported from a musculoskeletal problem. To give a baseline for later reassessment, ask the patient to describe the intensity of the pain on a numeric scale from 0 to 10 (0 = no pain, 10 = most severe pain imaginable). Reassessments over time help to determine the effectiveness of any treatment plan. Ask the patient about measures used to manage pain. Are there any other problems, such as joint swelling or muscle weakness? If so, are there any adjustments that help with the problem?

Self-perception–self-concept pattern. Many chronic musculoskeletal problems lead to deformities and a reduction in activities. This can have a serious negative impact on the patient's body image and sense of personal worth. Assess the patient's feelings about these changes and any effect on interactions with family and friends.

Role-relationship pattern. Impaired mobility and chronic pain from musculoskeletal problems can negatively affect the patient's ability to perform in roles of spouse, parent, and/or employee. The ability to pursue and maintain meaningful social and personal relationships can be affected by musculoskeletal

TABLE 66.2 HEALTH HISTORY

Musculoskeletal System

Health Perception–Health Management Pattern
- Describe your usual daily activities.
- Do you have any problems performing these activities?[a] Describe what you do if you have trouble dressing, preparing meals and feeding yourself, performing basic hygiene, writing, using the phone, or maintaining your home.
- Do you have to lift heavy objects? Does your work or exercise involve repetitive motion or joint stress? Describe any special equipment you use or wear when you work or exercise that helps protect you from injury.
- Do you take any drugs or herbal products to manage your musculoskeletal problem? If so, what are their names and what are the expected effects?

Nutritional-Metabolic Pattern
- What is your usual daily intake of food and snacks?
- Do you have problems preparing your food?
- What diet supplements do you take? Do you take calcium or vitamin D supplements?
- What is your weight? Describe any recent weight loss or gain.

Elimination Pattern
- Does your musculoskeletal problem make it hard for you to reach the toilet in time?[a]
- Do you need any assistive devices or equipment to manage toileting?[a]
- Do you have constipation related to decreased mobility or drugs taken for your musculoskeletal problem?[a]

Activity-Exercise Pattern
- Do you need help in completing your usual daily activities because of a musculoskeletal problem?[a]
- Describe your usual exercise pattern. Do you have musculoskeletal symptoms before, during, or after exercising?[a]
- Are you able to move all your joints comfortably through full range of motion?
- Do you use any prosthetic or orthotic devices?[a]

Sleep-Rest Pattern
- Do you have any problems sleeping because of a musculoskeletal problem?[a]
- Do you need frequent position changes at night?[a]
- Do you wake up at night because of musculoskeletal pain?[a]
- Describe any practices you use to help you sleep at night.[a]

Cognitive-Perceptual Pattern
- Describe any musculoskeletal pain you have. How do you manage your pain? Ask about adjunctive therapies, such as heat and cold, or complementary and alternative therapies, such as acupuncture.

Self-Perception–Self-Concept Pattern
- Have changes in your musculoskeletal system (posture, walking, muscle strength) and decreased ability to do certain things affected how you feel about yourself?[a]
- Have these changes affected your lifestyle?[a]

Role-Relationship Pattern
- Do you live alone?
- Describe how family, friends, or others help you with your musculoskeletal problem.
- Describe the effect of your musculoskeletal problem on your work and your social relationships.

Sexuality-Reproductive Pattern
- Describe any sexual concerns related to your musculoskeletal problem.

Coping–Stress Tolerance Pattern
- Describe how you deal with problems such as pain, weakness, or immobility that have resulted from your musculoskeletal problem.

Value-Belief Pattern
- Describe any cultural practices or religious beliefs that may influence the treatment of your musculoskeletal problem.

[a]If yes, describe.

BOX 66.1 GENETIC RISK ALERT

Autoimmune Diseases
- Many autoimmune diseases of the musculoskeletal system have a genetic basis involving human leukocyte antigens (HLAs).
- These diseases include ankylosing spondylitis, rheumatoid arthritis, and SLE.

Osteoporosis
- Genetic factors contribute to osteoporosis by influencing bone mineral density and bone size, quality, and turnover.

Osteoarthritis, Gout, and Scoliosis
- A genetic predisposition is a contributing risk factor in all these diseases.

Muscular Dystrophy
- The most common types of muscular dystrophy are X-linked recessive disorders.

problems. Carefully ask the patient about role performance and relationships.

If the patient lives alone, any musculoskeletal problem and rehabilitation may make it hard or impossible to continue to do so. Assess how much help is available from family, friends, and other caregivers. Find out if other resources are needed, such as physical therapy and home health care.

Sexuality-reproductive pattern. Ask women about their menstrual history. Premenopausal amenorrhea can contribute to osteoporosis. Pain from musculoskeletal problems can affect the ability to obtain sexual satisfaction. Explore this area in a sensitive way. Help the patient feel comfortable discussing any sexual problems related to pain, movement, and positioning. More information on obtaining data in this area is discussed in Chapter 55.

Coping–stress tolerance pattern. Mobility limitations and pain are serious potential stressors that challenge the patient's coping resources. Recognize the potential for difficulty coping in the patient and family or significant other. Explore if a musculoskeletal problem is causing difficulties in coping and adjusting.

Value-belief pattern. Ask about cultural or religious beliefs that may influence acceptance of treatment for the musculoskeletal problem. These may include recommendations for diet, exercise, medication, and lifestyle changes.

Case Study

Subjective Data

(© pixelhead-photo/iStock/Thinkstock.)

A focused subjective assessment of G.A. revealed the following:

Medical History: Hypertension for 6 years. Type 2 diabetes for 11 years, 40-pack-year smoking history.

Medications: Metformin 500 mg PO bid; hydrochlorothiazide 50 mg PO bid.

Health Perception–Health Management: Currently smokes 1 pack of cigarettes per day. Is trying to quit but finding it difficult. Drinks alcohol at night.

Nutritional-Metabolic: G.A. is 5 ft, 2 in tall and weighs 160 lb (BMI 29.3 kg/m^2). Does not take any nutrition supplements. Avoids milk and other dairy products because they make her "gassy."

Activity-Exercise: Minimally active; does not exercise. Able to perform ADLs without assistance. Denies any history of musculoskeletal problems.

Cognitive-Perceptual: Rates toe pain at 8 on a scale of 0–10. Describes sharp, burning pain that increases in intensity with any movement.

Coping–Stress Tolerance: Is asking for pain medicine "as strong as you can give me."

Discussion Questions

1. What subjective assessment findings concern you most?
2. Is this an appropriate time to talk with G.A. about her weight?
3. Based on these subjective findings, what should be included in the physical assessment?

You will learn more about the physical assessment of the musculoskeletal system in the next section.

Answers available at http://evolve.elsevier.com/Lewis/medsurg

Objective Data

Physical Assessment

The basic musculoskeletal physical assessment involves inspection, palpation, neurovascular assessment, and range of motion, strength, and reflex testing. Other special tests can be used to assess for specific conditions. Conduct a general overview. While obtaining a careful health history, choose areas to concentrate on during the local assessment. Take specific measurements as indicated by the local assessment.

Inspection. Perform a systematic inspection. Start at the head and neck then moving to the upper extremities, lower extremities, and trunk. The regular use of a systematic approach is important to avoid missing any important aspects. Inspect the skin for general color, scars, or other overt signs of previous injury or surgery. Certain skin lesions require further assessment because they can indicate another problem. For example, butterfly rash over the cheeks and nose is a sign of SLE.

Note the patient's general posture and body build, muscle size and symmetry, and symmetry and contour of joints. Observe for any swelling, deformity, nodules or masses, and discrepancies in limb length or muscle size. Use the patient's opposite body part for comparison when you suspect an abnormality.

If the patient can move independently, assess posture and gait by watching the patient walk, stand, and sit. Musculoskeletal and neurologic problems can result in abnormal gait patterns.

TABLE 66.3 Synovial Joint Movements

Movement	Description
Abduction	Movement of part away from midline of body
Adduction	Movement of part toward midline of body
Circumduction	Circular motion of a body part from a combination of flexion, abduction, extension, and adduction
Dorsiflexion	Flexion of the ankle and toes toward the shin
Eversion	Turning of sole outward away from midline of body
Extension	Straightening of joint that ↑ angle between 2 bones
External rotation	Movement along longitudinal axis away from midline of body
Flexion	Bending of joint from muscle contraction that causes ↓ angle between 2 bones
Hyperextension	Extension in which angle exceeds 180 degrees
Internal rotation	Movement along longitudinal axis toward midline of body
Inversion	Turning of sole inward toward midline of body
Opposition	Moving the first and fifth metacarpals anteriorly from a flattened palm ("cupping position"); makes it possible to hold objects between the thumb and fingers
Plantar flexion	Flexion of the ankle and toes toward the plantar surface of the foot ("toes pointed")
Pronation	Turning of palm downward
Supination	Turning of palm upward

Palpation. Palpation usually proceeds head to toe. Examine the neck, shoulders, elbows, wrists, hands, back, hips, knees, ankles, and feet. Warm your hands to prevent muscle spasm, which can interfere with identifying essential landmarks or soft tissue structures. Carefully palpate any specific areas of concern because of a subjective report or abnormal appearance on inspection.

Both superficial and deep palpation are usually done consecutively. Consider the underlying anatomy structures and landmarks you are palpating. Palpate muscles and joints to assess temperature, tenderness, swelling, and crepitation. Establish the relationship of adjacent structures. Note the general contour, local landmarks, and any abnormal prominences. Note the specific anatomic location of any abnormal findings.

Motion. When assessing the patient's joint mobility, evaluate active and passive **range of motion (ROM)**. ROM is the full movement potential of a joint. Common movements that occur at the synovial joints, including *abduction, adduction, flexion,* and *extension,* are described in Table 66.3.

Measurements should be similar for active and passive maneuvers. *Active ROM* means the patient takes their own joints through all movements without assistance. *Passive ROM* occurs when someone else moves the patient's joints without their assistance through the full ROM. Be careful in performing passive ROM because of the risk for injury to underlying structures. If pain or resistance occurs, stop at once.

If you note deficits in active or passive ROM, assess functional ROM to see if joint changes are affecting the ability to perform ADLs. Ask the patient if activities, such as eating, grooming, dressing, and bathing, require help or cannot be done at all.

We use a goniometer to accurately assess ROM. It measures the angle of the joint (Fig. 66.7). We do not usually measure specific degrees of ROM of all joints. If a specific musculoskeletal

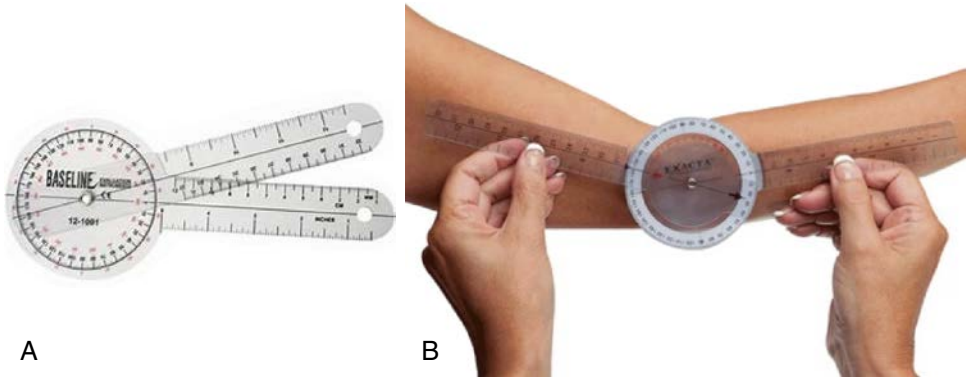

Fig. 66.7 (A) Goniometer. (B) Measurement of joint ROM using a goniometer. (From LaSala TT, Run-Kowzun T, Figueroa M: The effect of a Hatha yoga practice on hamstring flexibility, *J Bodywork Move Therap* 28:439-449, 2021.)

TABLE 66.4 Muscle Strength Scale

0/5	No detection of muscular contraction
1/5	Barely detectable flicker or trace of contraction with observation or palpation
2/5	Active movement of body part with elimination of gravity
3/5	Active movement against gravity only and not against resistance
4/5	Active movement against gravity and some resistance
5/5	Active movement against full resistance without evident fatigue (normal muscle strength)

problem has been identified, measure ROM of the affected joint. A less exact but valuable assessment method is simply to compare the ROM of 1 extremity with that on the opposite side.

Muscle-strength testing. Grade the strength of individual muscles or groups of muscles during contraction on a 5-point scale (Table 66.4). Grade normal muscle strength with full resistance to opposition as a 5/5 bilaterally. To test resistance to opposition, have the patient apply resistance as you exert a force. For example, have the patient try to extend the elbow while you try to flex it. Compare muscle strength with the strength of the opposite extremity. Note any subtle variations in muscle strength when comparing the patient's dominant and nondominant sides. Variations in strength also exist when comparing people.

Measurement. When you note limb length discrepancies or subjective problems, measure limb length and circumferential muscle mass. For example, if you observe an altered gait, measure leg length between the anterosuperior iliac crest and the bottom of the medial malleolus. Then compare it with the similar measurement of the opposite extremity. Measure muscle mass circumferentially at the largest area of the muscle. When recording measurements, record the exact location at which the measurements were obtained (e.g., left quadriceps muscle measured 15 cm above the patella). This tells the next examiner the exact area to measure and ensures consistency with reassessment.

Other. Note the use of an assistive device such as a walker or cane. Assess the patient for proper fit while reviewing the safe and correct technique for using a device. Regularly review with the patient the use of the assistive device to be sure it is still appropriate and safe. Ask the patient if they use the device regularly. If not, assess for reasons for inconsistent use.

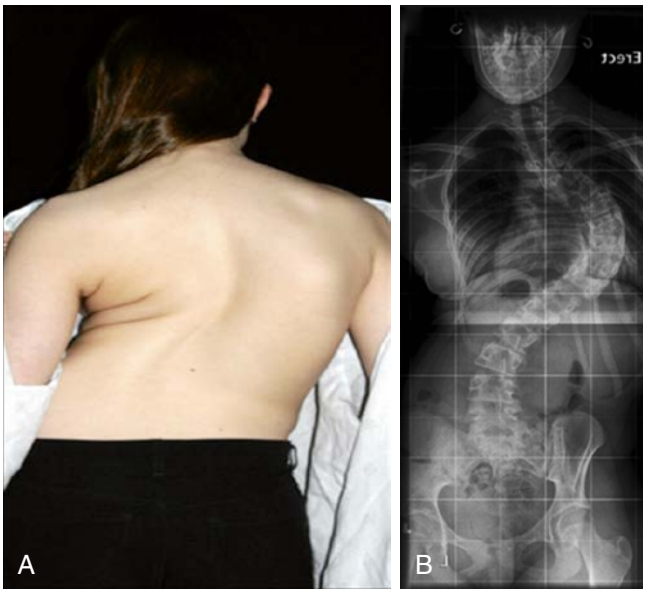

Fig. 66.8 (A) Thoracic scoliosis. (B) X-ray of same patient showing scoliosis greater than 90 degrees. (From Hawary R, Chukwunyerenwa C: Update on evaluation and treatment of scoliosis, *Pediatr Clin North Am* 61:1223, 2014.)

Scoliosis is a lateral S-shaped curvature of the thoracic and lumbar spine. Unequal shoulder and scapula height is usually noted when the patient is observed from the back (Fig. 66.8). Ask the patient to place the hands together above the head as if diving into a swimming pool and slowly bend forward at the waist, allowing assessment of thoracic rib prominence or paravertebral muscle prominence in the lumbar spine. Advanced scoliosis can impair lung and heart function.

The *straight-leg-raising test* is done on the patient with sciatica or leg pain. With the patient supine, passively raise the leg 60 degrees or less. The test is positive if the patient reports pain along the distribution of the sciatic nerve. A positive test shows nerve root irritation from intervertebral disc prolapse and herniation, especially at level L4–5 or L5–S1.

Assessment of reflexes is discussed in Chapter 60. Table 66.5 shows an example of how to record a normal physical assessment of the musculoskeletal system. Abnormal assessment findings of the musculoskeletal system are described in Table 66.6. A *focused assessment* is used to evaluate previously identified musculoskeletal problems and to monitor for signs of new problems (Box 66.2).

Case Study

Objective Data: Physical Assessment

(© pixelhead-photo/iStock/Thinkstock.)

A focused assessment of G.A. reveals the following: BP 128/94, heart rate 88, respiratory rate 26, temp 96.8°F, O_2 saturation 98%. Alert and oriented × 3. Lungs are clear bilaterally. Left great toe is red and swollen. No open wounds. Tremendous pain on palpation and with any movement of the left great toe. +1 Pedal pulses bilaterally.

Discussion Questions

1. What physical assessment findings concern you most?
2. Based on results of the subjective and physical assessment, what diagnostic studies might you expect to be ordered for G.A.?

You will learn more about diagnostic studies related to the musculoskeletal system in the next section.

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

DIAGNOSTIC STUDIES OF MUSCULOSKELETAL SYSTEM

Many diagnostic studies are used to assess the musculoskeletal system. Tables 66.7 and 66.8 present the most common studies.

Imaging, including x-rays, MRI, and bone scans, has greatly improved orthopedic care. The **x-ray** is the most common diagnostic study used to assess musculoskeletal problems and to monitor treatment effectiveness. Because bones are denser than other tissues and contain calcium, most x-rays are absorbed by the bone tissue and do not penetrate it. Dense areas show as white on the standard x-ray. X-rays provide information about bone deformity, joint congruity, bone density, and calcification in soft tissue. X-rays are useful for diagnosing fractures. They also help assess genetic, developmental, infectious, inflammatory, malignant, metabolic, and degenerative problems.

Synovial fluid can be obtained for analysis through an arthrocentesis (Table 66.9). The fluid is assessed for volume, color, clarity, viscosity, and mucin clot formation. Normal synovial fluid is transparent and colorless or straw colored. It should be scant in amount and of low viscosity. Fluid from an infected joint may be purulent and thick or gray and thin. In gout, the fluid may be whitish yellow. Blood may be aspirated if there is hemarthrosis due to injury or a bleeding disorder.

The mucin clot test indicates the character of the protein portion of the synovial fluid. Normally a white, ropelike mucin clot is formed. In the presence of inflammation, the clot fragments easily. The fluid is examined grossly for floating fat globules, which indicate bone injury. In septic arthritis, protein content is increased, and glucose is considerably decreased. Presence of uric acid crystals suggests a diagnosis of gout. A Gram stain and culture also may be done to assess for the presence and type of infection.

TABLE 66.5 Normal Physical Assessment of the Musculoskeletal System

- Ordinary spinal curvatures
- No muscle atrophy or asymmetry
- No joint swelling, deformity, or crepitation
- No tenderness on palpation of spine, joints, or muscles
- Full ROM of all joints without pain or laxity
- Muscle strength of 5/5

TABLE 66.6 ASSESSMENT ABNORMALITIES

Musculoskeletal System

Finding	Description	Possible Cause and Significance
Achilles' tendonitis	Pain in ankle and posterior calf, initially when running or walking. Can progress to pain at rest.	Stress on Achilles tendon over time causing inflammation.
Ankylosis	Stiffness and fixation of a joint.	Chronic joint inflammation and destruction (e.g., rheumatoid arthritis).
Antalgic gait	Shortened stride with minimal weight bearing on the affected side, resulting in a limp.	Pain or discomfort in the lower extremity on weight bearing. Can be due to trauma or other problems.
Ataxic gait	Staggering, uncoordinated gait often with sway.	Neurogenic problems (e.g., spinal cord lesion).
Atrophy	↓ Size and strength of muscle leading to ↓ function and tone.	Muscle denervation, contracture, prolonged disuse from immobilization.
Boutonnière deformity	Finger abnormality, flexion of proximal interphalangeal (PIP) joint and hyperextension of the distal interphalangeal (DIP) joint of the fingers (see Fig. 69.4B).	Typical deformity of rheumatoid and psoriatic arthritis. Caused by disruption of extensor tendons over the fingers.
Contracture	Resistance of movement of muscle or joint due to fibrosis of supporting soft tissues.	Shortening of muscle or ligaments, tightness of soft tissue, incorrect positioning of immobilized extremity.

TABLE 66.6 ASSESSMENT ABNORMALITIES—cont'd

Musculoskeletal System

Finding	Description	Possible Cause and Significance
Crepitation (crepitus)	Frequent, audible crackling sound with palpable grating that accompanies movement.	Fracture, dislocation, temporomandibular joint dysfunction, osteoarthritis.
Dislocation	Separation of 2 bones from their normal position within a joint.	Trauma, surrounding soft tissue problem.
Festinating gait	While walking, neck, trunk, and knees flex and the body is rigid. Delayed start with short, quick, shuffling steps. Speed may ↑ as if patient is unable to stop (festination).	Neurogenic problems (e.g., Parkinson disease).
Ganglion cyst	Small fluid-filled mass over a tendon sheath or joint, usually on dorsal surface of wrist or foot.	Inflammation of tissues around a joint, which can increase in size or disappear.
Kyphosis (dowager's hump)	Exaggerated thoracic curvature.	Poor posture, tuberculosis, arthritis, osteoporosis, growth disturbance of vertebral epiphyses, vertebral fractures.
Lateral epicondylitis (tennis elbow)	Dull ache along outer aspect of elbow, worsens with twisting and grasping motions.	Injury, inflammation, and/or partial tearing of tendon at its insertion on epicondyle.
Limited range of motion (ROM)	Joint does not achieve expected degrees of motion.	Injury, inflammation, contracture.
Lordosis (swayback)	Exaggerated lumbar curvature.	Other spinal deformities, muscular dystrophy, obesity, flexion contracture of hip, congenital dislocation of hip.
Muscle spasticity	↑ Muscle tone (rigidity) with sustained muscle contractions (spasms); stiffness or tightness may interfere with gait, movement, speech.	Neuromuscular problems, such as multiple sclerosis, cerebral palsy.
Myalgia	General muscle tenderness and pain.	Chronic pain syndromes (e.g., fibromyalgia). Overuse, injury, or strain. May result from statin therapy.
Paresthesia	Numbness and tingling, often described as a "pins and needles" sensation.	Compromised sensory nerves, often due to edema in a closed space (e.g., cast, bulky dressing). Spinal stenosis.
Pes planus (flatfoot)	Abnormal flatness of the sole and arch of the foot.	Hereditary, muscle paralysis, mild cerebral palsy, early muscular dystrophy, injury to posterior tibial tendon.
Plantar fasciitis	Burning, sharp pain on heel and sole of foot. Worse in the morning with first step out of bed.	Chronic degenerative/reparative cycle resulting in inflammation.
Scoliosis	Asymmetric elevation of shoulders, scapulae, and iliac crests with lateral spine curvature (Fig. 66.8).	Idiopathic, congenital or neuromuscular condition, fracture or dislocation, osteomalacia.
Short-leg gait	A limp, unless corrective footwear used.	Leg length discrepancy of 1 in or more, often structural origin (e.g., arthritis, fracture).
Spastic gait	Short steps with dragging of foot. Jerky, uncoordinated, cross-knee (scissor) movement.	Neurogenic problems (e.g., cerebral palsy, hemiplegia).
Steppage gait	↑ Hip and knee flexion to clear the foot from the floor. Foot drop is evident, foot slaps down and along walking surface.	Neurogenic problems (e.g., peroneal nerve injury, paralyzed dorsiflexor muscles).
Subluxation	Partial dislocation of joint.	Instability of joint capsule and supporting ligaments (e.g., trauma, arthritis).
Swan neck deformity	Hyperextension of the PIP joint with flexion of the metacarpophalangeal (MCP) and DIP joints of the fingers (see Fig. 69.4D).	Typical deformity of rheumatoid and psoriatic arthritis. Caused by contracture of muscles and tendons.
Swelling	Enlargement, often of a joint due to fluid collection. Usually leads to pain, stiffness.	Trauma, inflammation.
Tenosynovitis	Superficial swelling, pain, and tenderness along a tendon sheath.	Inflammation that often occurs with infection, injury, or overuse.
Torticollis (wryneck)	Neck is rotated and laterally bent in unusual position to one side.	Prolonged contraction of neck muscles (congenital or acquired).
Ulnar deviation (ulnar drift)	Fingers drift to ulnar side of forearm (see Fig. 69.4A).	Typical deformity of rheumatoid arthritis due to tendon contracture.
Valgum deformity (knock-knees)	When knees are together and there is <1 in (2.5 cm) between the medial malleoli.	Poliomyelitis, congenital deformity, arthritis.
Varum deformity (bowlegs)	When knees are apart and the medial malleoli are together, a space of >1 in (2.5 cm) exists.	Arthritis, congenital deformity.

BOX 66.2 FOCUSED ASSESSMENT

Musculoskeletal System

Use this checklist to be sure key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Joint pain or stiffness	Y	N
Muscle weakness	Y	N
Bone pain	Y	N

Objective: Diagnostic

Check the results of the following diagnostic studies.

X-ray	✓
MRI or CT scan	✓
Bone scan	✓
Ultrasound	✓

Objective: Physical Assessment

Inspect and Palpate

Spine and extremities (compare sides) for alignment, contour, symmetry, size, gross deformities	✓
Joints for ROM, tenderness or pain, heat, crepitus, swelling	✓
Muscles (compare sides) for size, symmetry, tone, tenderness, or pain	✓
Bones for tenderness or pain	✓

TABLE 66.7 Serology Studies

Musculoskeletal System

Test	Reference Intervals	Description and Purpose
Aldolase	22–59 mU/L	Monitoring of muscular dystrophy, dermatomyositis.
Alkaline phosphatase	30–120 U/L (0.5–2.0 μkat/L)	Enzyme made by osteoblasts, needed for mineralization of organic bone matrix. ↑ in healing fractures, bone cancers, osteoporosis, osteomalacia, Paget disease.
Anticyclic citrullinated (anti-CCP)	Negative or <20.0 U	Assesses presence of CCP antibodies. More specific for rheumatoid arthritis than rheumatoid factor. Positive result indicates high likelihood of RA.
Anti-DNA antibody	<5 IU/mL	Detects serum antibodies that react with DNA. Most specific test for SLE.
Antinuclear antibody (ANA)	Negative at 1:40 dilution	Assesses presence of antibodies capable of destroying nucleus of tissue cells. Positive in 95% of patients with SLE. May be positive with scleroderma, rheumatoid arthritis, small number of normal persons.
Calcium	9.0–10.5 mg/dL (2.25–2.62 mmol/L)	Bone is primary organ for calcium storage. Calcium provides bone with rigid structure. ↓ in osteomalacia, kidney disease, hypoparathyroidism. ↑ in hyperparathyroidism, some bone tumors.
C-reactive protein (CRP)	<1.0 mg/dL	Used to diagnose inflammatory diseases, infections, active widespread cancer. Synthesized by liver. Present in large amounts in serum 18–24 h after onset of tissue damage.
Creatine kinase (CK)	20–200 U/L	Highest concentration found in skeletal muscle. ↑ in muscular dystrophy, polymyositis, traumatic injuries.
Human leukocyte antigen (HLA)–B27	Negative	Antigen often present in autoimmune disorders, such as ankylosing spondylitis, rheumatoid arthritis.
Potassium	3.5–5.0 mEq/L (3.5–5.0 mmol/L)	Released into serum with cell destruction. ↑ with muscle trauma.
Phosphorus	3.0–4.5 mg/dL (0.97–1.45 mmol/L)	Amount present is indirectly related to calcium metabolism. ↓ Level found in osteomalacia. ↑ in chronic kidney disease, healing fractures, osteolytic metastatic tumor.
Rheumatoid factor (RF)	Negative or titer <1:17	Presence of autoantibody (rheumatoid factor) in serum. Not specific for rheumatoid arthritis. Seen in other connective tissue diseases and small number of normal persons.

TABLE 66.8 Diagnostic Studies

Musculoskeletal System

Study	Description and Purpose	Nursing Responsibilities
Basic x-ray	Evaluates structural or functional changes of bones and joints. Can give a general impression of bone density. In anteroposterior view, x-ray beam passes from front to back, allowing 1-dimensional view. Lateral position provides 2-dimensional view.	*Before:* Remove any radiopaque objects that can interfere with results. Explain procedure to patient. *During:* Avoid excess exposure of patient and self.
Bone scan	Injection of radioisotope (usually technetium [Tc]-99 m) that is taken up by bone. Uniform uptake of isotope is normal. ↑ Uptake seen in osteomyelitis, primary and metastatic cancer of bone, certain fractures. ↓ Uptake seen in areas of avascular necrosis.	*Before:* Explain that radioisotope is given 2 hr before procedure. Have patient void before scan. Tell patient that no harm will result from isotopes. *During:* Patient must lie completely still during scan. *After:* Increase fluids after scan.

TABLE 66.8 Diagnostic Studies—cont'd

Musculoskeletal System

Study	Description and Purpose	Nursing Responsibilities
Computed tomography (CT) scan	X-ray beam used with a computer to provide a 3D picture. Used to identify soft tissue abnormalities, bony abnormalities, and various types of musculoskeletal trauma.	*Before:* Evaluate renal function before contrast medium used. Assess if patient is allergic to shellfish since the contrast is iodine based. Patient may need to be NPO 4 h prior to study. If the patient is taking metformin, hold it the day of the test to prevent hypoglycemia or lactic acidosis. *During:* Warn patient that contrast injection may cause a feeling of being warm and flushed. Patient must lie completely still during scan. *After:* Encourage patient to drink fluids to avoid renal problems with any contrast.
Discogram	X-ray of cervical or lumbar intervertebral disc done after injecting contrast media into nucleus pulposus. Permits visualization of intervertebral disc abnormalities.	*Before:* Assess patient for allergy to contrast medium. Explain procedure. *After:* May have mild back pain for 1–2 days. Use as-needed analgesics.
Dual energy x-ray absorptiometry (DEXA)	Measures bone mineral density of spine, femur, forearm, total body. Assesses bone density with minimal radiation exposure. Used to diagnose metabolic bone disease (e.g., osteoporosis), monitor changes in bone density with treatment.	*Before:* Remove any radiopaque objects that can interfere with results. Explain procedure to patient.
Electromyogram (EMG)	Evaluates electrical potential of skeletal muscle contraction. Small-gauge needles are inserted into certain muscles. Needle probes are attached to leads that send information to EMG machine. Recordings of muscle electrical activity are traced on audio transmitter, oscilloscope, and recording paper. Provides information about lower motor neuron dysfunction and primary muscle disease.	*Before:* Explain procedure. Tell patient needle insertion will cause discomfort. Some HCPs restrict stimulants (e.g., caffeine) 2–3 hr prior. *After:* Assess needle sites for hematoma or inflammation. Use as-needed analgesics.
MRI	Radio waves and magnetic field used to view soft tissue. Used to diagnose avascular necrosis, disc disease, tumors, osteomyelitis, ligament tears, cartilage tears. Patient placed inside scanning chamber. Gadolinium may be injected IV to enhance visualization of structures.	*Before:* Oral and/or IV contrast injection may be used. Check for pregnancy, allergies, and renal function before test. Have patient remove all metal objects. Ask about any history of surgical insertion of staples, plates, dental bridges, or other metal appliances. Remove metallic foil patches. Patient may need to be fasting. Assess for claustrophobia and the need for antianxiety medication. *During:* Patient must lie completely still during test.
Myelogram with or without CT	Injection of a radiographic contrast medium into sac around nerve roots. CT scan may follow to show how bone is affecting the nerve roots. Sensitive test for nerve impingement, can detect subtle lesions and injuries.	*Before:* Give sedative as ordered. Have patient empty bladder. Tell patient that test is done with patient on tilting table that is moved during test. *After:* Keep patient flat for 1–2 hr after to prevent spinal headache. Encourage fluids. Monitor neurologic signs and VS. Headache, nausea, and vomiting may occur after.
Somatosensory evoked potential (SSEP)	Evaluates evoked potential of muscle contractions. Electrodes are placed on skin and provide recordings of electrical activity of muscle. Used to identify subtle dysfunction of lower motor neuron and primary muscle disease. Measures nerve conduction along pathways not accessible by EMG. Transcutaneous or percutaneous electrodes applied to the skin help identify neuropathy and myopathy. Used during spinal surgery for scoliosis to detect neurologic compromise when patient is under anesthesia.	*Before:* Tell patient that procedure is like an EMG but does not involve needles. Electrodes are applied to the skin.
Thermography	Uses infrared detector to measure degree of heat radiating from skin surface. Assess cause of inflamed joint and determine response to antiinflammatory drug therapy. Can evaluate skin temperature with complex regional pain syndrome (CRPS).	*Before:* Tell patient that procedure is painless and noninvasive.
Quantitative ultrasound (QUS)	Evaluates bone mineral density, elasticity, and strength of bone using ultrasound rather than radiation. Used to assess heel. Used in infants to help diagnosis congenital dysplasia of the hip (CDH).	*Before:* Tell patient that procedure is painless and noninvasive.

TABLE 66.9 Interventional Studies

Musculoskeletal System

Study	Description and Purpose	Nursing Responsibilities
Arthrocentesis	Incision or puncture of joint capsule to obtain samples of synovial fluid or to remove excess fluid. Local anesthesia and aseptic preparation are used before needle is inserted into joint and fluid aspirated. Used to diagnose joint inflammation, infection, meniscal tears, and subtle fractures.	*Before:* Explain procedure to patient. HCP may have patient be NPO prior. Usually done at bedside or in examination room. *After:* Send samples of synovial fluid to laboratory for examination (if indicated). Apply compression dressing and ice to decrease pain and swelling. Observe for leakage of blood or fluid on dressing. Assess the joint for any pain, fever, or swelling. Review activity restrictions.
Arthroscopy	Insertion of arthroscope into joint to see interior of joint cavity. Can be used for surgery (removal of loose bodies, biopsy); repair of joint structures; diagnosis of problems with meniscus, articular cartilage, ligaments, joint capsule. Structures that can be seen through an arthroscope include knee, shoulder, elbow, wrist, jaw, hip, ankle (Fig. 66.9).	*Before:* Explain procedure to the patient. Can be done in outpatient setting. Local or general anesthesia may be used. HCP may have patient be NPO prior. *After:* Cover wound with sterile dressing. Apply ice to decrease pain and swelling. Observe for bleeding. Assess the joint for any pain, weakness, or swelling. Review activity restrictions.

Fig. 66.9 Elbow arthroscopy in progress. Patient is positioned so monitor is clearly visible. (From Fournier M, Corning E, Witt A, et al.: Arthroscopically assisted fixation of terrible triad variant injuries of the elbow with small-bore needle arthroscopy, *Arthrosc Tech* 10:e1469–e1474, 2021.)

Case Study

Objective Data: Diagnostic Studies

(© pixehead-photo/iStock/Thinkstock.)

The HCP in the ED orders the following diagnostic studies:

- X-ray of left foot
- CBC, electrolytes
- Aspiration of the great toe

The x-ray of the foot shows minor soft tissue swelling but no evidence of fracture. Very mild arthritis is noted at the interphalangeal joint of the great toe. CBC and electrolytes are within normal limits. Aspiration of the interphalangeal joint shows clear synovial fluid. Protein and glucose are within normal limits. Microscopic analysis of the synovial fluid shows urate crystals.

Discussion Questions

1. Which diagnostic results are abnormal?
2. What diagnostic study results concern you most?

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. The bone cells that function in the formation of new bone tissue after a patient sustains a fracture are called
   - **a.** osteoids.
   - **b.** osteocytes.
   - **c.** osteoclasts.
   - **d.** osteoblasts.
2. When performing passive range of motion for a patient, the nurse puts the elbow joint through the movements of *(select all that apply)*
   - **a.** flexion and extension.
   - **b.** inversion and eversion.
   - **c.** pronation and supination.
   - **d.** flexion, extension, abduction, and adduction.
   - **e.** pronation, supination, rotation, and circumduction.
3. A patient with a torn ligament in the knee asks what the ligament does. The nurse would respond that ligaments
   - **a.** connect bone to bone.
   - **b.** provide strength to muscle.
   - **c.** lubricate joints with synovial fluid.
   - **d.** relieve friction between moving parts.
4. The increased risk for falls in the older adult is likely due to *(select all that apply)*
   - **a.** changes in balance.
   - **b.** decrease in bone mass.
   - **c.** loss of ligament elasticity.
   - **d.** erosion of articular cartilage.
   - **e.** decrease in muscle mass and strength.
5. The nurse obtained a health history of a patient with a fracture. Which problem, if reported by the patient, would most concern the nurse?

a. Diabetes
b. Hypertension
c. Chronic bronchitis
d. Nephrotic syndrome

6. When grading muscle strength, the nurse records a score of 3/5, which indicates
a. no detection of muscular contraction.
b. a barely detectable flicker of contraction.
c. active movement against full resistance without fatigue.
d. active movement against gravity but not against resistance.

7. An abnormal assessment finding of the musculoskeletal system is
a. equal leg length bilaterally.
b. ulnar deviation and subluxation.
c. full range of motion in all joints.
d. muscle strength of 5/5 in all muscles.

8. A patient is scheduled for a bone scan. The nurse explains that this diagnostic test involves
a. incision or puncture of the joint capsule.
b. insertion of small needles into certain muscles.
c. administration of a radioisotope before the procedure.
d. placement of skin electrodes to record muscle activity.

1. d; 2. a, c; 3. a; 4. a, b, c, e; 5. a; 6. d; 7. b; 8. c.

Mobility
Pain
Perfusion
Safety

LEARNING OUTCOMES

1. Discuss the etiology, pathophysiology, manifestations, and interprofessional and nursing management of soft tissue injuries.
2. Relate the sequence of events involved in fracture healing.
3. Compare closed reduction, casting, open reduction, and traction in terms of purpose, complications, and nursing management.
4. Assess the neurovascular condition of an injured extremity.
5. Explain common complications of a fracture and fracture healing.
6. Describe the interprofessional and nursing management of patients with various kinds of fractures.
7. Describe indications for and interprofessional and nursing management of the patient with an amputation.
8. Describe types of joint replacement surgery.
9. Prioritize management of the patient having joint replacement surgery.

KEY TERMS

amputation
arthrodesis
arthroplasty
bursitis
carpal tunnel syndrome (CTS)
compartment syndrome
debridement
dislocation
fat embolism syndrome (FES)
fracture
osteotomy
phantom limb sensation
repetitive strain injury (RSI)
sprain
strain
traction

The most common cause of musculoskeletal injury is a traumatic event resulting in fracture, dislocation, subluxation, and/or soft tissue injury. Most of these injuries are not fatal. However, accidents are 1 of the top 3 causes of death for persons ages 1 to 64 years.[1] The costs in terms of pain, disability, and expense are enormous. Nurses play a key role in teaching the public about basic principles of safety and accident prevention.

This chapter discusses musculoskeletal problems resulting from trauma and common orthopedic surgeries. After trauma or surgery, the injured area is often immobilized while healing occurs. We discuss the important role of the nurse in preventing complications (e.g., pressure injuries, constipation, infection, venous thromboembolism [VTE]) and promoting functional ability in patients with fractures and orthopedic surgery.

HEALTH PROMOTION

Teach people to take proper safety precautions to prevent injuries while at home or work, driving, or taking part in sports (Box 67.1). The morbidity from accidents can be reduced if people are aware of environmental hazards, use proper safety equipment, and apply safety and traffic rules. In the work setting, teach employees and employers to use proper safety equipment and decrease workplace hazards. Falls cause many musculoskeletal injuries in the home.

BOX 67.1 PROMOTING POPULATION HEALTH

Reducing the Risk for Musculoskeletal Injuries

- Wear seatbelts.
- Drive within posted speed limits.
- Avoid distracted driving (e.g., no texting, eating, talking on a cell phone).
- Do not drive under the influence of alcohol or drugs (prescribed or illicit).
- Warm up muscles before exercise.
- Use protective athletic equipment (helmets and knee, wrist, and elbow pads).
- Use proper safety equipment at work.

BOX 67.2 PROMOTING POPULATION HEALTH

Reducing Fall Risk

- Assess the living environment for safety risks.
- Wear functional, nonskid, hard-soled shoes.
- Avoid wet or slippery surfaces.
- Remove throw rugs and ensure adequate lighting in the home.
- Maintain clear paths to the bathroom for nighttime use.

TABLE 67.1 PATIENT & CAREGIVER TEACHING

Preventing Musculoskeletal Problems in Older Adults

To prevent musculoskeletal problems, include the following instructions when teaching older adults and their caregivers:

1. Use ramps in buildings and at street corners instead of steps to prevent falls.
2. Remove throw rugs from the home.
3. Treat pain and discomfort from osteoarthritis.
   - Rest in positions that decrease discomfort.
   - Use medication as prescribed for pain.
4. Use a walker or cane to help prevent falls.
5. Eat the amount and kind of foods needed to prevent weight gain. Obesity adds stress to joints, which may predispose to osteoarthritis.
6. Get regular and frequent exercise.
   - ADLs provide range-of-motion exercises. Tai Chi may be helpful.
   - Hobbies (e.g., jigsaw puzzles, needlework, model building) exercise finger joints and prevent stiffness.
   - Do daily weight-bearing exercise (e.g., walking) to improve bone health.
7. Use shoes with good support for safety and comfort.
8. Avoid sudden change in position. Rise slowly to a standing position to prevent dizziness, falls, and fractures.
9. Do not walk on uneven surfaces and wet floors.

Provide preventive teaching to high-risk persons (e.g., people with gait instability, vision impairment) (Box 67.2).

Encourage people, especially older adults, to take part in moderate exercise to help maintain muscle strength and balance. Table 67.1 describes ways to prevent common musculoskeletal problems in the older adult. Stress the importance of adequate calcium and vitamin D intake for bone health.

SOFT TISSUE INJURIES

Soft tissue injuries include sprains, strains, dislocations, and subluxations. They usually result from trauma. As more people have become involved in fitness programs or sports, the incidence of soft tissue injuries has increased. Table 67.2 describes common sports-related injuries. Sports injuries that often result in a visit to the emergency department (ED) for younger patients include sprains and strains, growth plate injuries, and repetitive motion injuries.[2]

SPRAINS AND STRAINS

Sprains and strains often result from abnormal stretching or twisting forces during vigorous activities. These injuries tend to occur around joints and in the spinal muscles.

A **sprain** is an injury to the ligaments surrounding a joint. Sprains are usually caused by a wrenching or twisting motion. Most occur in the ankle, wrist, and knee joints.[3] We classify sprains according to the degree of ligament damage. A *first-degree (mild) sprain* involves tears in only a few fibers, with mild tenderness and minimal swelling. A *second-degree (moderate) sprain* results in partial disruption of the involved tissue with more swelling and tenderness. A *third-degree (severe) sprain* is a complete tear of the ligament with moderate to severe swelling.

A **strain** is an excessive stretching of a muscle and its fascial sheath, often involving the tendon. Most strains occur in the large muscle groups, including the lower back, calf, and hamstrings. We classify strains as first degree (mild or slightly pulled muscle), second degree (moderate or moderately torn muscle), and third degree (severely torn or ruptured muscle). A defect in the muscle may be apparent or palpated through the skin if the muscle is torn. Because areas around joints are rich in nerve endings, the injury can be very painful.

Manifestations of sprains and strains are similar. They include pain, edema, decreased function, and bruising. Continued use of the joint, tendon, or ligament makes pain worse. Edema develops in the injured area because of the local inflammatory response.

Mild sprains and strains are usually self-limiting. Full function generally returns within 3 to 6 weeks. X-rays may be done to rule out a fracture. A severe sprain can cause an *avulsion fracture,* in which the ligament pulls loose a fragment of bone. The joint structure may become unstable, causing subluxation or dislocation. At the time of injury, *hemarthrosis* (bleeding into a joint space or cavity) or disruption of the synovial lining may occur. Severe strains may need surgical repair of the muscle, tendon, or surrounding fascia.

NURSING MANAGEMENT: SPRAINS AND STRAINS

Implementation

Health Promotion

Warming up muscles before exercising and vigorous activity, followed by stretching, may significantly reduce the risk for sprains and strains. Strength, balance, and endurance

TABLE 67.2 Soft Tissue Injuries

Injury	Description	Treatment
Anterior cruciate ligament tear	Tearing of ligament by deceleration forces with pivoting or odd positions of the knee or leg.	PT with rehabilitation, knee brace. If knee instability or further injury, reconstructive surgery may be done.
Impingement syndrome	Entrapment of soft tissues and nerves under coracoacromial arch of shoulder	NSAIDs. Rest until symptoms ↓, then begin gradual ROM and strength exercises.
Ligament injury	Tearing or stretching of ligament. Usually occurs from inversion, eversion, shearing, or torque applied to a joint. Characterized by sudden pain, swelling, and instability	Rest, ice, elevation of extremity if possible, NSAIDs. Protect affected extremity by use of brace. If symptoms persist, surgical repair may be needed.
Meniscus injury	Injury to fibrocartilage discs in knee. Characterized by popping, clicking, tearing sensation, effusion, and/or swelling	Rest, ice, elevation of extremity if possible, NSAIDs. Gradual return to regular activities. If symptoms persist, MRI to assess meniscus injury. Possible arthroscopic surgery.
Rotator cuff tear	Tear within muscle, tendons, or ligaments around shoulder	*If minor tear:* rest, NSAIDs, and gradual mobilization with ROM and strength exercises. *If major tear:* surgical repair.
Shin splints	Inflammation of periosteal bone *(periostitis)* along anterior calf. Caused by improper shoes, overuse, or running on hard pavement	Rest, ice, NSAIDs, proper shoes. Gradual ↑ in activity. If pain persists, x-ray to rule out tibial stress fracture
Tendonitis	Inflammation of tendon due to overuse or incorrect use	Rest, ice, NSAIDs. Gradual return to sport activity. Protective brace *(orthosis)* may be needed if symptoms recur.

BOX 67.3 PROMOTING POPULATION HEALTH

Health Impact of Physical Activity

- Helps with weight management
- Increases lean muscle and decreases body fat
- Helps maintain and improve bone mass
- Increases muscle strength, flexibility, and endurance
- Helps prevent high BP
- Reduces the risk for heart disease, diabetes, and colon cancer
- Enhances sense of well-being and reduces risk for depression

exercises are important (Box 67.3). Strength exercises that involve working against resistance build muscle strength and bone density. Balance exercises, which may overlap with some strength exercises, help prevent falls. Endurance exercises should start at a low level of effort and progress gradually to a moderate level.

Acute Care

If an injury occurs, immediate care focuses on (1) stopping the activity and limiting movement to the injured part, (2) applying ice packs to the injured area, (3) compressing the involved area, (4) elevating the extremity, and (5) providing analgesia as needed (Table 67.3). Most sprains and strains are treated in the outpatient setting.

RICE (*R*est, *I*ce, *C*ompression, *E*levation) may decrease local inflammation and pain for most musculoskeletal injuries. Movement should be restricted with the extremity rested as soon as pain is felt. Unless the injury is severe, prolonged rest is usually not needed.

There are several forms of cold therapy *(cryotherapy)*. Cold causes vasoconstriction in the soft tissue and reduces the transmission and perception of nerve pain impulses. These changes also reduce muscle spasms, inflammation, and edema. Cold is most useful when applied immediately after an injury has occurred and used for 24 to 28 hours. Apply ice no more than 20 to 30 minutes at a time. Do not apply ice directly to the skin.

Compression helps decrease edema and pain. We often use an elastic compression bandage. It can be wrapped around the injured part. To prevent edema and encourage fluid return, wrap the bandage starting distally (at the point farthest from the trunk of the body) and progress proximally (toward the trunk of the body). The bandage is too tight if there is numbness or tingling below the area of compression or pain or more swelling occurs beyond the edge of the bandage. Leave the bandage in place for 30 minutes, then remove it for 15 minutes. Use of an elastic wrap may provide extra support during training, athletic, and work activities.

Elevate the injured part above heart level, even during sleep, for 24 to 48 hours to help mobilize excess fluid from the area and prevent further edema. Mild analgesics and nonsteroidal antiinflammatory drugs (NSAIDs) may be used to manage patient discomfort.

After the acute phase (usually 24 to 48 hours), apply warm, moist heat to the affected part to reduce swelling and provide comfort. Heat applications should not exceed 20 to 30 minutes. Allow a "cool-down" time between applications. Encourage the patient to use the limb if the joint is protected by a cast, brace, splint, or taping. Joint movement maintains nutrition to the cartilage. Movement helps prevent *contracture* (stiffening) of tendons and ligaments. Muscle contraction improves circulation and helps resolve bruising and swelling.

Emphasize the importance of strength and conditioning exercises to prevent reinjury. The physical therapist may help with pain relief by using ultrasound or other interventions. They can teach the patient exercises to improve flexibility and strength.

TABLE 67.3 EMERGENCY MANAGEMENT

Acute Soft Tissue Injury

Cause	Assessment Findings	Interventions
• Crush injury • Direct blows • Falls • Motor vehicle crashes • Sports injuries	• Bruising • ↓ Movement with limited function or inability to bear weight (lower extremity) • ↓ Pulse, coolness, capillary refill >2 sec • ↓ Sensation • Edema • Muscle spasms • Pain, tenderness • Pallor • Shortening or rotation of extremity	**Initial** • Ensure airway, breathing, and circulation. • Perform neurovascular assessment of involved limb. • Elevate involved limb. • Apply compression bandage unless dislocation present. • Apply ice packs to affected area. • Immobilize affected extremity in the position found. Do *not* try to realign or reinsert protruding bones. • Anticipate x-rays of injured extremity. • Give analgesia as needed. • Give tetanus prophylaxis if there is an open fracture. • Give antibiotic prophylaxis for open fracture, large tissue defects, or mangled extremity injury. **Ongoing Monitoring** • Monitor for changes in neurovascular condition. • Implement weight-bearing restrictions as ordered for lower extremity involvement. • Anticipate compartment pressure monitoring if neurovascular assessment changes and compartment syndrome suspected.

DISLOCATIONS

Dislocation is the complete displacement or separation of the articular surfaces of the joint. *Subluxation* is a partial or incomplete displacement of the joint surface. Symptoms of subluxation are similar to a dislocation but are less severe. Many structures contribute to joint stability. Injury to, or excessive laxity of, ligaments is a major factor in dislocations or subluxations. Weak or atrophied muscles can cause chronic joint instability. Fibrocartilage structures, such as the labrum around hip and shoulder sockets and the meniscus at the knee, play an important role in joint stability. Even small tears to these structures can result in recurrent, chronic dislocations or subluxations.

Dislocations typically result from forces on the joint that disrupt the surrounding soft tissue support structures. The joints most often dislocated in the upper extremity include the thumb, elbow, and shoulder. The shoulder most often dislocates anteriorly. Posterior shoulder dislocations are rare. They typically only happen after electrocution or seizure. In the lower extremity, the hip is vulnerable to dislocation from severe trauma, often from motor vehicle crashes (Fig. 67.1). The kneecap *(patella)* may dislocate because of a sharp, direct blow or after a sudden twisting inward motion while the planted foot is pointed outward.

The most obvious sign of a dislocation is deformity. For example, if the hip dislocates in a posterior (or backward) direction, the affected limb may be shorter and internally rotated. Other manifestations include local pain, tenderness, loss of function of the injured part, and swelling of soft tissues near the joint. Major complications include open joint injuries, *intraarticular* fractures (within the joint), *avascular necrosis* (bone cell death from blood supply), and damage to adjacent nerves and blood vessels.

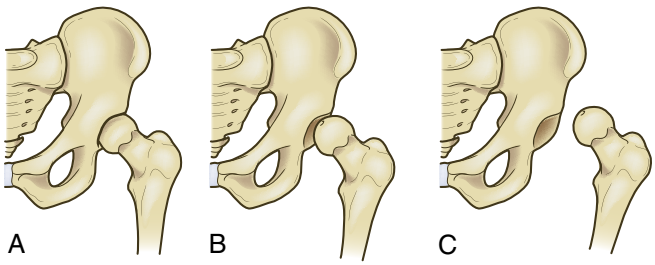

Fig. 67.1 Soft tissue injury of the hip. (A) Normal. (B) Subluxation (partial dislocation). (C) Dislocation.

X-rays can determine the extent of displacement. The joint may be aspirated to assess for hemarthrosis or fat cells. Fat cells in the aspirate indicate a probable intraarticular fracture.

Interprofessional and Nursing Care

A dislocation requires prompt attention. It is often considered an orthopedic emergency because it may be cause significant vascular injury. The longer the joint is dislocated, the greater the risk for avascular necrosis. The femoral head of the hip joint is especially susceptible to avascular necrosis. Compartment syndrome may occur after dislocation due to vascular injury and resulting ischemia. Neurovascular assessment is critical.

The first goal of care of a dislocation is to realign the dislocated part of the joint to its original anatomic position. Closed reduction (no incision) may be done under local or general anesthesia or IV moderate to deep sedation. Anesthesia is often needed to relax the muscle so that the bones can be manipulated. Sometimes, open reduction (joint visualized through surgery) may be needed. After reduction, the extremity is immobilized by a brace, splint, or sling, or by taping, to allow torn ligaments and surrounding tissue to heal.

Nursing care includes pain management and support and protection of the injured joint. After the joint has been reduced and immobilized, motion is usually restricted. A monitored rehabilitation program can prevent further instability and joint problems. Gentle range-of-motion (ROM) exercises may be done if the joint is stable and well supported. An exercise program slowly restores the joint to its original ROM without causing another dislocation. The patient should gradually return to normal activities.

A patient who has dislocated a joint may be at greater risk for repeated dislocations because of damage or laxity to the supporting structures. Activity restrictions may be imposed on the affected joint to decrease the risk for repeated dislocations.

REPETITIVE STRAIN INJURY

Repetitive strain injury (RSI) and *cumulative trauma disorder* are terms used to describe injuries resulting from prolonged force or repetitive movements and awkward postures. RSI is also called *repetitive trauma disorder, nontraumatic musculoskeletal injury, overuse syndrome* (sports medicine), *regional musculoskeletal disorder,* and *work-related musculoskeletal disorder.* Repeated movements strain the tendons, ligaments, and muscles, causing tiny tears that become inflamed. We do not know the exact cause of these disorders. No specific diagnostic tests exist, and diagnosis is often difficult.

Persons at risk for RSI include musicians, dancers, butchers, grocery clerks, vibratory tool workers, and those who frequently use a computer mouse and keyboard. Competitive athletes and poorly trained athletes may develop RSI. Swimming, overhead throwing (e.g., baseball), weightlifting, gymnastics, tennis, skiing, and kicking sports (e.g., soccer) require repetitive motion. Overtraining compounds the effects of RSI.

Other factors related to RSI include poor posture and positioning, poor workspace ergonomics, badly designed workplace equipment (e.g., computer keyboard), and repetitive lifting of heavy objects without sufficient muscle rest. Inflammation, swelling, and pain in the muscles, tendons, and nerves of the neck, spine, shoulder, forearm, and hand may result. Symptoms of RSI include pain, weakness, numbness, or impaired motor function.

RSI can be prevented through education and *ergonomics* (the science that promotes efficiency and safety in the interaction of humans and their work environment). For example, ergonomic considerations for those who work at a desk and use a computer include keeping the hips and knees flexed to 90 degrees with the feet flat, keeping the wrist straight to type, having the top of the computer monitor even with the forehead, and taking at least hourly stretch breaks.

Treatment is supportive. Pain management includes heat or cold therapy, NSAIDs, and rest. Physical therapy (PT) focuses on strength and conditioning exercises. Teach the patient about lifestyle changes and ways to modify equipment and/or activity.

CARPAL TUNNEL SYNDROME

Carpal tunnel syndrome (CTS) is caused by compression of the median nerve. It enters the hand at the wrist through the narrow carpal tunnel (Fig. 67.2). The carpal tunnel is formed by ligaments and bones. CTS is the most common compression neuropathy in the upper extremity. It is associated with hobbies or work that require continuous wrist movement (e.g., musicians, carpenters, computer operators).

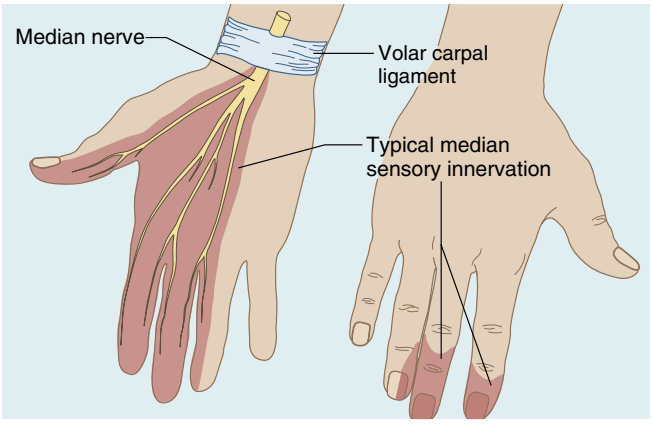

Fig. 67.2 Wrist structures involved in carpal tunnel syndrome. Median nerve distribution. *Shaded areas* show the locations of pain in carpal tunnel syndrome. (From Buttaravoli P: *Minor emergencies,* ed 3, Philadelphia, 2012, Saunders.)

CTS is often caused by pressure from trauma or edema (from inflammation of a tendon *[tenosynovitis]*), cancer, rheumatoid arthritis (RA), or soft tissue masses, such as ganglia. Hormones may be involved because CTS often occurs during the premenstrual period, pregnancy, and menopause. Persons with diabetes, peripheral vascular disease (PVD), and RA have a higher incidence of CTS because of swelling that changes blood flow to the nerve and narrows the carpal tunnel.[4] Women are more likely than men to develop CTS, possibly because of a smaller carpal tunnel.

Manifestations of CTS are impaired sensation, pain, numbness, or weakness in the distribution of the median nerve (Fig. 67.2). Numbness and tingling may awaken the patient at night. Shaking the hands often relieves these symptoms. Clumsiness in performing fine hand movements is common.

The patient may have a positive Tinel sign and Phalen sign. Elicit *Tinel sign* by tapping over the median nerve as it passes through the carpal tunnel in the wrist. A positive response is a sensation of tingling in the distribution of the median nerve over the hand. Test for *Phalen sign* by allowing the wrists to fall freely into maximum flexion and maintain the position for longer than 60 seconds. A positive response is a sensation of tingling in the distribution of the median nerve over the hand. In late stages, atrophy of the muscles around the base of the thumb results in recurrent pain and eventual dysfunction of the hand.

Interprofessional and Nursing Care

To prevent CTS, teach employees and employers to identify risk factors. Adaptive devices, such as wrist splints, may be worn to hold the wrist in a slight extension and relieve pressure on the median nerve. Special keyboard pads and computer mice that help prevent repetitive pressure on the median nerve are available for computer users. Other ergonomic changes include workstation changes, change in body positions, and frequent breaks from work activities.

Care is directed toward relieving the underlying cause of the nerve compression. Early symptoms can usually be relieved by stopping the aggravating movement and by resting the hand and wrist by immobilization in a hand splint. Splints worn at night help keep the wrist in a neutral position. This may reduce night pain and numbness. PT with hand and wrist exercises may lessen symptom severity. A corticosteroid injection directly into the carpal tunnel may give short-term relief. The patient may need to consider a change in occupation because of discomfort and sensory changes.

Carpal tunnel release is generally done if symptoms last more than 6 months or if there is significant impairment to conduction on electromyography (EMG). Surgery involves severing the band of tissue around the wrist to reduce pressure on the median nerve (Fig. 67.2). Surgery is done in the outpatient setting using local anesthesia. The types of carpal tunnel release surgery include open release and endoscopic surgery. In *open release surgery*, an incision is made in the wrist and then the carpal ligament is cut to enlarge the carpal tunnel. *Endoscopic carpal tunnel release* is done through 1 or more small puncture incisions in the wrist and palm. A camera is attached to a tube, and the carpal ligament is cut. The endoscopic approach may allow a faster recovery and cause less discomfort than traditional open release surgery.

Although symptoms may be relieved right after surgery, full recovery may take months. After surgery, assess the hand's neurovascular status. Teach the patient about wound care and assessments to perform at home.

ROTATOR CUFF INJURY

The rotator cuff is made up of 4 muscles in the shoulder: the supraspinatus, infraspinatus, teres minor, and subscapularis muscles. These muscles stabilize the humeral head in the glenoid fossa and assist with ROM of the shoulder and rotation of the humerus.

A tear in the rotator cuff may occur as a gradual, degenerative process due to aging, repetitive stress (especially overhead arm motions), or injury to the shoulder. In sports, repetitive overhead motions, such as in swimming, weightlifting, and swinging a racquet (tennis, racquetball), often cause injury. The rotator cuff can tear because of sudden adduction forces applied to the cuff while the arm is held in abduction. Other causes include (1) falling onto an outstretched arm and hand, (2) a blow to the upper arm, (3) heavy lifting, or (4) repetitive work motions.

Manifestations include shoulder weakness, pain, and decreased ROM. The patient usually has severe pain when the arm is abducted between 60 and 120 degrees (the painful arc). A positive *drop arm test* is a sign of rotator cuff injury. In this test, the arm is abducted 90 degrees, and the patient is asked to slowly lower the arm to the side. If the arm falls suddenly, rotator cuff injury is suspected. An x-ray is not helpful in the diagnosis. MRI can usually confirm a tear.

The patient with a partial tear or cuff inflammation may be treated with rest, ice, and heat, NSAIDs, corticosteroid injections into the subacromial space, ultrasound, and PT. If the patient does not respond to conservative treatment or if a complete tear is present, surgical repair may be done. Most repairs are arthroscopic procedures done as an outpatient (Fig. 67.3). If the tear is extensive, part of the acromion may be surgically removed *(acromioplasty)* to relieve compression of the rotator cuff during movement. A shoulder immobilizer with an abduction pillow is typically used for 6 weeks after surgery to limit shoulder movement. However, the shoulder should not be immobilized for too long because "frozen" shoulder *(arthrofibrosis)* may occur. Pendulum exercises and other passive exercises typically begin the first postoperative day. Active PT starts after 6 weeks of immobilization. Weight restrictions for lifting are usually given. Full recovery may take 6 to 12 months.

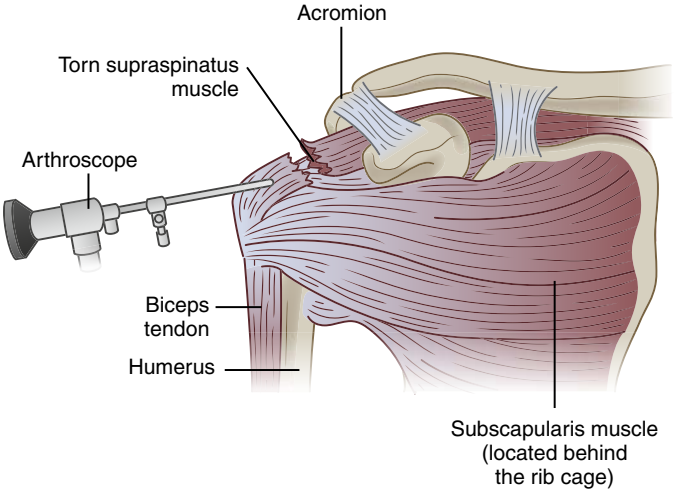

Fig. 67.3 A torn rotator cuff is repaired using arthroscopic surgery.

MENISCUS INJURY

The menisci are crescent-shaped pieces of fibrocartilage in the knee. Menisci are also found in other joints, including the acromioclavicular (AC), sternoclavicular, and temporomandibular joints. Meniscus injuries are associated with ligament sprains common among athletes in sports such as basketball, football, soccer, and hockey.[5] These activities produce rotational stress when the knee is in varying degrees of flexion and the foot is planted or fixed. A blow to the knee can cause shearing of the meniscus between the femoral condyles and tibial plateau, causing a torn meniscus. Older adults and people who have jobs that require squatting or kneeling are at risk for degenerative tears.[5]

Meniscus injuries alone do not usually cause significant edema because most cartilage is avascular. However, an acutely torn meniscus may present with local tenderness, pain, and effusion (Fig. 67.4). Pain occurs with flexion, internal rotation, and then extension of the knee *(McMurray's test)*. The patient may feel that the knee is unstable. They often report that the knee "clicks," "pops," "locks," or "gives way." Quadriceps atrophy is usually present if the injury has been present for some time. Traumatic arthritis may occur from repeated meniscus injury and chronic inflammation.

MRI can confirm the diagnosis before arthroscopy. The patient's age, occupation, sport activities, degree of pain, and dysfunction may affect the decision whether to have surgery.

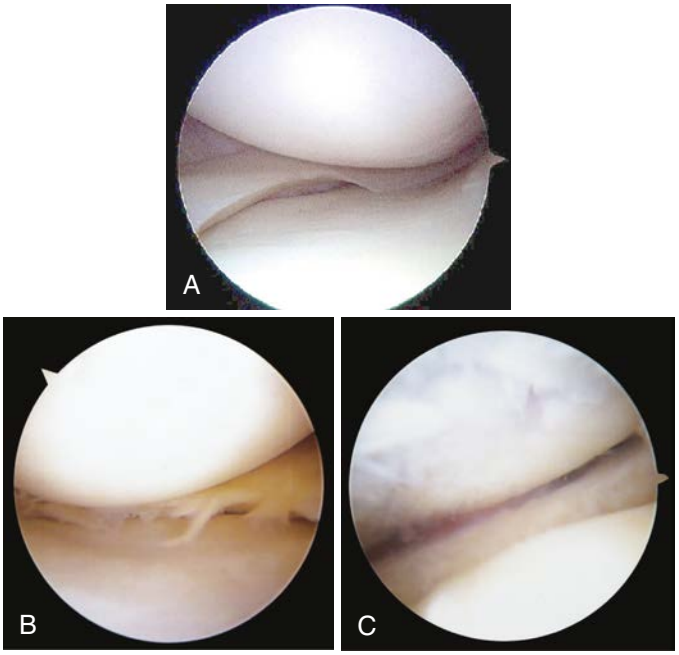

Fig. 67.4 Arthroscopic views of the meniscus. (A) Normal meniscus. (B) Torn meniscus. (C) Surgically repaired meniscus. (A, From David Lintner, MD, Houston, TX, www.drlintner.com. B and C, Courtesy Peter Bonner, Placitas, NM.)

Interprofessional and Nursing Care

Most meniscus injuries are treated in an outpatient setting. The acutely injured knee should be examined within 24 hours of injury. Initial care involves ice, immobilization, and use of crutches with weight bearing as tolerated. Using a knee brace or immobilizer during the first few days after the injury protects the knee and offers some pain relief.

After acute pain has decreased, PT can help the patient regain knee flexion and muscle strength to aid in returning to full function. Teach athletes to do warm-up exercises to reduce the risk for sports-related injuries. In older adults with degenerative meniscus tears, progressive exercise therapy may improve neuromuscular function and muscle strength.

Surgical repair or excision of part of the meniscus *(meniscectomy)* may be needed (see Fig. 67.4). Meniscal surgery is done by arthroscopy. Pain relief may include NSAIDs or other analgesics. Rehabilitation starts soon after surgery. PT includes quadriceps and hamstring strength exercises and ROM. When the patient's strength is back to its preinjury level, they can resume normal activities.

ANTERIOR CRUCIATE LIGAMENT INJURY

Knee injuries account for more than 50% of all sports injuries. The most commonly injured knee ligament is the anterior cruciate ligament (ACL). ACL injuries are usually noncontact injuries that occur when a person pivots, lands from a jump, or stops abruptly when running. Patients often report coming down on the knee, twisting, and hearing a pop, followed by acute knee pain and swelling. The knee may feel unstable. Athletes usually cannot continue playing. ACL injury can result in a partial tear, a complete tear, or an *avulsion* (tearing away) from the bones that form the knee (Fig. 67.5).

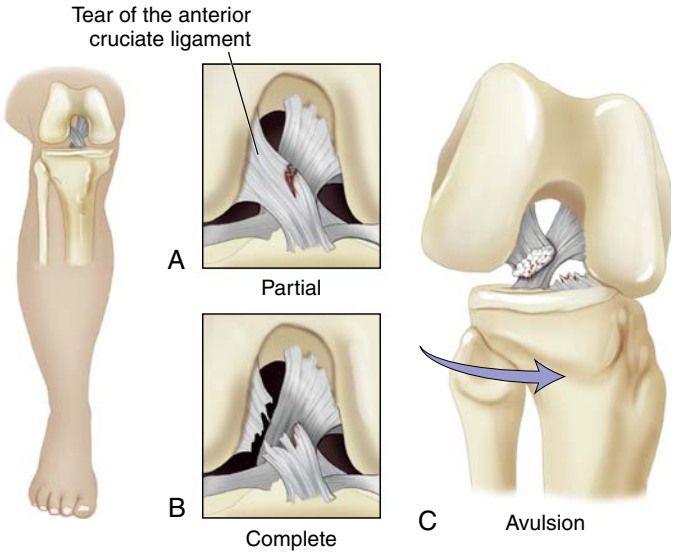

Fig. 67.5 ACL injury. (A) Partial tear. (B) Complete tear. (C) Avulsion.

A positive *Lachman's test* suggests an ACL tear. This test is done by flexing the knee 15 to 30 degrees and pulling the tibia forward while stabilizing the femur. The test is positive for an ACL tear if forward motion of the tibia occurs with the feeling of a soft or indistinct endpoint. MRI can diagnose an ACL tear and coexisting conditions, including a fracture, meniscus tear, and ligament injuries.

Interprofessional and Nursing Care

Prevention programs can significantly reduce ACL injuries in athletes. Conservative treatment for an intact ACL injury includes rest, ice, NSAIDs, elevation, and ambulation as tolerated with crutches. If present, a tight, painful effusion may be aspirated. A knee immobilizer or hinged knee brace may provide support. PT often helps the patient maintain knee joint motion and muscle tone.

Reconstructive surgery is usually recommended for physically active patients who have sustained severe injury to the ACL and meniscus. In reconstruction, the torn ACL tissue is removed and replaced with graft tissue. ROM is encouraged soon after surgery. The knee is placed in a brace or immobilizer. Rehabilitation with PT is critical. Progressive weight bearing is determined by the type of surgery. A safe return to the prior level of function may take 6 to 8 months.

BURSITIS

Bursae are closed sacs that are lined with synovial membrane and contain a small amount of synovial fluid. They are found at sites of friction, such as between tendons and bones and near the joints. **Bursitis** (inflammation of the bursa) results from repeated or excessive trauma or friction, gout, RA, or infection.

Symptoms include warmth, pain, swelling, and limited ROM in the affected part. Common sites are the hands, elbows, shoulders, knees, and greater trochanters of the hip. Improper body

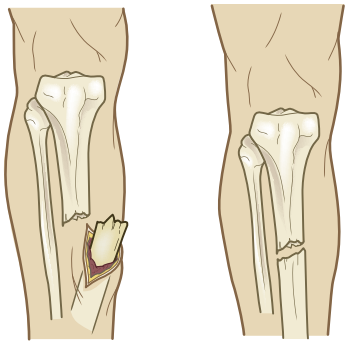

Fig. 67.6 Fracture classification by communication with the external environment.

mechanics, repetitive kneeling (e.g., carpet layers, coal miners, gardeners), jogging in worn-out shoes, and prolonged sitting with crossed legs are common precipitating activities.

Try to determine and correct the cause of the bursitis. Rest is often the only treatment needed. The affected part may be immobilized in a compression dressing or splint. Ice and NSAIDs can reduce pain and inflammation. Aspiration of the bursal fluid and intraarticular corticosteroid injection may be needed. If the bursal wall has become thickened and continues to interfere with normal joint function, surgical excision *(bursectomy)* may be done. Septic bursae may be treated with oral antibiotics but usually need surgical incision and drainage.

FRACTURES

Classification

A **fracture** is a disruption or break in the continuity of bone. Traumatic injuries cause most fractures. Other fractures are due to a disease process, such as cancer or osteoporosis *(pathologic fracture)*.

We classify fractures in several ways. Fractures are described as *open* or *closed* based on communication with the external environment (Fig. 67.6). In an *open fracture*, the skin is broken, and bone exposed, causing soft tissue injury. An open fracture usually results from severe external forces. In a *closed fracture*, the skin is intact over the site.

We also describe fractures as complete or incomplete. A fracture is *complete* if the break goes completely through the bone. An *incomplete* fracture occurs partly across a bone shaft, but the bone is still intact. An incomplete fracture is often the result of bending or crushing forces applied to a bone.

Fractures are identified by the direction of the fracture line. Types include linear, oblique, transverse, longitudinal, and spiral fractures (Fig. 67.7).

Finally, we describe fractures as displaced or nondisplaced. In a *displaced* fracture, the 2 ends of the broken bone are separated from each other and out of their normal positions. Displaced fractures are often *comminuted* (more than 2fragments) or *oblique* (Fig. 67.7). In a *nondisplaced* fracture, the bone fragments stay in alignment. Nondisplaced fractures are usually transverse, spiral, or greenstick (Fig. 67.7).

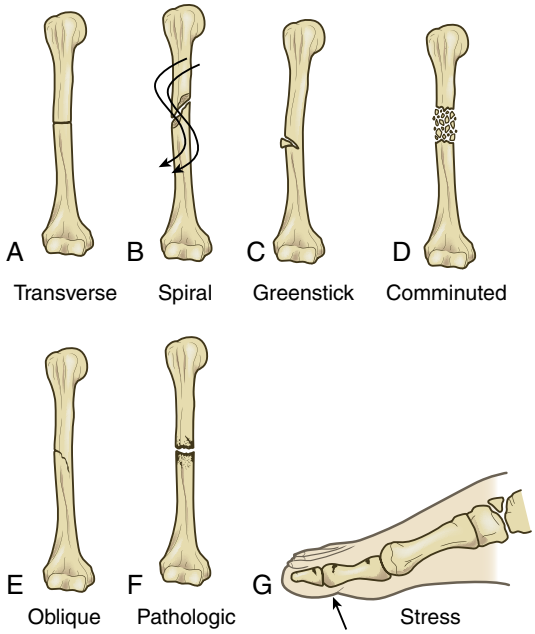

Fig. 67.7 Types of fractures. (A) Transverse fracture: the line of the fracture extends across the bone shaft at a right angle to the longitudinal axis. (B) Spiral fracture: the line of the fracture extends in a spiral direction along the bone shaft. (C) Greenstick fracture: an incomplete fracture with 1 side splintered and the other side bent. (D) Comminuted fracture: a fracture with more than 2 fragments. The smaller fragments appear to be floating. (E) Oblique fracture: the line of the fracture extends across and down the bone. (F) Pathologic fracture: a spontaneous fracture at the site of a diseased bone. (G) Stress fracture: occurs in bone that is subject to repeated stress, such as from jogging or running.

Manifestations

Manifestations include immediate pain, decreased function, and inability to bear weight or use the affected part (Table 67.4). The patient guards and protects the extremity against movement. Obvious deformity may be present.

Fracture Healing

Bone goes through a complex multistage healing process, or union (Fig. 67.8). Healing occurs in 6 stages:

1. *Fracture hematoma:* When a fracture occurs, bleeding creates a hematoma that surrounds the ends of the bone fragments. The hematoma is composed of extravasated blood that changes from a liquid to a semisolid clot in the first 72 hours after injury.
2. *Granulation tissue:* During this stage, active phagocytosis absorbs the products of local necrosis. The hematoma converts to granulation tissue. Granulation tissue (consisting of new blood vessels, fibroblasts, and osteoblasts) forms the basis for new bone substance *(osteoid)* during days 3 to 14 after injury.
3. *Callus formation:* As minerals (calcium, phosphorus, and magnesium) and new bone matrix are deposited in the osteoid, an unorganized network of bone is formed and woven about the fracture parts. *Callus* is mainly composed of cartilage, osteoblasts, calcium, and phosphorus. It usually appears by the end of the second week after injury. An x-ray can show evidence of callus formation.

TABLE 67.4 Manifestations of Fracture

Manifestation	Significance
Bruising	
Discoloration of skin from extravasation of blood in subcutaneous tissues.	May appear immediately after injury and distal to injury. Reassure patient that process is normal, and discoloration will resolve.
Crepitation	
Grating or crunching of bony fragments, causing palpable or audible crunching or popping sensation.	May ↑ chance for nonunion if bone ends are allowed to move excessively. Micromovement of fragments (postfracture) helps in osteogenesis (new bone growth).
Deformity	
Abnormal position of extremity or part from original forces of injury and action of muscles pulling fragment into abnormal position. Seen as a loss of normal bony contours.	Classic sign of fracture. If uncorrected, it may cause problems with bony union and restoration of function of injured part.
Edema and Swelling	
Disruption or penetration of skin or soft tissues by bone fragments, or bleeding into surrounding tissues.	Unchecked bleeding and swelling in closed space can occlude blood vessels and damage nerves (e.g., ↑ risk for compartment syndrome).
Loss of Function	
Disruption of bone or joint, preventing functional use of limb or part.	Fracture must be managed properly to ensure restoration of function to limb or part.
Muscle Spasm	
Irritation of tissues and protective response to injury and fracture.	May displace nondisplaced fracture or prevent it from reducing spontaneously.
Pain and Tenderness	
Muscle spasm due to involuntary reflex action of muscle, direct tissue trauma, ↑ pressure on nerves, movement of fracture fragments.	Prompt the patient to splint muscle around fracture and reduce motion of injured area.

4. *Ossification:* Ossification of the callus occurs from 3 weeks to 6 months after the fracture and continues until the fracture has healed. Callus ossification is sufficient to prevent movement at the fracture site when the bones are gently stressed. However, the fracture is still evident on x-ray. During this stage of *clinical union,* the patient may be allowed limited mobility, or we may remove the cast.
5. *Consolidation:* As callus continues to develop, the distance between bone fragments decreases and eventually closes. Ossification continues and can be equated with *radiologic union,* which occurs when an x-ray shows complete bony union. This phase can occur up to 1 year after injury.

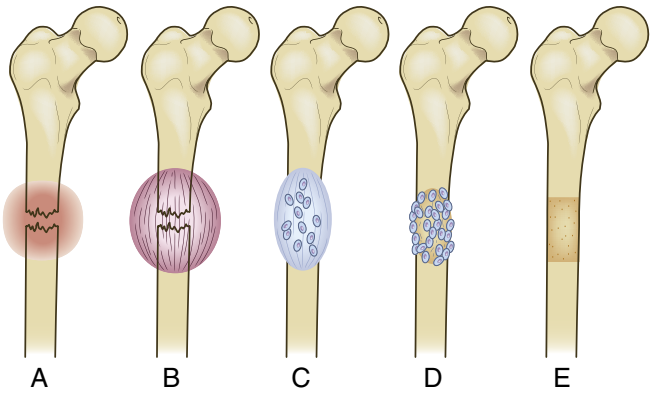

Fig. 67.8 Bone healing (schematic representation). (A) Bleeding at fractured ends of the bone with hematoma formation. (B) Organization of hematoma into fibrous network. (C) Invasion of osteoblasts, lengthening of collagen strands, and deposition of calcium. (D) Callus formation: new bone is built up as osteoclasts destroy dead bone. (E) Remodeling is accomplished as excess callus is resorbed and trabecular bone is laid down.

6. *Remodeling:* Excess bone tissue is resorbed in the last stage of bone healing, and union is complete. Gradual return of the injured bone to its preinjury structural strength and shape occurs. Bone remodels in response to physical loading stress. Initially, stress is provided through exercise. Weight bearing is gradually introduced. New bone is deposited in sites subjected to stress and resorbed at areas of little stress.

Many factors influence the time needed for complete fracture healing. They include displacement and site of the fracture, blood supply, other local tissue injury, immobilization, and use of internal fixation devices (e.g., screws, pins). Ossification may be slowed or even stopped by inadequate immobilization, excessive movement of fracture fragments, infection, poor nutrition, and systemic disease (e.g., diabetes).[6] Healing time for fractures increases with age. For example, an uncomplicated midshaft femur fracture heals in 3 weeks in an infant and in 20 weeks in an adult. Smoking increases fracture healing time. Fracture healing may not occur in the expected time *(delayed union)* or may not occur at all *(nonunion).* Table 67.5 describes complications of fracture healing.

Interprofessional Care

The overall goals of fracture treatment are (1) anatomic realignment of bone fragments through reduction, (2) immobilization to maintain realignment, and (3) restoration of normal or near-normal function of the injured part. Table 67.6 outlines the management of fractures.

Fracture Reduction

Closed reduction. *Closed reduction* is the nonsurgical, manual realignment of bone fragments to their anatomic position. Traction and countertraction are manually applied to the bone fragments to restore position, length, and alignment. Closed reduction is usually done while the patient is under local or general anesthesia. Traction, casting, splints, or orthoses (braces) may be used after reduction to maintain alignment and immobilize the injured part until healing occurs.

TABLE 67.5 Complications of Fracture

Healing

Complication	Description
Angulation	Fracture heals in abnormal position in relation to midline of structure (type of malunion).
Delayed union	Fracture healing progresses more slowly than expected. Healing eventually occurs.
Malunion	Fracture heals in expected time but in unsatisfactory position. May cause deformity or dysfunction.
Myositis ossificans	Deposition of calcium in muscle tissue at site of significant blunt muscle trauma or repeated muscle injury.
Nonunion	Fracture does not heal despite treatment. No x-ray evidence of callus formation.
Pseudoarthrosis	Type of nonunion occurring at fracture site in which a false joint is formed with abnormal movement at site.
Refracture	New fracture occurs at original fracture site.

TABLE 67.6 Interprofessional Care

Fractures

Diagnostic Assessment
- History and physical assessment
- X-ray
- CT scan, MRI

Management

Fracture Reduction
- Manual traction
- Closed reduction
- Skeletal traction
- Open reduction

Fracture Immobilization
- Casting or splinting
- Skeletal traction
- External fixation
- Internal fixation

Open Fractures
- Surgical debridement and irrigation
- Tetanus and diphtheria immunization
- Prophylactic antibiotic therapy

Open reduction. *Open reduction* is the correction of bone alignment through surgery. It usually includes internal fixation of the fracture with wires, screws, pins, plates, intramedullary rods, or nails. The type and location of the fracture, patient age, and concurrent disease influence the decision to use open reduction. The main risks of open reduction are infection, complications of anesthesia, and effects of preexisting medical conditions (e.g., diabetes). However, open reduction internal fixation (ORIF) facilitates early ambulation, decreasing the risk for complications related to prolonged immobility.

Traction. **Traction** is the application of a pulling force to an injured or diseased body part or extremity. Traction is used to (1) prevent or reduce pain and muscle spasm (e.g., whiplash, unrepaired hip fracture), (2) immobilize a joint or part of the body, (3) reduce a fracture or dislocation, and (4) treat a pathologic joint condition (e.g., tumor, infection). Traction can also (1) provide immobilization to prevent soft tissue damage, (2) promote active and passive exercise, (3) expand a joint space during arthroscopic procedures, and (4) expand a joint space before major joint reconstruction.

Fig. 67.9 Buck's traction is most often used for fractures of the hip and femur. (Courtesy Mary Wollan, RN, BAN, ONC, Spring Park, MN.)

Traction devices apply a pulling force on a fractured extremity to attain realignment, while *countertraction* pulls in the opposite direction. The most common types of traction are skin traction and skeletal traction. *Skin traction* is generally used for short-term treatment (48 to 72 hours) until skeletal traction or surgery is possible. Tape, boots, or splints are applied directly to the skin. They help decrease muscle spasms in the injured extremity. Traction weights are usually 5 to 10 lb (2.3 to 4.5 kg). *Buck's traction* is a type of skin traction sometimes used for the patient with a hip, knee, or femur fracture (Fig. 67.9). Pelvic or cervical skin traction may require heavier weights applied intermittently. In skin traction, regular skin assessment is a priority because pressure points and skin breakdown may develop quickly. Assess key pressure points every 2 to 4 hours.

Skeletal traction is used to align injured bones and joints or to treat joint contractures and congenital hip dysplasia. It provides a long-term pull that keeps the injured bones and joints aligned. To apply skeletal traction, the HCP inserts a pin or wire into the bone, and weights are attached to align and immobilize the injured body part. Weight for skeletal traction ranges from 5 to 45 lb (2.3 to 20.4 kg). Too much weight can result in delayed union or nonunion. The major complications of skeletal traction are infection at the pin insertion site and the effects of prolonged immobility.

A common type of skeletal traction is balanced suspension traction (Fig. 67.10). Fracture alignment depends on the correct positioning and alignment of the patient while the traction forces stay constant. For extremity traction to be effective, forces must be pulling in the opposite direction *(countertraction)*. Countertraction is supplied by the patient's body weight or by weights pulling in the opposite direction. Elevating the end of the bed can help. Traction must be maintained continuously. Keep the weights off the floor and moving freely through the pulleys.

Fracture Immobilization

Fracture immobilization is achieved with casts, braces, splints, immobilizers, and external and internal fixation devices.

Fig. 67.10 Balanced suspension skeletal traction. Most often used for fractures of the femur, hip, and lower leg. (Courtesy Zimmer, Inc.)

Casts. A *cast* is a temporary immobilization device often applied after closed reduction. A cast usually immobilizes the joints above and below a fracture. This restricts tendon and ligament movement, thus assisting with joint stabilization while the fracture heals. A cast often allows the patient to perform many normal ADLs while providing stability. The 2 most common cast materials are natural (plaster of Paris) and fiberglass. We use fiberglass casts most often because they are lighter, relatively waterproof, and longer wearing than plaster of Paris.[7] They also allow early weight bearing. Plaster of Paris is used mainly for contact casting for treating diabetic foot ulcers.[8]

To apply a cast on an extremity, first cover the affected part with stockinette that is cut longer than the extremity. Then place cotton padding over the stockinette, with extra padding for bony prominences. If using plaster of Paris, immerse it in warm water and then wrap and mold it around the affected part. The number of layers of plaster bandage and the technique of application determine the strength of the cast. The plaster sets within 15 minutes. It is not strong enough for weight bearing until about 36 to 72 hours after application. The decision about weight bearing is made by the HCP. Casts made of fiberglass or other synthetic materials (thermolabile plastic, thermoplastic resins, polyurethane) are activated by submersion in cool or tepid water. Then they are molded to fit the torso or extremity.

Leave a fresh plaster cast uncovered to allow air circulation. Covering the cast allows heat to build up in the cast. This may cause a burn and delay drying. Avoid direct pressure on the cast during the drying period. Handle the cast gently with an open palm to avoid denting the cast. Once the cast is thoroughly dry, the rough edges may be *petaled* to minimize skin irritation. Petaling also prevents plaster of Paris debris from falling into the cast and causing irritation or pressure necrosis. Place several strips (petals) of tape over the rough areas to ensure a smooth cast edge.

Upper extremity injuries. An acute fracture or soft tissue injury of the upper extremity can be immobilized by using a (1) sugar-tong splint, (2) posterior splint, (3) short arm cast, or (4) long arm cast (Fig. 67.11). The *sugar-tong splint* is applied for acute wrist injuries or injuries that may result in significant swelling. Splints are placed over a well-padded forearm, beginning at the phalangeal joints of the hand, extending up the dorsal aspect of the forearm around the distal humerus, and then down the volar aspect of the forearm to the distal palmar crease. The splinting material is wrapped with either elastic bandage or bias stockinette. The sugar-tong posterior splint adjusts for early swelling in the fractured extremity.

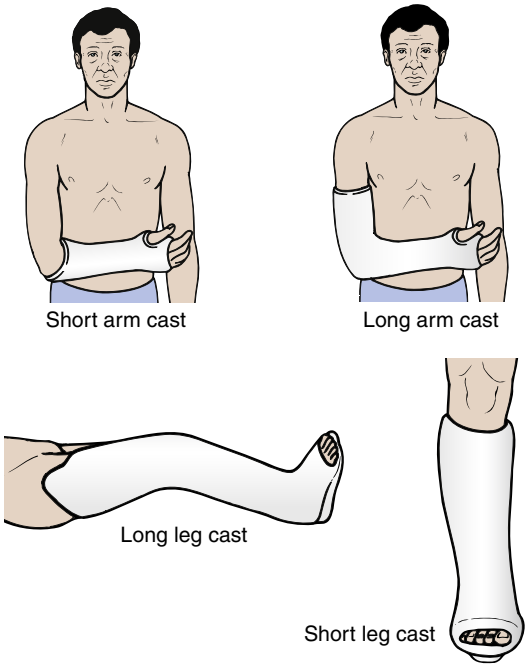

Fig. 67.11 Common types of casts.

The *short arm cast* is often used to treat stable wrist or metacarpal fractures. An aluminum finger splint can be placed in a short arm cast to treat finger injuries. The short arm cast is a circular cast extending from the distal palmar crease to the proximal forearm. This cast immobilizes the wrist and allows unrestricted elbow motion.

The *long arm cast* is often used for stable forearm, elbow, or unstable wrist fractures. It is similar to the short arm cast but extends to the proximal humerus, restricting motion at the wrist and elbow. Support the extremity and reduce edema by elevating the extremity with a sling. When a hanging arm cast is used for a proximal humerus fracture, avoid elevation or use of a supportive sling. The hanging provides traction and maintains fracture alignment.

When a sling is used, ensure the axillary area is well padded to prevent skin breakdown from direct skin-to-skin contact. Apply the sling carefully to avoid putting excess pressure on the neck. Encourage movement of the fingers (unless contraindicated). This decreases edema by enhancing the pumping action of blood vessels. Teach the patient to actively move joints of the upper extremity if not immobilized to prevent stiffness and contractures.

Vertebral injuries. The *body jacket brace* is used for immobilization and support for stable spine injuries of the thoracic or lumbar spine. The brace goes around the chest and abdomen,

extending from above the nipple line to the pubis. After applying a brace, assess the patient for superior mesenteric artery syndrome *(cast syndrome)*. This condition occurs if the brace is too tight, compressing the superior mesenteric artery against the duodenum. The patient may have abdominal pain, abdominal pressure, nausea, and vomiting. Assess the abdomen for decreased bowel sounds (there may be a window in the brace over the umbilicus). Treatment of cast syndrome includes gastric decompression with a nasogastric (NG) tube and suction. Assess respiratory status, bowel and bladder function, and areas of pressure over the bony prominences, especially the iliac crest. The brace may have to be adjusted or removed if any complications occur.

Lower extremity injuries. Injuries to the lower extremity can be immobilized with a long leg cast, short leg cast, cylinder cast, or prefabricated splint or immobilizer. The usual indications for a long leg cast are an unstable ankle fracture, soft tissue injuries, a fractured tibia, and knee injuries. The cast usually extends from the base of the toes to the groin and gluteal crease. The short leg cast is used for stable ankle and foot injuries. A cylinder cast is used for knee injuries or fractures. It extends from the groin to the malleoli of the ankle. A Robert Jones dressing may be used temporarily to limit mobility of a joint. It is composed of soft padding materials (absorption dressing and cotton sheet wadding), splints, and an elastic wrap or bias-cut stockinette.

With a lower extremity cast or dressing, elevate the extremity above the heart on pillows for the first 24 hours. After that, a casted extremity should not be placed in a dependent position, as this may increase edema. After cast application, observe for signs of compartment syndrome. Note increased pressure, especially in the heel, anterior tibia, head of the fibula, and malleoli. Increased pressure presents as pain or a burning feeling in these areas.

Prefabricated knee and ankle splints and immobilizers are used in many settings. This type of immobilization is easy to apply and remove. This allows us to observe the affected joint for swelling and skin breakdown (Fig. 67.12). Depending on the injury, removing the splint or immobilizer promotes ROM of the affected joint and faster return to function.

The *hip spica cast* is mainly used for femur fractures in children to immobilize the affected extremity and trunk. It extends from above the nipple line to the base of the foot (single spica) and may include the opposite extremity up to an area above the knee (spica and a half) or both extremities (double spica). Assess the patient with a hip spica cast for the same problems associated with the body jacket brace.

External fixation. An *external fixator* is composed of metal pins and wires that are inserted into the bone and attached to external rods to stabilize the fracture while it heals (Fig. 67.13). It can be used to apply traction or to compress fracture fragments and immobilize reduced fragments when the use of a cast or traction is not appropriate. The external device holds fracture fragments in place similar to a surgically implanted internal device. External fixation is mainly used for complex fractures with extensive soft tissue damage, correcting congenital bony defects, nonunion or malunion, and limb lengthening.

External fixation is often used to try to salvage extremities that otherwise may need amputation. Perform ongoing assessment

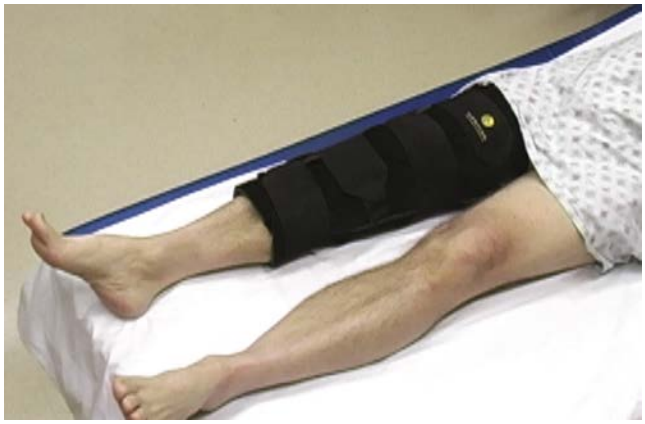

Fig. 67.12 Knee immobilizer. (From Naples RM, Ufberg JW: *Roberts and Hedges' Clinical procedures in emergency medicine and acute care*, Philadelphia, 2020, Elsevier.)

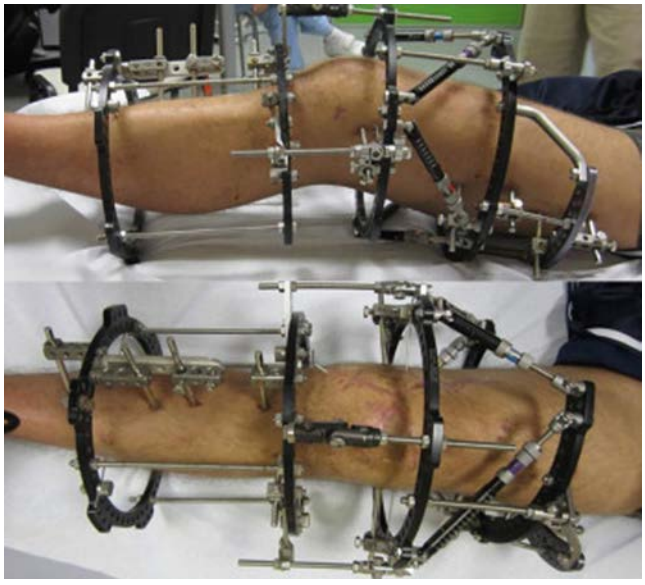

Fig. 67.13 External fixation of tibial fracture. (From Krettke C, Hawi N: *Skeletal trauma: basic science, management, and reconstruction*, ed 6, Philadelphia, 2020, Elsevier.)

for pin loosening and infection. Infection may require removing the device. Teach the patient and caregiver about meticulous pin care. Although each HCP has a protocol for pin care cleaning, chlorhexidine is often used.[9]

Internal fixation. Internal fixation devices (pins, plates, intramedullary rods, metal and bioabsorbable screws) are surgically inserted to realign and maintain position of bony fragments (Fig. 67.14). These metal devices are biologically inert and made from stainless steel, vitallium, or titanium. Proper alignment and bone healing are evaluated regularly by x-rays.

Electrical Bone Growth Stimulation

Electrical bone growth stimulation can promote healing, especially with fracture nonunion or delayed union. It stimulates new bone, cartilage, and blood vessel formation.[10] There are noninvasive, semi-invasive, and invasive methods of electrical bone growth stimulation. Noninvasive stimulators use direct

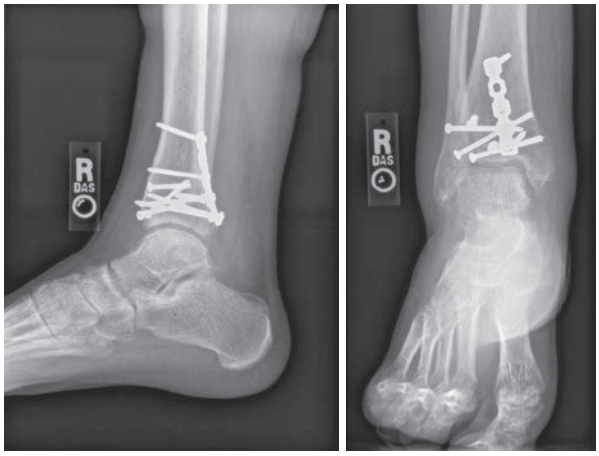

Fig. 67.14 Views of internal fixation devices to stabilize a fractured tibia and fibula. (From Jeremy Lewis, MD, Albuquerque, NM.)

current or pulsed electromagnetic fields (PEMFs) to generate a weak electrical current. Electrodes are typically in a band applied over the patient's skin or cast and worn 10 to 12 hours each day, usually while the patient is sleeping. Semi-invasive or percutaneous bone growth stimulators use an external power supply and electrodes that are inserted through the skin and into the bone. Invasive stimulators require surgical implantation of a current generator in an IM or subcutaneous space. An electrode is implanted in the bone fragments.

Drug Therapy

Patients with fractures have varying degrees of pain. Muscle relaxants, such as carisoprodol (Soma), cyclobenzaprine, or methocarbamol, may be given to manage pain from muscle spasms.

We give tetanus and diphtheria toxoid or tetanus immunoglobulin to the patient with an open fracture when their immunization status cannot be confirmed. Bone-penetrating antibiotics, such as a cephalosporin (e.g., cefazolin), are given prophylactically before surgery.

Nutrition Therapy

Proper nutrition helps ensure optimal soft tissue and bone healing. An adequate energy source promotes muscle strength and tone, builds endurance, and provides energy for ambulation and gait-training skills. The diet must include adequate protein (e.g., 1 g/kg of body weight), vitamins (especially B, C, and D), calcium, potassium, phosphorus, and magnesium. Low serum protein and vitamin C deficiencies interfere with tissue healing. Immobility and bone healing increase calcium needs.

A fluid intake of 2000 to 3000 mL/day promotes optimal bladder and bowel function. Adequate fluid and a high-fiber diet with fruits and vegetables prevent constipation. If immobilized in bed with skeletal traction or in a body jacket brace, the patient should eat 6 small meals. This helps avoid overeating that can cause abdominal pressure and cramping.

❖ NURSING MANAGEMENT: FRACTURES

◆ Assessment

Obtain a brief history of the traumatic episode, mechanism of injury, and position in which the patient was found from the patient or witnesses. As soon as possible, the patient should be transported to an ED. There we do a thorough assessment and start treatment (Table 67.7). Subjective and objective data that

TABLE 67.7 EMERGENCY MANAGEMENT

Fractured Extremity

Cause	Assessment Findings	Interventions
Blunt Trauma • Direct blow • Fall • Forced flexion or hyperextension • Motor vehicle crash • Pedestrian event • Twisting force **Penetrating Trauma** • Blast • Gunshot **Other** • Pathologic condition • Violent muscle contraction (seizures) • Crush injury	• Bruising • ↓ Distal pulses • Deformity or unnatural position of affected limb • Edema • Grating (crepitus) • Loss of function • Muscle spasm • Numbness, tingling • Tenderness, pain • Warmth at site • Wound over injured site, exposure of bone	**Initial** • Treat life-threatening injuries first. • If unresponsive, assess circulation, airway, and breathing. • If responsive, monitor airway, breathing, and circulation. • Control external bleeding with direct pressure or sterile pressure dressing and elevation of the extremity. • Assess neurovascular condition distal to injury before and after splinting. • Elevate injured limb if possible. • Do not try to straighten fractured or dislocated joints. • Do not manipulate protruding bone ends. • Apply ice packs to affected area. • Obtain x-rays of affected limb. • Give tetanus prophylaxis if there is a break in skin integrity. • Mark location of pulses to aid repeat assessment. • Splint fracture site, including joints above and below fracture site. **Ongoing Monitoring** • Assess vital signs, level of consciousness, O_2 saturation, neurovascular condition, pain. • Assess for compartment syndrome (excessive pain, pain with passive stretch of the affected extremity muscles, pallor, paresthesia, with late signs of paralysis and pulselessness). • Assess for FES (dyspnea, chest pain, temperature elevation).

TABLE 67.8 NURSING ASSESSMENT

Fracture

Subjective Data

Important Health Information

Health history: Traumatic injury, long-term repetitive forces (stress fracture), bone or systemic diseases, prolonged immobility, osteopenia, osteoporosis

Medications: Corticosteroids (osteoporotic fractures); analgesics

Surgery or other treatments: First aid treatment of fracture, musculoskeletal surgeries

Functional Health Patterns

Health perception–health management: Calcium and vitamin D supplementation

Activity-exercise: Loss of motion or weakness of affected part, muscle spasms

Cognitive-perceptual: Sudden and severe pain in affected area; numbness, tingling, loss of sensation distal to injury; ongoing pain that increases with activity (stress fracture)

Objective Data

Cardiovascular

Reduced or absent pulse distal to injury, ↓ skin temperature, delayed capillary refill

General

Apprehension, guarding of injured site

Musculoskeletal

Restricted or lost function of affected part; local bony deformities, abnormal angulation; shortening, rotation, or crepitation of affected part; muscle weakness

Neurovascular

Paresthesia, absent or ↓ sensation, hypersensation

Skin

Lacerations, pallor and cool skin or bluish and warm skin distal to injury; bruising, edema at fracture site

Possible Diagnostic Findings

Identification and extent of fracture on x-ray, bone scan, CT scan, or MRI

you should obtain from a person with a fracture are outlined in Table 67.8.

If a fracture is suspected, immobilize the extremity in the position in which it is found. Unnecessary movement increases risk for damage to adjacent nerves and blood vessels. It may also convert a closed fracture to an open fracture.

Neurovascular Assessment

Perform a thorough neurovascular assessment of the affected extremity, distal to the fracture site. Musculoskeletal injuries may cause changes in the neurovascular status of an injured extremity. Poor positioning, physiologic responses to the traumatic injury, and application of a cast or constrictive dressing can cause nerve or vascular damage, usually distal to the injury. Record clinical findings before fracture treatment. This way, if a problem occurs later, it will help determine if it was missed during the original assessment or a result of treatment.

The neurovascular assessment consists of *peripheral vascular assessment* (color, temperature, capillary refill, peripheral pulses, edema) and *peripheral neurologic assessment* (sensation, motor function, pain). Throughout the neurovascular assessment, compare both extremities to obtain an accurate assessment.

Assess an extremity's color (pink, pale, cyanotic) and temperature (hot, warm, cool, cold) around the injury. Pallor or a cool-to-cold extremity below the injury could indicate arterial insufficiency. A warm, cyanotic extremity could indicate poor venous return. Next, assess capillary refill. A delay in returning to its original color (greater than 3 seconds) can occur with arterial insufficiency.

Compare pulses on the unaffected and injured extremities to identify differences in rate or quality. This contralateral evaluation is critical. A decreased or absent pulse distal to the injury can indicate vascular problems and insufficiency. Assess peripheral edema. Pitting edema may be present with severe injury.

Assess ulnar, median, and radial nerve function to evaluate sensation and motor innervation in the upper extremity. Assess motor function by asking the patient to (1) abduct the fingers (ulnar nerve), (2) oppose the thumb and small finger (median nerve), and (3) flex and extend the wrist (or the fingers, if in a cast) (radial nerve). In the lower extremity, assess the patient's ability to perform dorsiflexion (peroneal nerve) and plantar flexion (tibial nerve). Evaluate sensory function of the peroneal nerve by touching the web space between the big and second toes. Stroke the plantar surface (sole) of the foot to assess sensory function of the tibial nerve.

The patient may report *paresthesia* (abnormal sensation [e.g., numbness, tingling]) and hypersensation or hyperesthesia. Partial or full loss of sensation (paresis or paralysis) may be a late sign of neurovascular damage. Teach the patient to immediately report any changes in sensation or the ability to move the digits in the affected extremity.

Clinical Problems

Clinical problems for the patient with a fracture may include:

- Musculoskeletal problem
- Risk for infection
- Pain

Additional information on clinical problems and interventions for the patient with a fracture is presented in eNursing Care Plan 67.1 (on the website for this chapter).

Planning

The overall goals are that the patient with a fracture will (1) have healing with no associated complications, (2) have acceptable pain relief, and (3) achieve maximal rehabilitation potential.

Implementation

Acute Care

Patients with fractures may be treated in an ED or an HCP's office and released to home care. They may need hospitalization for varying amounts of time. Specific nursing measures depend on the setting and type of treatment.

Preoperative care. If surgery is needed to treat a fracture, patients must be prepared. In addition to the usual preoperative nursing care (see Chapter 18), teach the patient about the type of immobilization and assistive devices that will be used. Discuss expected activity limitations after surgery. Assure them that nursing staff will help meet their personal needs until they can resume self-care. Review pain management strategies.

Postoperative care. In general, nursing care after surgery involves monitoring vital signs and applying general principles of postoperative nursing care (see Chapter 20). Perform frequent neurovascular assessment of the affected extremity to detect early and subtle changes. Follow any limitations related to turning, positioning, and extremity support. Minimize pain and discomfort through proper alignment and positioning. Frequently observe dressings or casts for any signs of bleeding or drainage. Report an increase in size of the drainage area to the HCP. If a wound drainage system is in place, regularly measure the volume of drainage and assess its character (e.g., bloody, purulent). Report increased or purulent drainage at once to the HCP. Maintain the patency of any drainage systems, using aseptic technique to avoid contamination.

Other nursing actions depend on the type of immobilization used. A blood salvage and reinfusion system may be used to allow recovery and reinfusion of the patient's own blood. The blood is retrieved from a joint space or cavity; then the patient receives this blood in the form of an autotransfusion. Autotransfusion is discussed in Chapter 31.

Other measures. Patients often have reduced mobility because of a fracture. Plan care to decrease risk for the many possible complications of immobility. Prevent constipation by increasing patient activity. Maintain high fluid intake (more than 2500 mL/day unless contraindicated) and a diet high in bulk and roughage (fresh fruits and vegetables). If these measures are not effective in continuing the patient's normal bowel elimination pattern, give stool softeners, laxatives, or suppositories. Maintain a regular time for elimination to promote bowel regularity (Table 67.9).

Renal stones can develop from bone demineralization due to reduced mobility. Hypercalcemia from demineralization causes a rise in urine pH and stone formation from calcium precipitation. Unless contraindicated, maintain a fluid intake of 2500 mL/day to decrease the risk for stone formation. Renal stones are discussed in Chapter 50.

Rapid deconditioning of the cardiopulmonary system can occur from prolonged bed rest, resulting in orthostatic hypotension and decreased lung capacity. Unless contraindicated, decrease these effects by having the patient sit on the side of the bed, allowing their lower limbs to dangle over the bedside. Have the patient perform standing transfers. When the patient is allowed to increase activity, assess for orthostatic hypotension. Assess patients for signs of VTE. VTE is discussed in Chapter 41.

TABLE 67.9 NURSING MANAGEMENT

Caring for the Patient With a Cast or Traction

- Perform neurovascular assessment on the affected extremity.
- Monitor pain intensity and give prescribed analgesics.
- Determine correct body alignment to enhance traction.
- Monitor skin integrity around cast and at traction pin sites.
- Monitor cast during drying for denting or flattening.
- Teach patient and caregiver about cast care or traction and measures to prevent complications (e.g., ROM exercises).
- Assess for complications of immobility (e.g., constipation, VTE, kidney stones, atelectasis) and develop a plan to minimize those complications.
- Supervise assistive personnel (AP):
  - Position casted extremity above heart level as directed by RN.
  - Apply ice to cast as directed by RN.
  - Maintain body position and integrity of traction (if trained in this procedure).
  - Help with passive and active ROM exercises.
  - Notify RN about reports of pain, tingling, or decreased sensation in the affected extremity.

Collaborate With Physical Therapist

- Assess current mobility and need for assistance.
- Teach safe ambulation with assistive device based on weight-bearing restrictions.
- Establish exercise plan and teach patient to perform exercises safely.
- Coordinate PT with RN so that patient can receive timely analgesia.
- Discuss home environment with patient and identify modifications to promote safety (e.g., stair training).

Collaborate With Occupational Therapist

- Assess impact of patient's condition on ability to perform ADLs.
- Teach use of assistive devices (e.g., long-handled reacher, shoe donner) to promote self-care while maintaining activity restrictions.

Traction. When slings are used with traction, regularly inspect exposed skin areas. Pressure over a bony prominence created by wrinkled sheets or blankets may cause pressure necrosis. Persistent skin pressure may impair blood flow and cause injury to peripheral nerves and blood vessels. Assess skeletal traction or external fixation pin sites for signs of infection. Pin site care may vary. It often includes regularly cleansing with chlorhexidine, rinsing with sterile saline, and drying the area with sterile gauze.

External rotation of the affected extremity is a classic assessment finding for a patient with unrepaired hip fracture. If skin traction is ordered before surgery, apply traction without trying to reposition or realign the extremity. Movement of fracture fragments can occur during repositioning, causing increased pain and possible nerve impingement. Keep the patient in the center of the bed in a supine position to provide adequate countertraction.

If exercise is allowed, encourage patient participation in a simple exercise program based on activity restrictions. Have the patient perform frequent position changes, ROM exercises of unaffected joints, deep-breathing exercises, and isometric exercises. These activities should be done several times each day. Teach the patient to use the trapeze bar (if permitted) to raise the body off the bed for linen changes and placement of the bedpan. Encourage and help the hospitalized patient to stay connected with friends and family by telephone or through social media resources.

TABLE 67.10 PATIENT & CAREGIVER TEACHING

Cast Care

After a cast is applied, include the following instructions when teaching the patient and the caregiver:

Do

1. Apply ice directly over fracture site for first 24 hr (avoid getting cast wet by keeping ice in plastic bag and protecting cast with cloth).
2. Check with HCP before getting fiberglass cast wet.
3. Dry cast thoroughly if inadvertently exposed to water.
   - Blot dry with towel.
   - Use hair dryer on low setting until cast is thoroughly dry.
4. Elevate extremity above heart level for first 48 hr.
5. Regularly move joints above and below cast.
6. Use hair dryer on cool setting for itching inside the cast.
7. Report signs of possible problems to HCP:
   - Increasing pain despite elevation, ice, analgesia.
   - Swelling with pain and discoloration of toes or fingers.
   - Pain during movement.
   - Burning or tingling under cast.
   - Sores or foul odor under cast.
8. Keep appointment to have fracture and cast checked.

Do Not

1. Get cast wet.
2. Remove any padding.
3. Insert any objects inside cast.
4. Bear weight on new cast for 48 hr (not all casts are made for weight bearing; check with HCP when unsure).
5. Cover cast with plastic for prolonged periods.

Ambulatory Care

Cast care. Most uncomplicated fractures are treated in an outpatient setting. Whatever the type of cast material, a cast can interfere with circulation and nerve function if it is applied too tightly or excess edema occurs after application. Frequent neurovascular assessment of the immobilized extremity is critical. Teach the patient to recognize and promptly report tightness of the cast and areas of pressure or discomfort. Explain the importance of elevating the extremity above heart level to promote venous return and applying ice to control or prevent edema during the initial phase. However, if you suspect compartment syndrome, do not elevate the extremity above the heart.

Patient and caregiver teaching is important to prevent complications. Table 67.10 describes patient and caregiver instructions for cast care. Teach the patient to exercise joints above and below the cast. Tell the patient not to scratch or place anything inside the cast because this may cause skin injury and infection. For itching, direct a hair dryer on a cool setting under the cast. Confirm the patient's and caregiver's understanding of these instructions before discharge. A follow-up phone call is appropriate. Home care nursing visits may be needed, especially for the patient with a body jacket brace.

The cast is typically removed in the outpatient setting. Patients often fear being cut by the oscillating blade of the cast saw. Reassure the patient that damage to the skin is unlikely. Teach the patient about possible changes in the appearance of the extremity beneath the cast (e.g., dry, wrinkled skin; atrophied muscle; foul odor). The patient may be scared to use the injured extremity after cast removal.

Ambulation. Know the overall goals of PT in relation to the patient's abilities, needs, and tolerance. The physical therapist is responsible for mobility training and teaching about the use of assistive aids (cane, crutches, walker). Reinforce these instructions. The patient with lower extremity fractures usually starts mobility training when able to sit in bed and dangle the feet over the side. Work with the physical therapist to give analgesia before a PT session.

When the patient begins to ambulate, know their weight-bearing status and the correct technique if the patient is using an assistive device. Ambulation occurs in different degrees of weight-bearing: (1) non–weight-bearing (no weight on the involved extremity), (2) touch-down/toe-touch weight bearing (contact with floor for balance but no weight borne), (3) partial–weight-bearing ambulation (25% to 50% of weight borne), (4) weight bearing as tolerated (based on pain and tolerance), and (5) full–weight-bearing ambulation (no limitations).

Assistive devices. Devices for ambulation range from a cane (can relieve up to 40% of the weight normally borne by a lower limb) to a walker or crutches (may allow for complete non–weight-bearing ambulation). The HCP decides which device is best, balancing the need for maximum stability and safety with the need for maneuverability in small spaces, such as bathrooms. Discuss with the patient lifestyle requirements and help select a device that allows the patient to feel most secure and independent. The technique for using assistive ambulation devices varies. The involved limb is usually advanced at the same time or immediately after advance of the device. The uninvolved limb is advanced last. Canes are held in the hand opposite the involved extremity.

Place a transfer belt (gait belt) around the patient's waist to provide stability while teaching the patient how to use an assistive device. Discourage the patient from reaching for furniture or relying on another person for support. A patient with inadequate upper limb strength or poorly fitted crutches bears weight at the axilla rather than at the hands. This can damage the neurovascular bundle that passes across the axilla. If verbal coaching does not correct the problem, teach the patient another form of ambulation (e.g., walker) until strength is adequate.

Patients who must ambulate without weight bearing need enough upper limb strength to lift their own weight at each step. Because the muscles of the shoulder girdle and upper arm may not be accustomed to this work, patients require focused training for this task. Push-ups, pull-ups using the overhead trapeze bar, and weightlifting develop the triceps and biceps muscles. Straight-leg raises and quadriceps-setting exercises strengthen the quadriceps muscles.

Psychosocial concerns. Short-term rehabilitative goals address the transition from dependence to independence in performing simple ADLs. They are directed at preserving or increasing strength and endurance. Long-term rehabilitative goals are aimed at preventing problems from musculoskeletal

TABLE 67.11 Problems Associated With Musculoskeletal Injuries

Problem	Description	Nursing Considerations
Atrophy	• ↓ Muscle mass occurs from disuse after prolonged immobilization. • Loss of nerve function can cause muscle atrophy.	• Isometric strength exercises as able with immobilization device helps reduce amount of atrophy. • Muscle atrophy interferes with and prolongs rehabilitation process.
Contracture	• Abnormal condition of joint characterized by flexion and fixation. • Caused by atrophy and shortening of muscle fibers and ligaments or by loss of normal elasticity of skin over joint.	• Can be prevented by frequent position change, correct body alignment, active-passive ROM exercises several times a day. • Intervention requires gradual progressive stretching of muscles or ligaments in region of joint.
Footdrop	• Plantar-flexed position of the foot occurs when Achilles's tendon in ankle shortens because it has been allowed to assume an unsupported position. • Peroneal nerve palsy (a compression neuropathy) can cause footdrop and spinal nerve compression.	• For patient with long-term injuries, support foot in neutral position to ↓ risk for footdrop. • Once footdrop has developed, can significantly hinder ambulation and gait training. • May need splint to keep feet in neutral position. • High-top athletic shoes may help. Apply at scheduled times to keep feet in neutral position.
Muscle spasms	• Caused by involuntary muscle contraction after fracture, muscle strain, or nerve injury. • May last several weeks. • Pain from muscle spasms is often intense and can last from several seconds to several minutes.	• Measures to ↓ intensity of muscle spasms are similar to actions for pain management. • Do not massage muscle spasms. Massage may stimulate muscle tissue contraction that ↑ spasm and pain. • Thermotherapy, especially heat, may reduce muscle spasm.
Pain	• Common with fractures, edema, muscle spasm. • May be mild to severe and described as aching, dull, burning, throbbing, sharp, or deep.	• Causes include incorrect positioning and alignment of extremity, incorrect support of extremity, sudden movement of extremity, immobilization device that is applied too tightly or incorrectly, constrictive dressings, motion at fracture site. • Determine causes of pain so that corrective action can be taken.

injury (Table 67.11). During the rehabilitative phase, help the patient adjust to any problems caused by the injury (e.g., separation from family, financial impact, loss of income from inability to work, potential for disability). Assess patients for posttraumatic stress disorder. This is especially important if significant injury to others or fatalities occurred with the incident.

The caregiver may have a key role in providing long-term care. Teach the caregiver how to help with strength and endurance exercises, mobility, and promoting activities that enhance the quality of daily living. Offer support and encouragement while actively listening to the patient's and caregiver's concerns.

◆ Evaluation

The expected outcomes are that the patient with a fracture will:

- Report satisfactory pain management
- Show proper care of cast or immobilizer
- Have uncomplicated bone healing

COMPLICATIONS OF FRACTURES

Most fractures heal without complications. Complications may be direct or indirect. *Direct complications* include infection, problems with bone union, and avascular necrosis. *Indirect complications* include compartment syndrome, VTE, fat embolism syndrome (FES), breakdown of skeletal muscle *(rhabdomyolysis),* and hypovolemic shock. Most musculoskeletal injuries are not life threatening. Death after a fracture is usually due to damage to underlying organs and vascular structures or complications of the fracture or immobility. Open fractures, fractures with severe blood loss, and fractures that damage vital organs (e.g., lung, heart) are medical emergencies requiring immediate attention.

Infection

Open fractures and soft tissue injuries have a high rate of infection. Communication of the fracture site with the outside environment can contaminate the site with microorganisms or foreign bodies. Damage to the surrounding soft tissue and blood vessels impairs the ability of defense mechanisms to respond to microorganisms. Dying or contaminated tissue is an ideal medium for many common pathogens, including anaerobic bacilli, such as *Clostridium tetani*. Measures to prevent infection and osteomyelitis are important.

Open fractures require surgical debridement. The wound is cleaned by saline lavage in the operating room. Gross contaminants are irrigated and mechanically removed. Contused, contaminated, and devitalized tissue (muscle, subcutaneous fat, skin, and bone fragments) is surgically excised *(debridement).* The wound may be irrigated with antibiotic solution. Antibiotic-impregnated beads can be placed in the surgical site. Patients usually receive IV antibiotics for at least 3 days.[11] Surgical management and antibiotics have reduced the occurrence of infection. The amount of soft tissue damage determines if the wound is closed at the time of surgery or if it needs repeat debridement, closed suction drainage, and/or skin grafting.

Compartment Syndrome

Compartment syndrome is a condition in which swelling causes increased pressure within a limited space (muscle

compartment). Because the fascia surrounding the muscle has limited ability to stretch, continued swelling can cause pressure that compromises the function of blood vessels and nerves in the compartment. Capillary perfusion is reduced below a level needed for tissue life. Compartment syndrome often involves the leg but can occur in any muscle group.

There are 38 compartments in the upper and lower extremities. Two basic causes of compartment syndrome are (1) decreased compartment size resulting from restrictive dressings, splints, casts, excessive traction, or premature closure of fascia; and (2) increased compartment contents due to bleeding, inflammation, edema, or IV infiltration.

Edema can create enough pressure to obstruct circulation and cause venous occlusion, which further increases edema. Arterial flow is eventually compromised, causing ischemia in the extremity. As ischemia continues, muscle and nerve cells are destroyed. Fibrotic tissue eventually replaces healthy tissue. Contracture, disability, and loss of function can occur. Delays in diagnosis and treatment may lead to irreversible muscle and nerve ischemia. The extremity may become functionally useless or severely impaired.

Compartment syndrome is usually due to fractures (especially of long bones), extensive soft tissue damage, and crush injury. Distal humerus and proximal tibial fractures are the most common ones associated with compartment syndrome. Compartment injury can also occur after knee or leg surgery. Prolonged pressure on a muscle compartment may result when someone is trapped under a heavy object or a person's limb is trapped beneath the body because of response to drugs or alcohol.

Clinical Manifestations

Compartment syndrome may occur initially from the body's physiologic response to the injury, or it may be delayed for several days after the original insult or injury. Ischemia can occur within 4 to 8 hours after the onset of compartment syndrome.

One or more of the "6 *P*s" are specific to compartment syndrome: (1) *pain* out of proportion to the injury that is not managed by opioid analgesics, and *pain* on passive stretch of muscle in the compartment; (2) increasing *pressure* in the compartment; (3) *paresthesia* (numbness and tingling); (4) *pallor,* coolness, and loss of normal color of the extremity; (5) *paralysis* or loss of function; and (6) *pulselessness* (decreased or absent peripheral pulses).

Interprofessional Care

Prompt diagnosis of compartment syndrome is critical. Perform regular neurovascular assessment on all patients with fractures, especially those with injury of the extremities or soft tissue in these areas. Early recognition and effective treatment of compartment syndrome are essential to avoid permanent damage to muscles and nerves.

Carefully assess the location, quality, and intensity pain (see Chapter 9). Pain unrelieved by drugs and out of proportion to the level of injury is one of the *first* signs of compartment syndrome. Paresthesia is also an early sign. Notify the HCP immediately of these changes. Relieving the source of pressure (e.g., cast is cut [bivalved] or dressing loosened by order of the HCP)

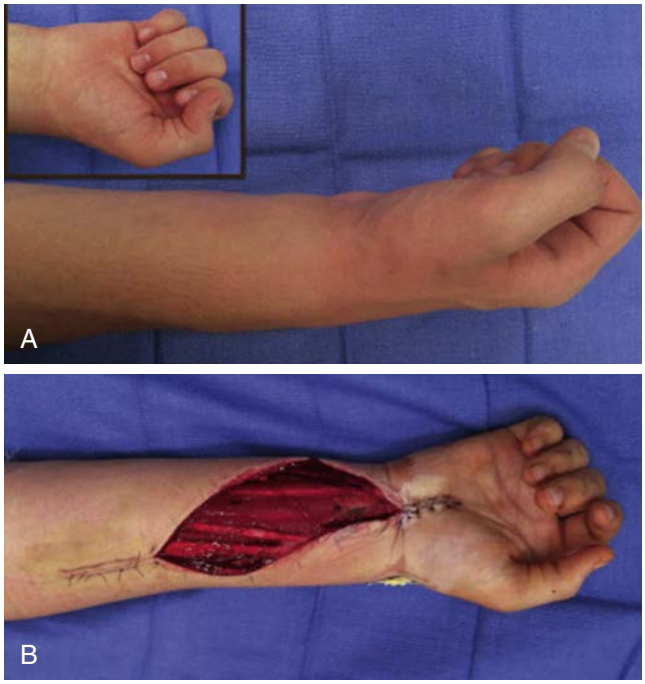

Fig. 67.15 (A) Fracture of the distal radius with distal forearm compartment syndrome. (B) Fasciotomy used to treat compartment syndrome. (From Stevanovic MV, Sharpe F: *Green's operative hand surgery*, ed 7, Philadelphia, 2017, Elsevier.)

typically decreases pain and paresthesia and can avoid compartment syndrome. Reducing traction weight may decrease external pressures on the extremity. Pulselessness and paralysis are late signs of compartment syndrome. Do not wait until these late signs occur to contact the HCP. Amputation may be needed due to prolonged ischemia.

With suspected compartment syndrome, do not elevate the extremity above the heart. Similarly, do not apply cold compresses. They may cause vasoconstriction and worsen compartment syndrome.

Surgical decompression (e.g., fasciotomy) of the involved compartment may be needed (Fig. 67.15). The fasciotomy site is left open for several days to allow adequate soft tissue decompression. Infection resulting from delayed wound closure is a potential problem after fasciotomy. In severe cases of compartment syndrome, amputation is done.

CHECK YOUR PRACTICE

Your 22-year-old male patient had a fall while rock climbing. He returned from surgery 8 hours ago with a long leg cast placed for open fractures of the femur and tibia. He continually reports pain that IV morphine does not seem to help.

- How will you assess his neurovascular condition?
- What signs and symptoms would suggest the development of compartment syndrome?
- What is the most likely intervention if compartment syndrome is developing?

Venous Thromboembolism

Veins of the lower extremities and pelvis are at great risk for clot (thrombus) formation after a fracture, especially a hip fracture. VTE may occur after total hip or total knee replacement

surgery. In patients with limited mobility, inactivity of muscles that normally help pump venous blood from the extremities to the heart worsens venous stasis.

Because of the high risk for VTE in the orthopedic surgical patient, prophylactic anticoagulant drugs should be given for at least 10 to 14 days.[12] The most common agents used include (1) warfarin (Coumadin), (2) low-molecular-weight heparin (LMWH) (e.g., enoxaparin [Lovenox], fondaparinux), (3) aspirin, or (4) a factor Xa inhibitor (e.g., rivaroxaban [Xarelto], apixaban).[12] Have the patient dorsiflex and plantar flex the ankle of an affected lower extremity against resistance and perform ROM exercises on the unaffected leg. For upper extremity injuries, have the patient flex and extend the wrist if not immobilized by a cast or splint and perform ROM exercises on the unaffected arm. They may wear compression gradient stockings (antiembolism hose) or using intermittent pneumatic compression devices.[12] VTE is discussed in Chapter 41.

SAFETY ALERT

Anticoagulant Therapy

- Monitor for signs of bleeding (e.g., nosebleeds, hematuria).
- Teach patient signs of bleeding and what to do if bleeding occurs.
- Teach patient safe self-injection if taking an injectable anticoagulant after discharge.
- Encourage patient to keep appointments for laboratory testing to monitor effects of warfarin (if prescribed).

Fat Embolism Syndrome

Fat embolism syndrome (FES) is characterized by fat globules entering the circulatory system from fractures. They collect in areas with abundant blood vessels, especially the lungs and brain. FES contributes to mortality from fractures. The fractures most often associated with FES are those of the long bones, ribs, tibia, and pelvis. FES can occur after joint replacement, burns, pancreatitis, liposuction, crush injuries, and bone marrow transplantation.[13]

Two theories about FES exist. According to the mechanical theory, fat emboli originate from fat released from the marrow of injured bone. The fat enters systemic circulation, where it travels to other organs. As fat droplets become stuck in small blood vessels, local ischemia and inflammation occur. The biochemical theory suggests hormonal changes caused by trauma or sepsis stimulate systemic release of free fatty acids (e.g., chylomicrons) that form the fat emboli.

Clinical Manifestations

Early recognition of FES is crucial to prevent patient death. Most patients have symptoms within 24 to 48 hours after injury.[13] Severe forms have occurred within hours of injury. Fat emboli in the lungs cause hemorrhagic interstitial pneumonitis with signs and symptoms of acute respiratory distress syndrome (ARDS). These include chest pain, tachypnea, cyanosis, dyspnea, apprehension, tachycardia, and hypoxemia. These symptoms are caused by poor O_2 exchange. Changes in mental status due to hypoxemia are common. Petechiae on the neck, anterior chest wall, axilla, and head may help discern FES from other problems.[13] They may appear due to intravascular thromboses caused by decreased oxygenation. However, not all patients have petechiae. They may fade before they are noticed.

The clinical course of FES may be rapid and acute. In a short time, skin color can change from pallor to cyanosis. The patient may become comatose. No specific laboratory tests aid in the diagnosis. However, certain abnormalities may be present. These include fat cells in blood, urine, or sputum; a decrease of PaO_2 to less than 60 mm Hg; decreased platelet count and hematocrit; and high erythrocyte sedimentation rate (ESR). The ECG may show ST segment and T-wave changes. A chest x-ray may show bilateral pulmonary infiltrates.

Interprofessional care. Management of FES is supportive and related to managing symptoms. The patient needs appropriate respiratory support (see Chapter 28). Administer O_2 to treat hypoxia. ECMO or mechanical ventilation may be an option if a satisfactory PaO_2 cannot be obtained. Some patients develop pulmonary edema and/or ARDS, leading to increased mortality. Most persons survive FES with few complications.

Cardiovascular problems are often managed with IV fluids, pulmonary vasodilators, peripheral vasoconstrictors, and inotropic drugs. There is currently no research supporting the use of steroids, heparin, or dextran in the treatment of FES.[13]

Preventing FES is important. Careful immobilization and handling of a long bone fracture are the most important factors in preventing FES. Reposition the patient as little as possible before fracture immobilization or stabilization to decrease the risk of dislodging fat droplets into the general circulation.

CHECK YOUR PRACTICE

You are caring for a 24-year-old male patient who had a femur fracture in a motorcycle accident last night. He is scheduled for ORIF later today. While doing your assessment, you notice that he seems very restless. You note some axillary petechiae.

- What complication would you suspect is occurring?
- Why is this patient at risk for this complication?
- What is the most important intervention for a patient with this complication?

Rhabdomyolysis

Rhabdomyolysis is a syndrome caused by the breakdown of damaged skeletal muscle cells. This breakdown causes the release of myoglobin into the bloodstream. Myoglobin precipitates and causes obstruction in renal tubules. This results in acute tubular necrosis and acute kidney injury (AKI). Because of possible muscle damage, assess urine output. Common signs are dark reddish-brown urine and symptoms of AKI (see Chapter 51).

TYPES OF FRACTURES

COLLES FRACTURE

A *Colles fracture* is a fracture of the distal radius. The styloid process of the ulna may be involved as well. The injury usually occurs when the patient falls on an outstretched arm and hand.

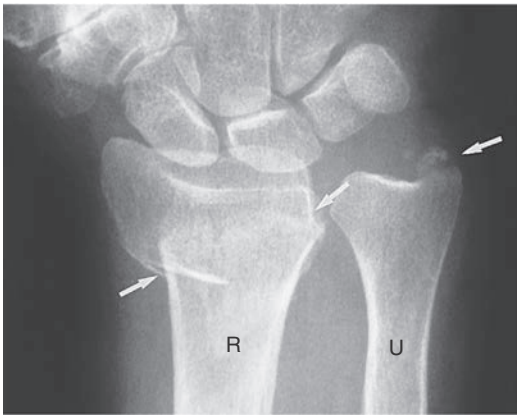

Fig. 67.16 Colles' fracture. Fracture of the distal radius *(R)* and ulnar *(U)* styloid from patient falling on the outstretched hand. (From Mettler FA: *Essentials of radiology,* ed 2, Philadelphia, 2005, Saunders.)

It is one of the most common types of fractures in adults. It most often occurs in patients over 50 years old whose bones are osteoporotic *(fragility fracture)* (Fig. 67.16). A younger person with a Colles' fracture caused by a low-energy force should be referred for an osteoporosis evaluation.

Symptoms include pain in the immediate area of injury, pronounced swelling, and dorsal displacement of the distal fragment (silver-fork deformity). This displacement appears as an obvious deformity of the wrist. The major complication is vascular insufficiency from edema. CTS can be a later complication.

A Colles' fracture is usually managed with closed reduction of the fracture and applying a splint or cast. If displaced, the fracture is typically managed with open reduction and internal or external fixation. Nursing care includes frequent neurovascular assessment and measures to reduce edema. Provide support and protect the extremity. Encourage active movement of the thumb and fingers to reduce edema and increase venous return. Teach the patient to perform active movements of the shoulder to prevent stiffness or contracture.

HUMERAL SHAFT FRACTURE

Fractures involving the shaft of the humerus are common among young and middle-aged adults. The most common symptoms are obvious displacement of the humeral shaft, shortened extremity, abnormal mobility, and pain. Complications include radial nerve injury and injury to the brachial artery due to laceration, transection, or muscle spasm.

Treatment depends on the specific fracture location and displacement. Nonoperative treatment may include a hanging arm cast, shoulder immobilizer, sling and swathe (a type of immobilizer that prevents shoulder movement), or humeral cuff brace (Fig. 67.17).

The humeral cuff brace is typically used to stabilize mid-shaft humerus fractures. Two pieces of molded plastic are fitted together in a clam-shell configuration and held together with Velcro straps. The humeral cuff brace is a good option for nonoperative fracture management if the patient is at increased risk for complications.

When these devices are used, elevate the head of the bed to assist gravity in reducing the fracture. Allow the arm to hang

Fig. 67.17 Humeral cuff brace. (Courtesy Matthew C. Price, MS, RN, CNP, ONP-C, RNFA, Columbus, OH.)

freely when the patient is sitting or standing. Provide measures to protect the axilla and prevent skin breakdown. Carefully place absorbable composite dressing pads (e.g., ABD pads) in the axilla. Change them twice daily or as needed. Skin or skeletal traction may be used for reduction and immobilization.

During the rehabilitative phase, an exercise program to improve strength and motion of the injured extremity is important. Exercises should include assisted motion of the hand and fingers. The shoulder can be exercised if the fracture is stable. This helps prevent stiffness from frozen shoulder or fibrosis of the shoulder capsule.

CLAVICULAR FRACTURE

The clavicle is a frequently broken bone in children and young adults. Midshaft fractures account for 85% of all clavicle fractures. Injury is usually the result of a fall. Less often it happens from direct trauma to the bone. Common manifestations include pain at the fracture site, with or without obvious deformity, and limited shoulder range of motion. The patient often supports the affected side with the other hand and tilts the head toward the side of the fracture.

Most patients do not need surgery. Surgery is usually done only if the fracture is open. Treatment is aimed at maintaining comfort with splinting, ice, and analgesics. PT includes early ROM and strength exercises. Most clavicle fractures heal without complications. Contact sports should be avoided for 8 to 10 weeks.

PELVIC FRACTURE

Pelvic fractures range from relatively minor to life threatening, depending on the mechanism of injury and associated vascular

BOX 67.4 ETHICAL/LEGAL DILEMMAS

Entitlement to Treatment

Situation

D.C., a 35-year-old English tourist, was in a hang-gliding accident while touring the United States. She was taken to the regional trauma center for treatment of internal injuries, blood loss, and severe pelvic fractures. She has become septic, is now in renal failure, and has ARDS. She has no health insurance. Despite a poor chance of survival, her husband and parents want all possible measures to be taken.

Ethical/Legal Points for Consideration

- Federal law requires hospitals receiving federal funds through Medicare and Medicaid to provide emergency evaluation and treatment to stabilize patients (Emergency Medical Treatment and Active Labor Act [EMTALA]). Once the patient is stabilized, they are under no obligation to continue treatment and may transfer the patient to another facility.
- Discuss with the family treatment goals (e.g., recovery, survival, continued biologic existence, nonabandonment of the patient) and what they mean by wanting "everything done." There is no legal or ethical obligation to continue medical treatment when treatment goals cannot be met.
- Contact with the English consulate may result in collaboration to stabilize the patient and transport her to England.
- Neither HCPs nor hospitals are required to provide medically futile care (care that provides no benefit to the patient).
- Although her home country offers universal health care, D.C. assumed the risk when engaging in a potentially dangerous activity and did not obtain international health insurance coverage for her visit to a foreign country.

Discussion Questions

1. How can the nurse promote discussions with the family about treatment goals for D.C.?
2. Are family members able to state D.C.'s wishes for her own care in such a situation?

damage. They account for only 3% of adult fractures. Pelvic fractures have a high mortality rate. They may cause serious intraabdominal injury, including laceration and hemorrhage of the urethra, bladder, or colon. They can cause acute pelvic compartment syndrome. Paralytic ileus may occur after pelvic fracture. Patients may survive the pelvic injury, only to die from sepsis, FES, or VTE.

Abdominal assessment may show local swelling, tenderness, deformity, unusual pelvic movement, and bruising. Assess the neurovascular condition of the lower extremities and determine associated injuries. Pelvic fractures are diagnosed by x-ray and CT scan.

Treatment depends on the severity of the injury. Stable, nondisplaced fractures require little intervention. Ambulation with weight bearing as tolerated is typically encouraged. Complex or displaced fractures (e.g., open book fracture) need external fixation alone or combined with ORIF (e.g., screws), often done emergently. Use extreme care in handling or moving the patient, to prevent further injury. Because a pelvic fracture can damage other organs, assess bowel and urinary elimination. Regularly perform distal neurovascular assessment. Provide back care with adequate help or while the patient is raised from the bed by independent use of a trapeze (Box 67.4).

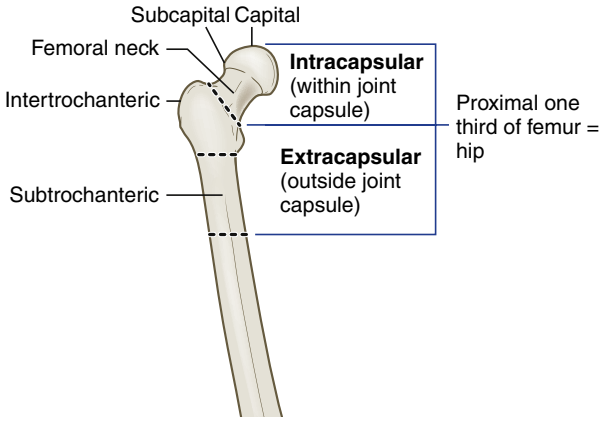

Fig. 67.18 Femur with location of various types of fracture.

HIP FRACTURE

Hip fractures are common in older adults. 95% of hip fractures result from a fall.[14] Many falls occur when getting in or out of a chair or bed. Falls to the side are the most common type seen in frail older adults. More than 300,000 patients are admitted to hospitals each year because of a hip fracture. Up to 37% of those patients die within 1 year of injury. Many older adults develop disabilities that require long-term care. Women suffer 75% of all hip fractures. In adults over 65 years old, hip fracture occurs more often in women because of osteoporosis.

Older adults may have low bone density *(osteopenia)* or osteoporosis, which increases their risk for fragility fractures. Other factors that increase the risk for a hip fracture in older adults include (1) increased risk for falling due to an altered center of gravity and inability to correct a postural imbalance, (2) decreased fat and muscle to act as local tissue shock absorbers, and (3) reduced skeletal strength. Other factors that increase the older adult's risk for falling include (1) gait and balance problems, (2) altered vision and hearing, (3) slowed reflexes, (4) orthostatic hypotension, and (5) medication use.

Hip fracture refers to a fracture of the proximal (upper) third of the femur, which extends 5 cm below the lesser trochanter (Fig. 67.18). Fractures within the hip joint capsule are *intracapsular fractures.* Intracapsular fractures are further identified by their specific locations: (1) *capital* (fracture of the head of the femur), (2) *subcapital* (fracture just below the head of the femur), and (3) *transcervical* (fracture of the femoral neck). These fractures, which are often associated with osteoporosis and minor trauma, are *fragility fractures.*

Extracapsular fractures occur outside the joint capsule. They are either (1) *intertrochanteric* (in a region between the greater and lesser trochanter) or (2) *subtrochanteric* (below the lesser trochanter). Most are caused by severe direct trauma or a fall.

Clinical Manifestations

Manifestations include external rotation, muscle spasm, shortening of the affected extremity, and severe pain and tenderness around the fracture site. Displaced femoral neck fractures may disrupt blood supply to the femoral head, resulting in avascular necrosis of the femoral head.

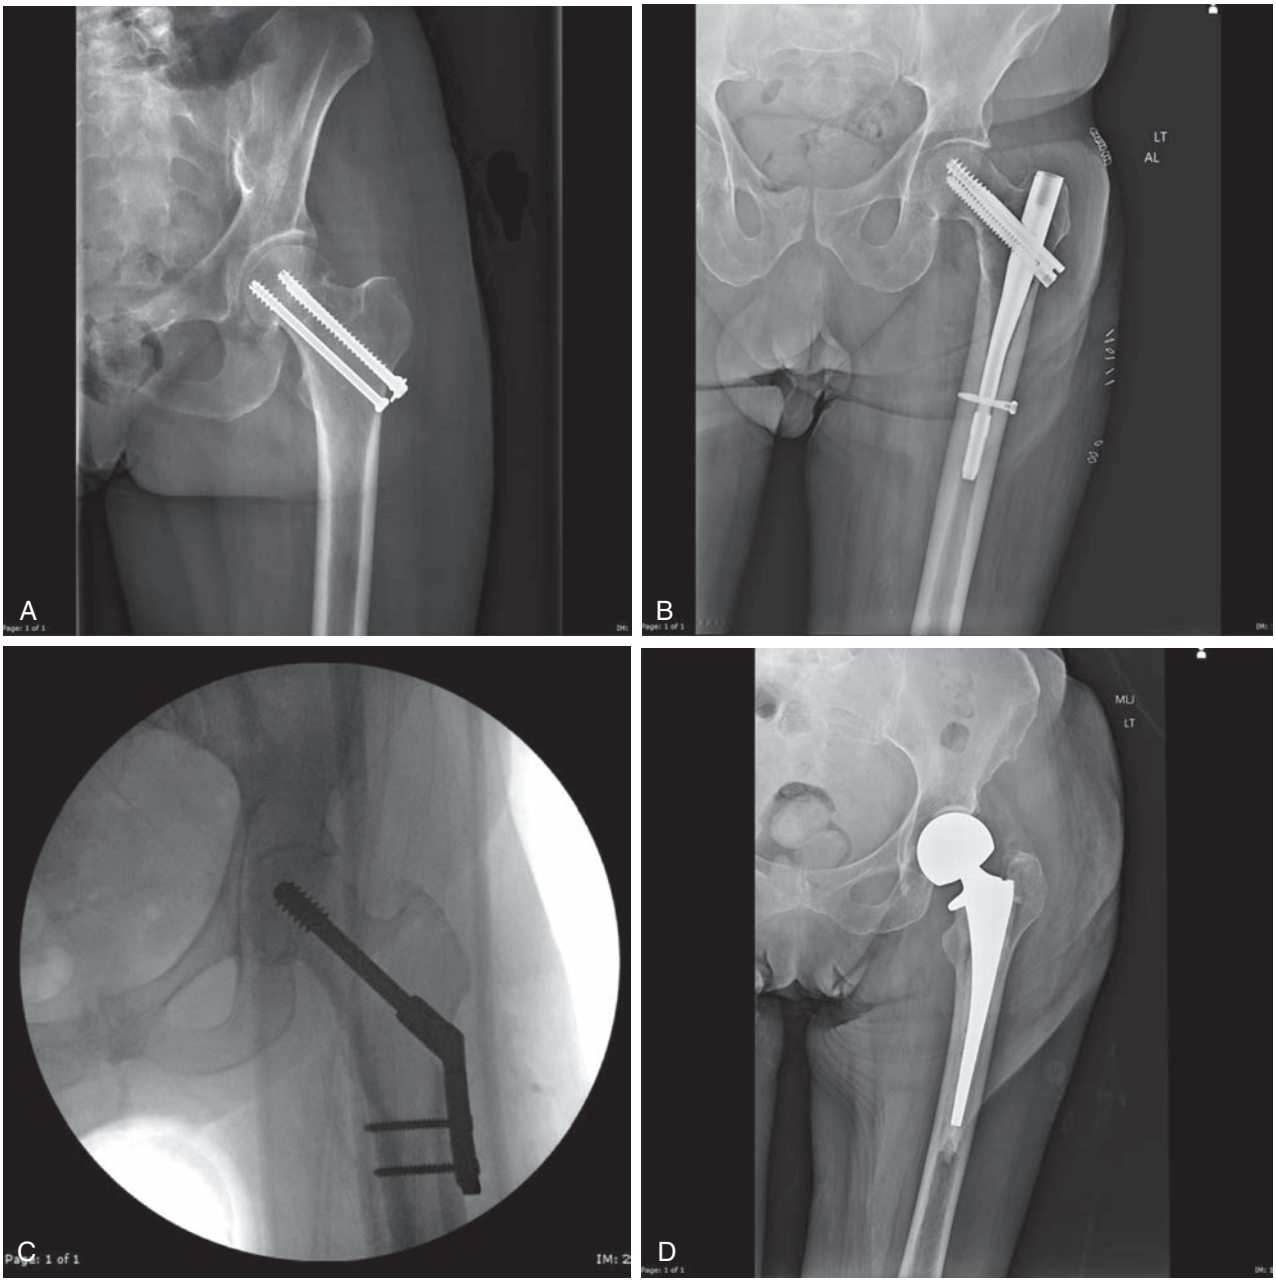

Fig. 67.19 Types of surgical repair for a hip fracture: (A) Closed reduction with percutaneous pinning. (B) Intramedullary nail. (C) Sliding hip screw. (D) Hemiarthroplasty. (Courtesy Matthew C. Price, MS, RN, CNP, ONP-C, RNFA, Columbus, OH.)

Interprofessional Care

Immediate surgery is the standard of care. Initially we may immobilize the affected extremity with Buck's traction (Fig. 67.9) if the patient's physical condition needs stabilized before they can have surgery. Buck's traction may be used for 24 to 48 hours to relieve painful muscle spasms.

Surgical treatment allows for early mobilization and decreases the risk for complications. The type of surgery depends on the location and severity of the fracture and the person's age. Options include (1) closed reduction with percutaneous pinning (CRPP) (minimally invasive surgery to stabilize the femoral neck and head with screws), (2) repair with internal fixation devices (e.g., hip compression screw, intramedullary devices), (3) replacement of the femoral head with a prosthesis (partial hip replacement or *hemiarthroplasty*, often used for fracture of the femoral neck) (Fig. 67.19), and (4) total hip replacement (involves both the femur and acetabulum) (Fig. 67.20).

❖ NURSING MANAGEMENT: HIP FRACTURE

◆ Implementation

◆ Preoperative Care

In addition to the usual preoperative nursing care (see Chapter 18), we may do teaching in the ED. Most patients do not have an extended preoperative period in which to receive instructions. Many are older adults. When planning treatment of the hip

Fig. 67.20 Total hip replacement (arthroplasty) with cementless femoral prosthesis of metal alloy with plastic acetabular socket.

fracture, consider the presence of any chronic health problems (e.g., diabetes, heart disease). We may have to delay surgery briefly until the patient's general health is stabilized. Begin to consider discharge plans because the length of stay after surgery will be no more than a few days.

Before surgery, severe muscle spasms can increase pain. Analgesics or muscle relaxants, comfortable positioning (unless contraindicated), and properly applied traction (if used) can help to manage the spasms.

Postoperative Care

Similar principles of patient care apply to any surgical procedure for hip fractures. In the initial postoperative period, assess vital signs, intake, and output. Monitor respiratory function and encourage deep breathing and coughing. Assess pain and give pain medication. Observe the dressing and incision for signs of bleeding. See eNursing Care Plan 67.2 for the orthopedic surgical patient (available on the website for this chapter).

Neurovascular impairment is possible. Assess the extremity for (1) color, (2) temperature, (3) capillary refill, (4) distal pulses, (5) edema, (6) sensation, (7) motor function, and (8) pain. Decrease edema by elevating the leg when the patient is in bed or in a chair. Pain in the affected extremity can be reduced by maintaining limb alignment with pillows between the patient's knees when turning the patient to the nonoperative side.

Encourage the patient to use the overhead trapeze bar and the opposite side rail to help in position changes. Avoid turning the patient to the affected side unless approved by the HCP. Have the patient exercise the unaffected leg and both arms.

Weight bearing on the involved extremity varies. Limited weight bearing is typically the only restriction for the patient who had ORIF of the hip fracture. The restriction continues until x-rays show adequate healing, usually 6 to 12 weeks. Teach the patient and caregiver about weight-bearing status after surgery.

The physical therapist usually supervises exercises for the affected extremity and ambulation when the HCP allows it. The patient is usually out of bed the first postoperative day. A physical therapist can teach the patient how to transfer out of the bed to a chair. In collaboration with the physical therapist, monitor the patient's ambulation for proper use of crutches or a walker. To be discharged home, the patient must show proper use of crutches or a walker over a functional distance (about 150 ft). The patient must be able to transfer to and from a chair and bed and to go up and down stairs.

If hemiarthroplasty or total joint replacement was done by a *posterior approach* (incision posterior to the midline of the greater trochanter down the femoral shaft), measures to prevent dislocation must be used (Table 67.12). Tell the patient and caregiver about positions and activities that increase the risk for dislocation (more than 90 degrees of flexion, adduction across the midline [crossing of legs and ankles], internal rotation of hip). Many daily activities reproduce these positions. These include (1) putting on shoes and socks, (2) crossing the legs or feet while seated, (3) assuming the side-lying position incorrectly, (4) standing up or sitting down while the hip is flexed more than 90 degrees relative to the chair, and (5) sitting on low seats, especially low toilet seats. Teach the patient to avoid these activities until the soft tissue capsule around the hip has healed enough to stabilize the prosthesis (usually at least 6 weeks).

Elevated toilet seats and chair alterations (e.g., raising the seat with a folded blanket, keeping a straight back) are needed. Avoid placing a soft pillow in a seat because sitting on it can cause internal rotation. If a foam abduction wedge is ordered to prevent joint dislocation, place it between the patient's legs (Fig. 67.21). Apply the top straps above the knee to avoid putting pressure on the peroneal nerve at the lateral tibial tubercle. Some HCPs want the patient to keep the abductor wedge in place except when bathing or walking.

TABLE 67.12 PATIENT & CAREGIVER TEACHING

Posterior Hip Replacement

After a hip replacement by posterior surgical approach, include the following instructions when teaching a patient and caregiver:

Do

- Use an elevated toilet seat.
- Place chair inside shower or tub and remain seated while washing.
- Use pillow between legs for first 6 weeks when lying on nonoperative side or when supine.
- Keep hip in neutral, straight position when sitting, walking, or lying.
- Notify HCP at once if severe pain, deformity, or loss of function occurs.
- Discuss personal risk factors for prosthetic joint infection with HCP and dentist before dental work.

Do Not

- Flex hip greater than 90 degrees (e.g., sitting in low chairs or toilet seats).
- Adduct hip (e.g., bring legs together at knees).
- Internally rotate hip (e.g., turn toward planted foot on affected side).
- Cross legs at knees or ankles.
- Put on own shoes or stockings without adaptive device (e.g., long-handled shoehorn or stocking-helper) for 4–6 weeks.
- Sit on chairs without arms. The arms of chairs will help the patient rise to a standing position.

Fig. 67.21 Maintaining abduction after total hip replacement. (Courtesy Mary Wollan, RN, BAN, ONC, Spring Park, MN.)

If hemiarthroplasty or total joint replacement was done by an *anterior approach* (incision is made in the front of the hip with patient lying on the back), the hip muscles are left intact. This approach provides a more stable hip in the postoperative period with a lower rate of complications. Precautions related to motion and weight bearing are few. They typically include instructions to avoid hyperextension.

The patient may not take a tub bath or drive for 4 to 6 weeks. An occupational therapist (OT) may teach the patient to use assistive devices, such as long-handled shoehorns, sock assists, and reachers or grabbers, to avoid bending over to pick up something on the floor. The knees must be kept apart. Teach the patient to never cross the legs or twist to reach behind.

Complications of femoral neck fracture include nonunion, avascular necrosis, dislocation, and osteoarthritis (OA). The affected leg may be shorter if the patient had an intertrochanteric fracture. A cane or shoe lift may be needed for safe ambulation.

Sudden severe pain, a lump in the buttock, limb shortening, and external rotation indicate prosthesis dislocation. This requires closed reduction with moderate to deep sedation or open reduction under general anesthesia to realign the femoral head in the acetabulum. If any of these signs occur (regardless of the setting), keep the patient NPO in anticipation of surgical intervention.

Help the patient and caregiver to adjust to restrictions and dependence because of the hip fracture. Anxiety and depression can easily occur. Creative nursing care and awareness of potential problems can help to prevent them. Tell the patient and caregiver about community services that can help with rehabilitation after hospital discharge.

CHECK YOUR PRACTICE

You are taking care of an 83-year-old patient who fell down the steps outside her house while getting her mail. She was diagnosed with a femoral neck fracture and Colles' fracture. She is returning to the clinical unit after surgery. She had a hemiarthroplasty for the femoral neck fracture and closed reduction of the Colles' fracture.

- Based on these injuries, what are some possible complications?
- How will you mobilize a patient with these injuries?
- What are your discharge concerns?

Ambulatory Care

Hospitalization averages 3 or 4 days. Older adults or patients who live alone may require care in a subacute rehabilitation unit, at a skilled nursing facility, or in an acute rehabilitation facility for a few weeks before returning home. If the patient has skilled nursing needs or is homebound for PT after discharge from postacute care, the HCP may order follow-up home health care.

Home care considerations include ongoing assessment of pain management, monitoring for infection, and VTE prevention. If incision is closed with metal staples, they will be removed at the HCP's office. Teach the patient who is receiving an anticoagulant to report signs of bleeding to the HCP (see Chapter 41). Review how to administer an injectable anticoagulant (if needed). Teach the patient receiving warfarin about required laboratory testing.

Exercises to restore strength and tone in the quadriceps and muscles around the hip are essential to improve function and ROM. These include quadriceps setting (e.g., pressing the kneecap down), gluteal muscle setting (e.g., tightening the buttocks), leg raises in supine and prone positions, and abduction exercises from the supine and standing positions (e.g., swinging the leg out but never crossing midline). The patient continues these exercises for many months after discharge. Teach the exercise program to the caregiver who will be encouraging the patient at home.

A physical therapist assesses ROM, ambulation, and adherence to the exercise program. The patient gradually increases the number of exercise repetitions and may add ankle weights. Swimming and stationary cycling may tone quadriceps and improve cardiovascular fitness. Teach the patient to avoid high-impact exercises and sports, such as jogging and tennis, because they may loosen the implant.

A physical therapist or home care nurse may perform a home assessment to identify hazards that may cause the patient to fall again. Homes can be made safer by (1) eliminating tripping hazards (e.g., throw rugs, uneven surfaces), (2) adding grab bars inside and outside the tub or shower, and beside the toilet, (3) adding railings on both sides of the stairs, and (4) installing better lighting.[14]

Calcium and vitamin D supplementation are given to patients with osteopenia or osteoporosis. A bisphosphonate drug (e.g., alendronate) may be prescribed to decrease bone loss or increase bone density. This reduces the chance of fracture. Osteoporosis is discussed in Chapter 68.

Evaluation

The expected outcomes are that the patient with a hip fracture will:

- Report satisfactory pain management
- Have uncomplicated bone healing
- Take part in exercise therapy

FEMORAL SHAFT FRACTURE

Because the femur can bend slightly to absorb stress, femoral shaft fracture occurs from a severe direct force. The force exerted to cause the fracture (e.g., from a motor vehicle crash

or gunshot wound) often also damages the adjacent soft tissue. These injuries may be more serious than the bone injury. Young adults have a high incidence of this type of fracture.

Displacement of fracture fragments often causes increased soft tissue damage. Considerable blood loss (1 to 1.5 L) can occur. The most common types of femoral shaft fracture include transverse, spiral, comminuted, oblique, and open (Figs. 67.6 and 67.7).

A femoral shaft fracture is marked by pain, notable deformity and angulation, shortening of the extremity, and inability to move the hip or knee. Complications include FES; nerve and vascular injury; and problems with bone union, open fracture, and soft tissue damage.

Initial management involves patient stabilization and fracture immobilization. Traction may be used as a temporary measure before surgery or in the patient unable to have surgery. Placement of an *intramedullary rod* is the most common surgical treatment for femoral shaft fracture. The metal rod is placed into the marrow canal of the femur. The rod passes across the fracture to keep fragments in position. Plates and screws also may be used. Internal fixation is preferred. It reduces the hospital stay and complications of prolonged bed rest. External fixation may be used for an open fracture.

After surgery, gluteal and quadriceps isometric exercises promote and maintain strength in the affected extremity. Encourage the patient to perform ROM and strength exercises for all uninvolved extremities to prepare for ambulation. The patient may be allowed to start non–weight-bearing activities with an assistive device (e.g., walker, crutches). Full weight bearing is usually restricted until x-rays show union of fracture fragments. Teach the patient to follow the HCP's instructions for weight bearing.

TIBIAL FRACTURE

Although the tibia is vulnerable to injury because it lacks a covering of anterior muscle, strong force is needed to cause a fracture. As a result, soft tissue damage, devascularization, and open fracture are common. The tibia is a common site for stress fracture. Complications include compartment syndrome, FES, delayed union or nonunion, and possible infection with an open fracture.

Treatment for closed tibial fractures is closed reduction followed by immobilization in a long leg cast. ORIF with intramedullary rods, plate fixation, or external fixation is needed for complex fractures and those with extensive soft tissue damage. An emphasis of care is maintaining quadriceps strength.

Assess the neurovascular condition of the affected extremity at least every 2 hours during the first 48 hours. Have the patient perform active ROM exercises with the uninvolved leg and the upper extremities to build the strength needed for crutch walking. When the HCP has determined the patient is ready for gait training, review principles of crutch walking introduced by the physical therapist. The patient may be non–weight bearing for 6 to 12 weeks, depending on healing. Home nursing visits may be needed to monitor the patient's progress if the patient is homebound.

STABLE VERTEBRAL FRACTURE

In a stable vertebral fracture, the fracture fragments are unlikely to move or cause spinal cord damage. This injury is often confined to the vertebral body (anterior part of the spinal column) in the lumbar region. Sometimes it involves the cervical and thoracic regions. Vertebral bodies are usually protected from displacement by intact spinal ligaments. Stable fractures of the vertebral column are usually caused by motor vehicle crashes, falls, diving, or sports injuries. Patients with osteoporosis have more than 700,000 vertebral compression fractures annually, many of which are stable.

Most patients with stable fractures have only brief periods of disability. If spinal ligaments are significantly disrupted, dislocation of the vertebrae may occur. Instability and injury to the spinal cord may result (unstable fracture). These injuries often require surgery. The most serious complication of vertebral fractures is fracture displacement, which can cause damage to the spinal cord (see Chapter 65). Although stable vertebral fractures are not associated with abnormal spinal cord pathology, all spinal injuries should be considered unstable and potentially serious until diagnostic tests determine the fracture to be stable.

The patient usually has pain and tenderness in the affected region of the spine. There may be a kyphotic deformity (flexion angulation of thoracic vertebrae) known as a *dowager's hump.* We can easily identify this deformity during the physical assessment (see Fig. 68.9). *Lordosis* and cervical spine involvement are possible. Sudden loss of function below the fracture indicates spinal cord impingement and paraplegia. Bowel and bladder problems may occur if there is interruption of the autonomic nervous system nerves or injury to the spinal cord.

The overall goal is to keep the spine in good alignment until union is achieved. Many nursing interventions are aimed at assessing for spinal cord trauma (see Chapter 65). Regularly evaluate vital signs and bowel and bladder function. Monitor the motor and sensory function of peripheral nerves distal to the injured region. Report any decline in neurovascular condition.

Treatment includes pain medication followed by early mobilization and bracing. The mattress should be firm to support the spinal column, relax muscles, decrease edema, and prevent potential compression on nerve roots. Teach the patient to keep the spine straight when turning by moving the shoulders and pelvis together. The patient will need to learn to logroll. Several days after the initial injury, the HCP may apply a specially constructed orthotic device (e.g., thoracolumbar sacral orthosis [TLSO]), a jacket cast, or a removable corset if there is no neurologic deficit. The device gives extra support during healing. It is used for a short period of time.

Lightweight bracing (e.g., Jewett or Bähler-Vogt brace) may be used for patients with stable vertebral compression fractures due to osteoporosis. Patients with osteoporosis may undergo vertebroplasty or balloon kyphoplasty. *Vertebroplasty* uses radioimaging to guide the injection of bone cement into a fractured vertebral body. When hardened, the cement stabilizes the vertebra and prevents further compression. *Balloon kyphoplasty* involves inserting a balloon into the vertebral body and then inflating it. This creates a cavity that is filled with bone cement

under low pressure to restore the height of the vertebral body. Kyphoplasty is now the surgery of choice for compression fractures. This is due to the decreased incidence of bone cement leakage into nearby structures (e.g., colon, lung) compared to vertebroplasty. Patients have decreased pain almost at once with these procedures. However, later compression fractures of adjacent vertebrae are a risk.

If the fracture is in the cervical spine, the patient may wear a hard cervical collar. Some cervical fractures are immobilized with a halo vest (see Fig. 65.8). This consists of a plastic jacket or cast fitted about the chest and attached to a halo held in place by skeletal pins inserted into the cranium. These devices immobilize the spine in the fracture area while allowing the patient to ambulate.

The patient with a stable vertebral fracture is discharged after (1) showing safe ambulation, (2) learning care of the cast or orthotic device, and (3) stating ways to address safety and security concerns related to the injury and treatment. Unstable vertebral fractures and spinal cord injuries are the subject of Chapter 65.

FACIAL FRACTURE

A person can fracture any bone of the face. Trauma, such as a motor vehicle crash, assault, or fall, is a common cause. After facial injury it is important to establish and maintain a patent airway and provide adequate ventilation. Suctioning may be needed to remove foreign material and blood. A surgically created airway *(tracheostomy)* may be needed if a patent airway cannot be maintained.

Facial fractures and cervical spine injuries often occur together. All patients with facial injuries should be treated as if they have a cervical injury until proven otherwise by assessment and CT scan or x-ray. Table 67.13 describes clinical manifestations of common facial fractures.

Related soft tissue injury often makes assessment of facial injury difficult. Perform oral and facial assessments after we have treated any life-threatening situations. Carefully assess eye muscles and cranial nerves III, IV, and VI. X-rays help determine the extent of the injury. CT scanning helps discern between bone and soft tissue injury.

Suspect injury to the eye when facial injury occurs, especially if the injury is near the orbit. If an eye-globe rupture is suspected, stop and place a protective shield over the eye. Signs of rupture include vitreous humor forced out of the eye. Brown tissue (iris or ciliary body) may be seen on the surface of the globe or penetrating through a laceration, with an off-center or teardrop-shaped pupil.

Specific treatment depends on the site and extent of the facial fracture and associated soft tissue injury. Immobilization or surgical stabilization may be needed. Maintain a patent airway and adequate nutrition throughout the recovery period.

Be sensitive about changes in appearance that may occur after facial fracture. Changes in appearance may be drastic. Edema and discoloration subside with time, but soft tissue injuries can cause permanent scarring.

MANDIBULAR FRACTURE

Mandibular fracture may result from trauma to the face or jaw. The fracture may be simple, with no bone displacement, or may involve loss of tissue and bone. Mandibular fracture may need immediate treatment to ensure the patient's survival. Long-term treatment is sometimes needed to restore satisfactory appearance and function.

Mandibular fractures may be done therapeutically to correct an underlying alignment problem *(malocclusion)* that cannot be adjusted by orthodontics alone. The mandible is resected during surgery and manipulated forward or backward to correct the occlusion problem.

Surgery includes immobilization, usually by wiring the jaws *(intermaxillary fixation)*. Internal fixation may be done with screws and plates. In a simple fracture with no loss of teeth, the lower jaw is wired to the upper jaw. Wires are placed around the teeth, and then cross-wires or rubber bands are used to hold the lower jaw tight against the upper jaw (Fig. 67.22). Arch bars may be placed on the maxillary and mandibular arches of the teeth. Vertical wires placed between the arch bars hold the jaws together. If teeth are missing or bone is displaced, other forms of fixation may be needed (e.g., metal arch bars in the mouth or insertion of a pin in the bone). Bone grafting may be needed. Immobilization is usually needed for only 4 to 6 weeks because the fractures often heal rapidly.

TABLE 67.13 Manifestations of Facial Fractures

Fracture	Manifestation
Frontal bone	Rapid edema that may mask underlying fractures
Mandible	Tooth fractures, bleeding, limited motion of mandible
Maxilla	Segmental motion (instability) of maxilla and tooth fracture at socket
Nasal bone	Displacement of nasal bones, nosebleed *(epistaxis)*
Periorbital bone	Possible frontal sinus involvement, entrapment of ocular muscles
Zygomatic arch	Depression of cheek bone *(zygomatic arch)* and entrapment of ocular muscles

Fig. 67.22 Intermaxillary fixation. (Courtesy R.A. Weinstein, Denver, CO.)

❖ NURSING MANAGEMENT: MANDIBULAR FRACTURE

Teach the patient before surgery about what is involved in the surgery, how their face will look afterward, and changes caused by the surgery. Reassure the patient about the ability to breathe normally, speak, and swallow liquids. Hospitalization for respiratory monitoring is brief unless there are other injuries or problems.

Postoperative care focuses on a patent airway, oral hygiene, communication, pain management, and adequate nutrition. Two potential problems in the immediate postoperative period are airway obstruction and aspiration of vomitus. Because the patient cannot open the jaws, an airway must be maintained. Observe for signs of respiratory distress (e.g., dyspnea; changes in rate, quality, and depth of respirations). After surgery place the patient on the side with the head slightly elevated.

Tape a wire cutter or scissors (for rubber bands) to the head of the bed. Send it with the patient when they are away from the bedside. The wire cutter or scissors may be used to cut the wires or elastic bands in case of an emergency requiring access to the pharynx or lungs (e.g., cardiac arrest or respiratory distress). Keep a picture nearby showing the appropriate wires to cut in an emergency. In some cases, cutting the wires may cause the entire facial and upper jaw structure to shift or collapse and worsen the problem. Keep a tracheostomy or endotracheal tray available.

If the patient begins to vomit or choke, try to clear the mouth and airway. Suction via the nasopharyngeal or oral route, depending on the extent of injury and type of repair. An NG tube can remove fluids and gas from the stomach to help prevent vomiting and aspiration. The NG tube can later be used as a feeding tube. Antiemetics may be given. Teach the patient to clear secretions and vomitus.

Oral hygiene is important. Teach the patient to remove food debris by rinsing the mouth often, especially after meals and snacks. Warm normal saline solution, water, or alkaline mouthwashes may be used. A syringe and soft irrigation catheter or a Water Pik may be effective for thorough oral cleansing. Inspect the mouth several times a day to see that it is clean. Use a tongue depressor to retract the cheeks. Keep the lips, corners of the mouth, and buccal mucosa moist. Cover any sharp edges of the wires with dental wax to prevent irritation of the buccal mucosa.

Communication may be a problem, especially in the early postoperative period. Establish an effective way of communicating before surgery (e.g., dry erase board, texting). The patient can usually speak well enough to be understood within a few days after surgery.

Adequate nutrition may be a challenge because the diet must be liquid. The patient easily tires of sucking through a straw or laboriously using a spoon. Work with the dietitian and patient to plan a diet with adequate calories, protein, and fluids. Liquid protein supplements may improve nutrition. The low-bulk, high-carbohydrate diet and intake of air through the straw contribute to constipation and gas. Ambulation, prune juice, and bulk-forming laxatives may help relieve these problems.

The patient is usually discharged with the wires in place. Encourage the patient to share feelings about the changes in appearance. Discharge teaching should include oral care, diet, how to handle secretions, how and when to use wire cutters or scissors, and when to notify the HCP.

AMPUTATION

An **amputation** is the removal of a body extremity by trauma or surgery. About 2 million Americans live with limb loss.[15] About 185,000 amputations occur each year in the United States. Just over half are due to PVD and diabetes. These patients often have peripheral neuropathy that progresses to deep ulcers and gangrene. Trauma is the other major cause. Injuries have affected over 1700 military veterans since 2003, with several losing more than 1 limb.[16] Other reasons for amputation include thermal injuries, tumors, osteomyelitis, and congenital limb disorders.

Diagnostic Studies

Diagnostic studies depend on the underlying reason for the amputation (Table 67.14). An increased white blood cell (WBC) count with abnormal differential may show infection. Vascular tests such as arteriography, Doppler studies, and venography give information about circulation in the extremity.

Interprofessional Care

Chronic illnesses and infection must be managed before an amputation is done. The goal of surgery is to preserve the greatest extremity length and function while removing all infected, pathologic, or ischemic tissue. Fig. 67.23 shows levels of amputation of upper and lower extremities. The type of amputation

TABLE 67.14 Interprofessional Care

Amputation

Diagnostic Assessment

- History and physical assessment
  - Physical appearance of soft tissues
  - Skin temperature
  - Sensory function
  - Quality of peripheral pulses
- Arteriography
- Venography
- Plethysmography (measures blood flow in the arms or legs)
- Transcutaneous ultrasonic Doppler recordings

Management

Medical

- Appropriate management of underlying disease
- Stabilize trauma victim

Surgical

- Residual limb management
- Immediate or delayed prosthesis fitting

Rehabilitation

- Coordination of prosthesis-fitting and gait-training activities
- Coordination of muscle-strength and PT programs

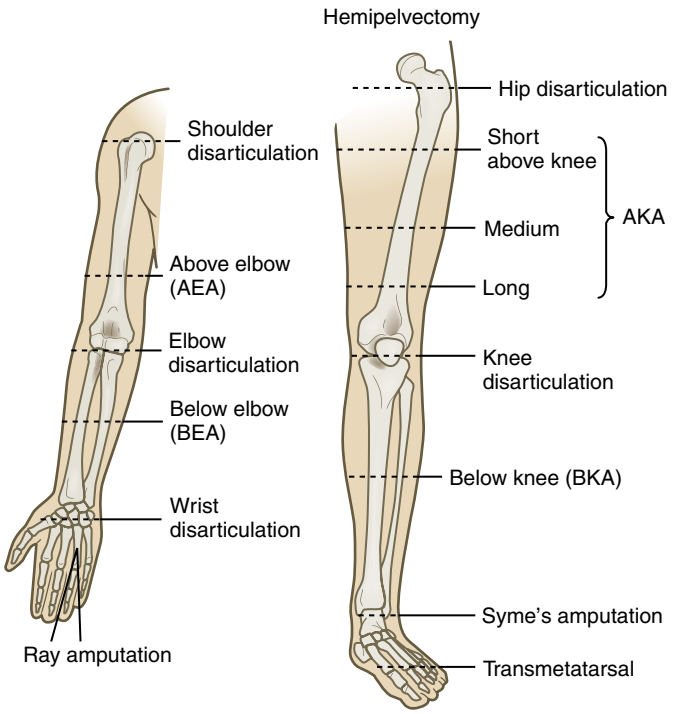

Fig. 67.23 Location and description of amputation sites of the upper and lower extremities. *AKA,* Above-the-knee amputation.

depends on the reason for the surgery. A closed amputation creates a weight-bearing *residual limb* (or stump). An anterior skin flap with dissected soft tissue padding covers the bony part of the residual limb. The skin flap is sutured posteriorly so that the suture line will not be in a weight-bearing area. Take special care to prevent accumulation of drainage, which can cause pressure and harbor bacteria that may cause infection.

Disarticulation is an amputation done through a joint. A *Syme's amputation* is a form of disarticulation at the ankle. After an open amputation *(guillotine amputation),* the surface of the residual limb is left uncovered with skin. This type of surgery is generally done to control actual or potential infection. The wound is usually closed later by a second surgery or closed by skin traction surrounding the residual limb.

❖ NURSING MANAGEMENT: AMPUTATION

◆ Assessment

Assess for any preexisting illnesses. If amputation is planned or elective, as for the patient with PVD, assess the patient's general health. Because most amputations are done for vascular problems, vascular and neurologic assessments are important (see Chapters 35 and 60).

◆ Clinical Problems

Clinical problems for the patient with an amputation may include:

- Impaired tissue integrity
- Pain
- Musculoskeletal problem
- Impaired role performance
- Negative self-esteem

◆ Planning

The overall goals are that the patient with an amputation will (1) have satisfactory pain management, (2) reach maximum rehabilitation potential (with the use of a prosthesis, if indicated), (3) cope with the body image changes, and (4) make satisfying lifestyle adjustments.

◆ Implementation

◆ Health Promotion

Control of illnesses, such as PVD, diabetes, chronic osteomyelitis, and pressure injuries, can eliminate or delay the need for amputation. Teach patients with these problems to carefully examine their lower extremities daily for signs of infection or skin breakdown. If the patient cannot do this, the caregiver should help. Teach the patient and caregiver to report changes in the feet or toes to the HCP. These include decreased or absent sensation, tingling, burning pain, cuts, or abrasions, and changes in skin color or temperature.

Review safety precautions for people taking part in recreational activities and potentially hazardous work. This role is important for the occupational health nurse.

◆ Acute Care

Reasons for amputation and the rehabilitation potential depend on a person's age, diagnosis, occupation, personality, resources, and support system. Be aware of the psychologic and social implications of amputation. Body image problems related to amputation often cause a patient to go through a grieving process. Use therapeutic communication to help the patient and caregiver through this process and develop a realistic attitude about the future.

Preoperative care. Reinforce information that the patient and caregiver have received about reasons for the amputation, proposed prosthesis, and mobility-training program. Help the patient and caregiver understand the need for the amputation. Assure them that rehabilitation can help with quality of life. If the amputation is done emergently after trauma, patient management is physically and emotionally more complicated.

To meet the patient's educational needs, know the level of amputation, type of dressings to be applied, and type of prosthesis to be used. Teach the patient to perform upper extremity exercises, such as push-ups in bed or the wheelchair, to promote arm strength for crutch walking and gait training. Discuss general postoperative nursing care. Review positioning, support, and residual limb care. If a compression bandage will be used after surgery, teach the patient about its purpose and how it will be applied. If immediate prosthesis use is planned, discuss general ambulation expectations. Tell the patient that the amputated limb may feel like it is still present after surgery. This phenomenon, termed **phantom limb sensation**, occurs in many amputees.

Postoperative care. General care for the patient who had an amputation depends largely on the patient's age, general state of health, and reason for the amputation. Monitor patients who had an amputation due to a traumatic injury for posttraumatic stress disorder because they may have had no time to prepare or even take part in the decision to have a limb amputated.

Fig. 67.24 A double amputee fitted with prostheses. (Photo courtesy US Army.)

TABLE 67.15 PATIENT & CAREGIVER TEACHING

Lower Extremity Amputation

After lower extremity amputation, include the following instructions when teaching the patient and caregiver:

1. Inspect the residual limb daily for signs of skin irritation, especially redness, abrasion, and odor. Especially evaluate areas prone to pressure.
2. Stop using the prosthesis if irritation develops. Have the area checked before resuming use of the prosthesis.
3. Wash the residual limb thoroughly each night with warm water and bacteriostatic soap. Rinse thoroughly and dry gently. Expose the residual limb to air for 20 min.
4. Do not use lotions, alcohol, powders, or oil on residual limb unless prescribed by the HCP.
5. Wear only a residual limb sock in good condition and supplied by the prosthetist.
6. Change residual limb sock daily. Launder in mild soap, squeeze, lay flat to dry.
7. Use prescribed pain management techniques.
8. Perform ROM to all joints daily. Perform general strength exercises (including for upper extremities) daily.
9. Do not elevate residual limb on a pillow.
10. Lay prone with hip in extension for 30 min, 3 or 4 times daily.

Prevention and detection of complications are important after surgery. Monitor vital signs. Assess dressings for hemorrhage. Use sterile technique during dressing changes to reduce the risk for wound infection. If an *immediate* postoperative prosthesis has been applied, carefully observe the surgical site. If excess bleeding occurs, notify the HCP at once. Keep a tourniquet available for emergency use.

Proper bandaging ensures the residual limb is shaped and molded for eventual prosthesis fitting (Fig. 67.24). The HCP usually orders a compression bandage to be applied right after surgery to support soft tissues, reduce edema, hasten healing, and minimize pain. Compression also promotes residual limb shrinkage and maturation. This bandage may be an elastic roll applied to the residual limb or a residual limb shrinker, which is an elastic stocking that fits tightly over the residual limb.

At first, the patient always wears the compression bandage except during PT and bathing. Remove and reapply the bandage several times daily. Take care to apply it snugly but not so tight as to interfere with circulation. Wash and change shrinker bandages daily. After the residual limb is healed, bandage it only when the patient is not wearing the prosthesis. Teach the patient to avoid dangling the residual limb over the bedside to decrease edema.

As the patient's condition improves, the HCP and physical therapist start and supervise an exercise program. We start active ROM exercises for all joints as soon as possible after surgery. To prepare for mobility, the patient should increase triceps and shoulder strength for lower limb support. The patient will need to learn to balance the altered body. The lost weight of an amputated limb requires adaptation of proprioception and coordination to prevent falls and injury.

Flexion contractures may delay rehabilitation. The most common and debilitating contracture is hip flexion. Hip adduction contracture is rare. To prevent flexion contractures, have patients avoid sitting in a chair for more than 1 hour with hips flexed or having pillows under the surgical extremity. Unless contraindicated, patients should lie on their abdomen for 30 minutes 3 or 4 times each day and position the hip in extension while prone.

Crutch walking starts as soon as the patient is physically able. Follow orders for weight bearing carefully to avoid injury to the skin flap and delay of tissue healing. Before discharge, teach the patient and caregiver about residual limb care, ambulation, contracture prevention, recognition of complications, exercise, and follow-up care (Table 67.15).

◆ Ambulatory Care

Success of rehabilitation depends on the patient's physical and emotional health. Chronic illness and deconditioning can complicate rehabilitation. The patient's previous ability to ambulate may affect the extent of recovery. Physical and occupational therapy must be a central part of the overall plan of care.

◆ Prostheses

Appropriate timing for the use of a prosthesis depends on satisfactory healing of the residual limb and the patient's general condition. The *delayed* prosthetic fitting may be the best choice for older adults, patients with infection, or patients who had amputations above the knee or below the elbow (Fig. 67.25). A temporary prosthesis may be used for partial weight bearing after sutures are removed. If there are no problems, the patient can bear full weight on a permanent prosthesis about 3 months after amputation.

Not all patients are candidates for prostheses. Using a prosthesis requires significant strength and energy for ambulation. For example, walking with a below-the-knee prosthesis requires 40% more energy than walking on 2 legs. An above-the-knee prosthesis requires 60% more. The seriously ill or debilitated

Fig. 67.25 Mirror therapy, a type of treatment that may reduce phantom limb sensation and pain. (US Navy photo courtesy Mass Communication Specialist Seaman Joseph A. Boomhower.)

patient may not have the upper body strength and energy needed to use a lower extremity prosthesis. Mobility with a wheelchair may be the most realistic goal for this patient.

When healing has occurred satisfactorily, and the residual limb is well molded, the patient is ready for prosthesis fitting. A prosthetist makes a mold of the residual limb and measures landmarks for creation of the prosthesis. The molded limb socket allows the residual limb to fit snugly into the prosthesis. The residual limb is covered with a stocking to ensure good fit and prevent skin breakdown. If the limb continues to shrink, causing a loose fit, a new socket must be made. The patient may need to have the prosthesis adjusted to prevent rubbing and friction between the residual limb and socket. Excessive movement of a loose prosthesis can cause severe skin irritation, breakdown, and gait problems.

Artificial limbs become an integral part of the patient's changed body image. Teach the patient to clean the prosthesis socket daily with mild soap and rinse thoroughly to remove irritants. Leather and metal parts of the prosthesis should not get wet. Encourage the patient to have regular maintenance on the prosthesis. Consider the condition of the patient's shoe. A badly worn shoe alters the gait and can damage the prosthesis.

Phantom Limb Sensations

Patients are often worried about phantom limb sensation because they still perceive pain in the missing part of the limb. As recovery and ambulation progress, phantom limb sensation and pain usually subside. However, the pain may become chronic. The patient may have shooting, burning, or crushing pain as well as feelings of coldness, heaviness, and cramping,

There is no one therapy for phantom limb sensation. Mirror therapy and virtual reality treatment reduce symptoms in some patients (Fig. 67.26). We think these therapies give visual information to the brain, replacing sensory feedback expected from the missing limb.[17]

Upper Limb Amputation

An upper limb amputation is often more devastating than for lower limb amputation. Despite technologic advances, we

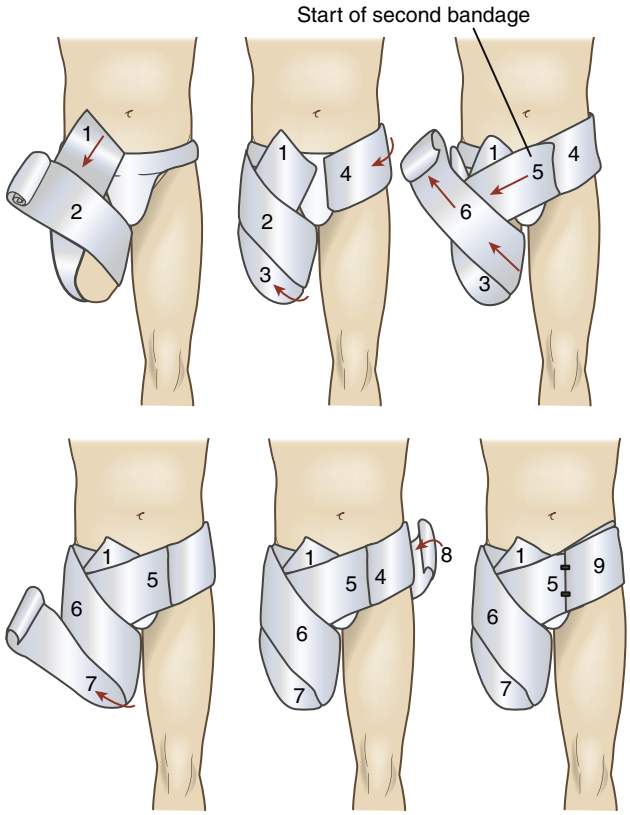

Fig. 67.26 Bandaging for the above-the-knee amputation residual limb. Figure-8 style covers progressive areas of the residual limb; 2 elastic wraps used.

cannot replicate the movements and functional capacity of our hands with upper extremity prostheses. The enforced dependency due to being 1-handed may be depressing and frustrating to the patient. Because most upper extremity amputations result from trauma, the patient likely had little time to adjust or be a part of the decision-making process.

Both immediate and delayed prosthetic fittings are possible for the below-the-elbow amputee. Prosthetic fitting is delayed for the above-the-elbow amputee. The usual functional prosthesis is the arm and hook. A cosmetic hand is available but has limited functional value. As with the lower limb prosthesis, patient motivation and perseverance are major factors contributing to a satisfactory outcome.

Evaluation

The expected outcomes are that the patient with an amputation will:

- Accept changed body image and integrate changes into lifestyle
- Have no evidence of skin breakdown
- Have reduction or absence of pain
- Become mobile within limitations imposed by amputation

COMMON JOINT SURGERIES

Surgery plays a vital role in the treatment and rehabilitation of patients with various joint problems. The goals of surgery are to relieve chronic pain, improve joint motion, correct deformity

and misalignment, and remove diseased cartilage. If the joint problem is not corrected, contraction with permanent limitation of motion may occur. There will be limited joint motion on physical assessment. Joint-space narrowing can be seen on x-rays.

TYPES OF JOINT SURGERIES

Synovectomy

Synovectomy (removal of synovial membrane) is done to remove inflamed tissue that is causing unacceptable pain or limiting ROM in RA. A synovectomy is best done early in the disease process when there is minimal bone or cartilage destruction. Removing the thickened synovium does not cure RA. It may relieve symptoms temporarily. Common sites for this surgery include the elbow, wrist, and fingers. Knee synovectomy is done less often because knee joint replacement is usually done.

Osteotomy

An **osteotomy** involves removing a wedge or slice of bone to restore alignment (joint and vertebral) and to shift weight bearing, thus relieving pain. Cervical osteotomy may be used to correct a kyphotic deformity in patients with ankylosing spondylitis. Halo vests and body jacket braces are worn until fusion occurs (3 to 4 months). Osteotomy is not effective in patients with inflammatory joint disease. Femoral osteotomy may provide some pain relief and improve motion in select patients with hip OA. Tibial osteotomy provides pain relief in some patients with knee instability or OA.

Care of a patient who had an osteotomy is similar to that of a patient with ORIF of a fracture at a comparable site. Internal wires, screws and plates, bone grafts, or an external fixator usually fixes the bone in place.

Debridement

Debridement is the removal of debris, such as pieces of bone or cartilage *(loose bodies)* or osteophytes, from a joint using a fiberoptic arthroscope. This procedure is usually done on an outpatient basis on the knee or shoulder. A compression dressing is applied after surgery. Weight bearing is permitted after knee arthroscopy. Patient teaching includes monitoring for signs of infection, managing pain, and restricting activity for 24 to 48 hours.

Arthroplasty

Arthroplasty is the reconstruction or replacement of a joint to relieve pain, improve or maintain ROM, and correct deformity. Arthroplasty is most often done on patients with OA, RA, avascular necrosis, congenital deformities or dislocations, and other systemic problems. Types of arthroplasty include surgical reshaping of the bones of the joints, replacement of part of a joint (hemiarthroplasty), and total joint replacement. Around 1 million Americans have knee and hip replacement surgery annually.[18] Arthroplasty is also available for elbows, shoulders, fingers, wrists, ankles, and feet.

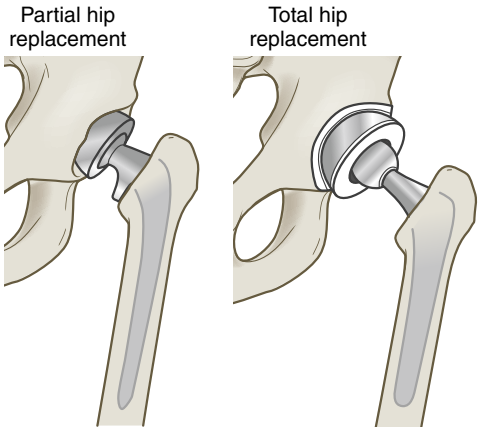

Fig. 67.27 Types of hip replacements.

Total Hip Arthroplasty

Total hip arthroplasty (THA), or a total hip replacement, provides significant relief of pain and improved function for patients with joint deterioration from OA, RA, and other conditions. THA is also used to treat hip fractures.

In THA, the prosthesis (implant) replaces the ball-and-socket joint formed by the upper shaft of the femur and pelvis (Fig. 67.27). Both the ball-and-socket components can be cemented in place with polymethyl methacrylate, which bonds to the bone. They may be inserted without cement (cementless). Cementless THA may provide longer stability by enabling growth of new bone tissue into the porous surface coating of the prosthesis. Cementless devices are better for younger, more active patients and patients with good bone quality as there is better bone growth into the components. The nursing care for a patient who had a THA is discussed in the section on nursing management of a patient with a hip fracture.

Hip Resurfacing Arthroplasty

An alternative to THA is hip resurfacing arthroplasty. It preserves and reshapes the femoral head (ball) rather than replacing it as in THA. The resurfaced femoral head is then capped by a metal prosthesis. Hip resurfacing may be an option for patients younger than age 60 with larger frames. A small number of patients have a femoral neck fracture after hip resurfacing. This is not possible with THA. Metal ions may be released into the bloodstream from the prosthesis. Patients may develop sensitivity or allergy to these ions.[19] Patients receiving a smaller femoral head (including many women) have a higher failure rate with a resurfaced implant when compared with patients receiving THA.

Knee Arthroplasty

Unrelieved pain and instability due to severe deterioration of the knee joint are the main reasons for total knee arthroplasty (TKA) or a total knee replacement (Fig. 67.28). Partial arthroplasty can be done on a patient with OA limited to 1 part (compartment) of the knee.

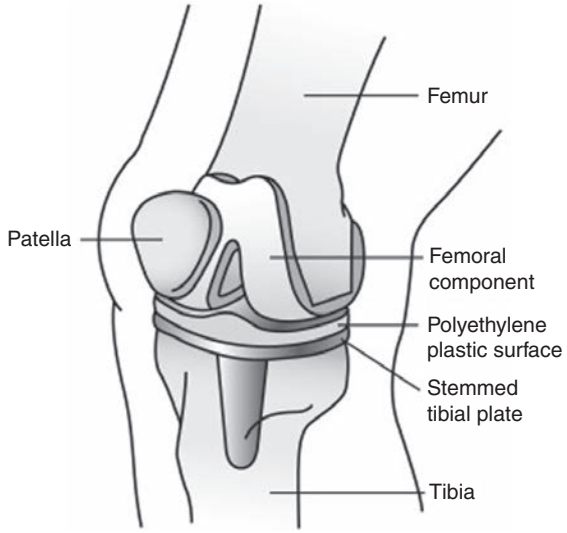

Fig. 67.28 Knee arthroplasty components. Up to 3 bone surfaces can be replaced in a total knee replacement. (Modified from Odom-Forren J: *Drain's perianesthesia nursing,* ed 7, St Louis, 2018, Elsevier.)

Right after surgery a compression dressing may be used to immobilize the knee in extension. This dressing is removed before discharge. If the patient is unable to perform a straight-leg raise, a knee immobilizer or posterior plastic shell to maintain extension may be used during ambulation and at rest for about 4 weeks.

After surgery, emphasis is on pain management and PT. Managing pain is a primary nursing goal. Doing so decreases the risk for complications and speeds the return to function. Adequate analgesia should be ordered at discharge to allow the patient to continue with the exercise program. Effective pain management is key to achieving positive rehabilitation outcomes.

PT begins early with isometric quadriceps setting. Therapy progresses to straight-leg raises and gentle ROM to increase muscle strength and obtain 90-degree knee flexion. Ambulation starts early with walking short distances, progressing to full weight bearing. An active home exercise program involves progressive ROM with muscle strength and flexibility exercises. After TKA, many patients with OA show significant improvement in mobility, motor function tests, and ability to complete daily tasks.

Finger Joint Arthroplasty

A silicone rubber arthroplastic device is used to restore function in the fingers of the patient with RA. Ulnar deviation often causes severe functional limitations of the hand. The main goal of hand surgery is to restore function related to grasp, pinch, stability, and strength rather than to correct cosmetic deformity. Before surgery, the patient should learn hand exercises, including flexion, extension, abduction, and adduction of the fingers.

After surgery, the patient will have a bulk dressing. Keep the hand elevated. Perform regular neurovascular assessment. Monitor for signs of infection. Success of the surgery depends largely on the postoperative treatment plan. An OT plays a key role. After the dressing is removed, a guided splinting program is started. Patients wear splints while sleeping and do hand exercises at least 3 or 4 times a day for 10 to 12 weeks. Teach the patient to avoid lifting heavy objects.

Elbow and Shoulder Arthroplasty

Elbow and shoulder replacements is not as common as other arthroplasties. Shoulder replacements are done in patients with severe pain because of RA, OA, avascular necrosis, or trauma. A special type of shoulder replacement, called a reverse total shoulder arthroplasty, may be done for pain and dysfunction caused by massive, irreparable rotator cuff tears. Shoulder replacement is usually considered if the patient has adequate surrounding muscle strength and bone density.

Rehabilitation is longer and more difficult than with other joint surgeries. If the patient needs elbow and shoulder joint replacements, the elbow is usually done first because elbow pain interferes with shoulder rehabilitation. Most patients have no pain at rest or minimal pain with activity after elbow and shoulder arthroplasty. Functional improvements contribute to better hygiene and increased ability to perform ADLs.

Ankle Arthroplasty

Total ankle arthroplasty (TAA) is indicated for RA, OA, trauma, and avascular necrosis. Although TAA is not widespread, it is a good alternative to fusion for treatment of severe ankle arthritis in certain patients. Available devices include several fixed-bearing devices and a mobile-bearing cementless prosthesis. This device more closely imitates natural ankle function.

Ankle fusion is preferred over arthroplasty because the result is more durable. However, fusion leaves the patient with a stiff foot and the inability to change heel height. TAA achieves a more normal gait pattern. After surgery, the patient may not bear weight for 6 weeks. They need to elevate the extremity to reduce edema and maintain immobilization as directed by the HCP.

Arthrodesis

Arthrodesis is the surgical fusion of a joint. This procedure is done only if articular surfaces are too severely damaged or infected to allow joint replacement or if reconstructive surgery fails. Arthrodesis relieves pain and provides a stable but immobile joint. The fusion is usually done by removing the articular hyaline cartilage and adding bone grafts across the joint surface. The affected joint must be immobilized until bone healing has occurred. Common areas fused are wrist, ankle, cervical spine, lumbar spine, and metatarsophalangeal (MTP) joint of the big toe.

Complications of Joint Surgery

Infection is a serious complication of joint surgery, especially joint replacement surgery. The most common causative organisms are streptococci and staphylococci. Infection may lead to pain and loosening of the prosthesis, often requiring further surgery. Measures to reduce infection include the use of specially designed self-contained operating suites, operating rooms with laminar airflow, and prophylactic antibiotic administration.

VTE is a serious complication after joint surgeries, especially those involving the lower extremities. Provide prophylactic measures, such as anticoagulant drugs, use of intermittent pneumatic compression devices, and early ambulation. Assess patients for signs of VTE. VTE is discussed in Chapter 41.

❖ NURSING AND INTERPROFESSIONAL MANAGEMENT: JOINT SURGERY

◆ Preoperative Care

The primary goal of preoperative assessment is to identify risk factors for postoperative complications so we can implement measures to promote optimal outcomes. A careful history includes (1) medical diagnoses and complications, such as diabetes; (2) pain tolerance and management preferences; (3) current functional level and expectations after surgery; (4) current social support; and (5) home care needs after discharge. The patient should be free from infection, breaks in skin integrity, and acute joint inflammation.

Preoperative teaching about the expected hospital course and postoperative management at home is important for the patient and caregiver. Explain postoperative care, including early mobility, the need to maintain hydration, and VTE prophylaxis. Assure the patient that analgesia will be available. A preoperative PT visit allows practice of postoperative exercises and measurement for crutches or other assistive devices. Provide opportunities for practice with assistive devices.

If lower extremity surgery is planned, assess upper extremity muscle strength and joint function to determine the type of assistive devices needed for ambulation and ADL performance. Discuss ways to maximize the usefulness and longevity of the prosthesis. Patients need to realize that recovery does not occur rapidly. Talking with other people who have had joint arthroplasty may help the patient better understand the reality of rehabilitation.

Begin discharge planning. Review the duration of the hospital stay and expected postoperative events so that the patient and caregiver can prepare. Advanced planning helps to allow for a discharge home. Assess the patient's support. Identify their care partner. Who is going to help the patient at home? Will the patient need homemaker or meal services? It is preferable that the patient goes home after a total joint arthroplasty. Discuss the safety and accessibility of the home environment (e.g., throw rugs, cords). Are the bathroom and bedroom on the first floor? Are door frames wide enough to accommodate a walker? Discharge to a subacute or extended care facility should be planned beforehand. The older patient may need to go to a facility for a few weeks to regain independent living skills, if there is no social support available.

◆ Postoperative Management

Nursing care of the patient having orthopedic surgery is outlined in Table 67.16. Other nursing interventions are presented in eNursing Care Plan 67.2 (available on the website for this chapter). The hospital stay after arthroplasty can be a few hours after surgery to 2 days depending on preoperative planning, postoperative course, and need for PT after surgery. Many hip and knee replacement surgeries are done at ambulatory surgical centers. Same day surgery is a trend expected to increase.

TABLE 67.16 NURSING MANAGEMENT

Care of the Patient After Joint Surgery

- Perform neurovascular assessment on the affected extremity.
- Monitor pain intensity and give prescribed analgesics.
- Maintain correct body alignment.
- Provide wound care, including dressing changes.
- Assess for complications of immobility (e.g., constipation, VTE) and develop a plan to minimize those complications.
- Assist with initial ambulation then help as needed.
- Assist patient, caregiver(s), and family in planning for discharge care.
- Supervise assistive personnel (AP):
  - Record oral intake and output.
  - Obtain vital signs and pulse oximetry.
  - Aid patient with nutrition, elimination, and hygiene needs.
  - Maintain body position and assist with ambulation.
  - Help with passive and active ROM exercises.
  - Notify RN about reports of pain, tingling, or decreased sensation in the affected extremity.

Collaborate With Physical Therapist

- Assess current mobility and need for assistance.
- Teach safe ambulation with assistive device based on weight-bearing restrictions.
- Establish exercise plan and teach patient to perform exercises safely.
- Coordinate PT with RN so that patient can receive timely analgesia.
- Discuss home environment with patient and identify modifications to promote safety.

Regularly perform neurovascular assessment. Give ordered analgesics. Assess patient comfort often during the postoperative period. Monitor for postoperative complications. Teach the patient to report complications. Review signs of infection (e.g., fever, increased pain, drainage) and dislocation of the prosthesis (e.g., pain, loss of function, shortening or malalignment of an extremity).

Assess ROM at regular intervals to promote functional performance. In general, the affected joint is exercised, and we encourage ambulation as early as possible. PT and ambulation enhance mobility, build muscle strength, and reduce the risk for VTE. Specific protocols vary according to the patient, type of prosthesis, and HCP preference.

VTE risk reduction includes hydration, shorter surgery time, early mobility, and use of anticoagulant medications. Most prophylactic anticoagulant drugs are given for at least 10 to 14 days.[12] Some patients need therapy for up to 35 days. If the patient is taking warfarin, therapy starts on the day of surgery, and the INR and prothrombin times are measured daily. Therapy with LMWH (e.g., enoxaparin), apixaban, or rivaroxaban usually starts the morning after surgery.

Case Study

Hip Fracture and Revision Arthroplasty

(© aronaze/ iStock.com.)

Patient Profile

M.C. is a 64-year-old man who had both hips replaced (left 6 years ago, right 2 years ago). He has a history of hypothyroidism. He was admitted to the ED after tripping over a short retaining wall in his backyard while gardening. He landed on his right side.

Subjective Data

- Acute, severe pain in right hip, unable to bear weight on right leg.
- Takes cholecalciferol (vitamin D_3) 1000 IU every day without calcium supplement. States calcium upsets his stomach.
- Reports loss of about 30 lb in the last year through diet and exercise. Exercises 3 times a week.
- Lives in multilevel house with his wife. Bedrooms are on the second level.
- Has smoked ½ pack of cigarettes a day for the 30 years.
- Describes himself as "a very light social drinker."

Objective Data

- 5 ft, 9 in tall, 175 lb

Diagnostic Studies

- X-rays show periprosthetic right proximal femur fracture at the greater trochanter with loss of fixation in the femoral part of the THA
- Normal CBC, chest x-ray
- Serum calcium 8.1 mg/dL

Interprofessional Care

- Revision of femoral part of his right total hip replacement with open reduction of the femoral fracture and fixation with 3 wires
- Medications:
  - IV morphine sulfate 2 mg IV every 3 hr as needed
  - Cefazolin 1 gram IV every 8 hr for 24 hr
  - Enoxaparin 40 mg subcutaneous daily for 4 weeks
  - Calcium citrate 600 mg plus 800 IU vitamin D orally daily
  - Levothyroxine (Synthroid) 125 mcg orally daily
- PT for transfers, gait, and stair training
- Occupational therapy for ADLs training
- Discharge planning based on mobility limitations and need for continued PT and OT

Discussion Questions

1. ***Recognize:*** How do M.C.'s previous total joint surgeries affect his recovery after this surgery?
2. ***Analyze***: What are the most likely postoperative complications M.C. could develop?
3. ***Analyze:*** In considering his patient profile, what issues can you identify that may affect his bone healing?
4. ***Plan:*** As you plan care for M.C., what are the priority nursing interventions?
5. ***Prioritize:*** What is the interprofessional team's top priority at this time?
6. ***Act:*** What do you need to assess to determine his readiness for discharge?
7. ***Safety:*** What safety precautions should we implement for M.C.?
8. ***Evaluate:*** Why is satisfactory pain management an important postoperative nursing goal for M.C.?
9. ***Evaluate:*** What outcomes would indicate nursing care was effective?

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. The nurse in urgent care suspects an ankle sprain when a patient describes
- **a.** being hit by another soccer player during a game.
- **b.** having ankle pain after sprinting around the track.
- **c.** dropping a 10-lb weight on his lower leg at the health club.
- **d.** twisting his ankle while running bases during a baseball game.

2. A patient with a humeral fracture is returning for a 4-week checkup. The nurse explains that initial evidence of healing on x-ray is indicated by
- **a.** formation of callus.
- **b.** complete bony union.
- **c.** hematoma at the fracture site.
- **d.** presence of granulation tissue.

3. A patient with a comminuted fracture of the tibia is to have an open reduction with internal fixation (ORIF) of the fracture. The nurse explains that ORIF is indicated when
   a. the patient cannot tolerate prolonged immobilization.
   b. the patient cannot tolerate the surgery for a closed reduction.
   c. other nonsurgical methods cannot achieve adequate alignment.
   d. a temporary cast would be too unstable to provide normal mobility.
4. The nurse suspects a neurovascular problem based on assessment of
   a. exaggerated strength with movement.
   b. increased redness and heat below the injury.
   c. decreased sensation distal to the fracture site.
   d. purulent drainage at the site of an open fracture.
5. A patient with a stable, closed humeral fracture has a temporary splint with bulky padding applied with an elastic bandage. The nurse suspects early compartment syndrome when the patient has
   a. increasing edema of the limb.
   b. muscle spasms of the lower arm.
   c. bounding pulse at the fracture site.
   d. pain when passively extending the fingers.
6. The nurse would monitor a patient with a pelvic fracture for
   a. changes in urine output.
   b. petechiae on the abdomen.
   c. a palpable lump in the buttock.
   d. sudden increase in blood pressure.
7. The nurse teaches the patient with an above-the-knee amputation that the residual limb should not be routinely elevated because this position promotes
   a. hip flexion contracture.
   b. clot formation at the incision.
   c. skin irritation and breakdown.
   d. increased risk for wound dehiscence.
8. A patient with osteoarthritis is scheduled for total hip arthroplasty. The nurse explains the purpose of this procedure is to *(select all that apply)*
   a. fuse the joint.
   b. replace the joint.
   c. prevent further damage.
   d. improve or maintain ROM.
   e. decrease the amount of destruction in the joint.
9. A patient is scheduled for total ankle replacement. The nurse should tell the patient that after surgery he should avoid
   a. lifting heavy objects.
   b. sleeping on the back.
   c. abduction exercises of the affected ankle.
   d. bearing weight on the affected leg for 6 weeks.

1. d; 2. a; 3. c; 4. c; 5. d; 6. a; 7. a; 8. b, d; 9. d.

Musculoskeletal Problems

Diane Ryzner

http://evolve.elsevier.com/Lewis/medsurg/

CONCEPTUAL FOCUS

Functional Ability
Mobility
Pain
Safety

LEARNING OUTCOMES

1. Describe the pathophysiology, clinical manifestations, and interprofessional and nursing management of osteomyelitis.
2. Discern among the types, clinical manifestations, and interprofessional management of bone cancer.
3. Discuss the genetic basis and clinical course of muscular dystrophy.
4. Discern between the causes and characteristics of acute and chronic low back pain.
5. Describe the postoperative nursing management of a patient who had spine surgery.
6. Discuss the etiology and nursing management of common foot problems.
7. Describe the etiology, pathophysiology, clinical manifestations, and nursing and interprofessional management of osteomalacia, osteoporosis, and Paget disease.

KEY TERMS

degenerative disc disease (DDD)
hallux valgus
herniated disc
low back pain
muscular dystrophy (MD)
osteochondroma
osteomalacia
osteomyelitis
osteopenia (Table 68.14)
osteoporosis
osteosarcoma
Paget disease
sarcoma

We were made to move! This chapter reviews a variety of acute and chronic musculoskeletal problems unrelated to trauma that affect the musculoskeletal system. These include osteomyelitis, bone cancer, foot problems, back pain, and metabolic bone diseases. These problems can lead to changes in mobility that affect almost every system in the body. They are a common source of pain and physical limitations that restrict the ability to fully take part in activities of daily living (ADLs), leading to disability. The nurse plays a key role in assessing pain and functional ability and initiating interventions to prevent injury and maintain mobility.

OSTEOMYELITIS

Etiology and Pathophysiology

Osteomyelitis is a severe infection of the bone, bone marrow, and surrounding soft tissue. A number of pathogens can cause osteomyelitis (Table 68.1).[1] *Staphylococcus aureus* is the most common cause.

Infecting microorganisms can invade by indirect or direct entry. *Indirect entry* (hematogenous) is usually from an infection with 1 microorganism. Indirect injury accounts for only 20% of cases. It most often affects children younger than 17 years. Risk factors in adults are older age, debilitation, hemodialysis, sickle cell disease, and IV drug use. The vertebrae are the most common site of infection in adults.[2]

Direct entry (contiguous) osteomyelitis accounts for 80% of case. It most often affects adults.[2] It can occur when an open wound (e.g., penetrating wounds, fractures, surgery) allows microorganisms to enter the body. Osteomyelitis can be related to a foreign body, such as an implant or an orthopedic prosthetic device (e.g., plate, total joint prosthesis). It may occur in the feet of patients with diabetes or vascular disease–related ulcers or in the hips or sacrum near a pressure injury. More than 1 microorganism is usually involved.

TABLE 68.1 Organisms Causing Osteomyelitis

Organism	Predisposing Problem
Escherichia coli	Urinary tract infection
Fungi, mycobacteria	Immunocompromised host
Mycobacterium tuberculosis	Tuberculosis
Neisseria gonorrhoeae	Gonorrhea
Pseudomonas	Puncture wounds, IV drug use
Salmonella	Sickle cell disease
Staphylococcus aureus	Pressure injury, penetrating wound, open fracture, orthopedic surgery, vascular insufficiency (e.g., diabetes, atherosclerosis)
Staphylococcus epidermidis	Indwelling prosthetic devices (e.g., joint replacements, fracture fixation devices)
Streptococcus viridans	Abscessed tooth, gingival disease

After entering the blood, microorganisms grow, and pressure increases because of the nonexpanding nature of most bone. This increased pressure eventually leads to ischemia and vascular compromise of the periosteum. The infection spreads through the bone cortex and marrow cavity, obstructing blood flow and causing and necrosis.

Bone death occurs due to ischemia. The area of dead bone eventually separates from the surrounding living bone, forming *sequestra*. The part of the periosteum that continues to have a blood supply forms new bone called *involucrum* (Fig. 68.1). Antibiotics or white blood cells (WBCs) have difficulty reaching the sequestrum through the blood. Thus sequestrum may become a reservoir for microorganisms that spread to other sites, including the lungs and brain. If the sequestrum does not resolve or is not debrided surgically, a sinus tract may develop. Chronic, purulent drainage from the tract results.

Clinical Manifestations and Complications

Acute osteomyelitis refers to the initial infection or an infection of less than 1 month in duration. Local manifestations include constant bone pain that worsens with activity and is unrelieved by rest; swelling, tenderness, and warmth at the site; and restricted movement of the affected part. Systemic manifestations include fever, night sweats, chills, restlessness, nausea, and malaise. Later signs include drainage from skin sinus tracts or the fracture site.

Chronic osteomyelitis is a bone infection that lasts longer than 1 month or an infection that did not respond to initial antibiotic treatment. Chronic osteomyelitis may be a continuous, persistent problem or recurrent, with exacerbations and remissions (Fig. 68.2). Systemic manifestations are lessened. Local signs of infection become more common, including constant bone pain and swelling and warmth at the infection site. Over time, granulation tissue turns to scar tissue. The avascular scar tissue is an ideal site for continued microorganism growth because it cannot be penetrated by antibiotics.

Long-term, and mostly rare, complications of osteomyelitis include septicemia, septic arthritis, pathologic fractures, and amyloidosis.

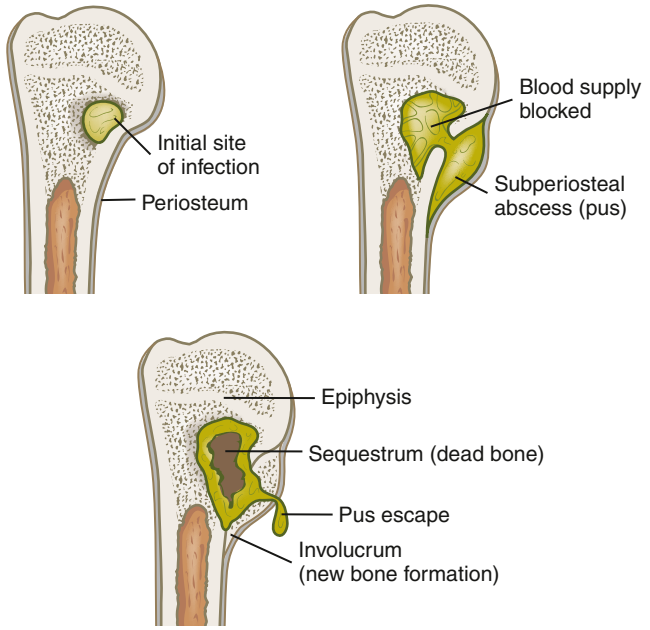

Fig. 68.1 Development of osteomyelitis infection with involucrum and sequestrum.

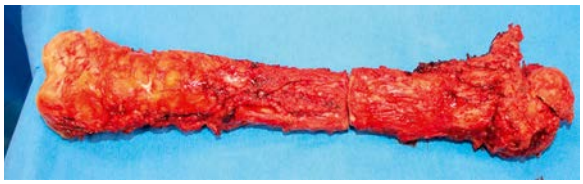

Fig. 68.2 Left femur with severe bone damage due to osteomyelitis. (From Trung DT, Dinh HN, Le NT, et al.: Total femur replacement in a patient with chronic persistence osteomyelitis, *Int J Surg Case Rep* 84:106067, 2021.)

Diagnostic Studies

Bone or soft tissue biopsy is the definitive way to identify the causative agent. Blood and wound cultures are often positive. Increased WBC count and erythrocyte sedimentation rate (ESR) may occur. High C-reactive protein (CRP) may occur with acute infection. Signs of osteomyelitis usually do not appear on x-rays until 2 to 4 weeks after the initial clinical symptoms. By this time, the disease will have progressed. Compared with x-rays, CT scan may be better in assessing the extent of infection. In the acute phase, MRI may be better than CT in detecting bone marrow edema, an early sign of osteomyelitis. Radionuclide bone scans (technetium-99m) also show abnormalities earlier than x-rays. A WBC scan (indium-111–labeled cells) may help pinpoint the area of infection.[2]

Interprofessional Care

Prolonged antibiotic therapy is the treatment of choice for acute osteomyelitis if bone ischemia has not yet occurred. Cultures or a bone biopsy should be done, if possible, before starting drug therapy. Any related soft tissue abscess or ulceration often needs surgical debridement or drainage.

Most patients start on IV antibiotics then switch to oral therapy. However, some may only receive oral agents.[3] The antibiotic

used depends on culture results and the infection itself (e.g., complexity, cause). Common antibiotics used include oxacillin, nafcillin, clindamycin, vancomycin, ceftriaxone, ciprofloxacin, and linezolid (see Table 15.8).

IV antibiotic therapy may need to continue at home for 4 to 6 weeks. A few persons need therapy for 3 to 6 months. Patients may be discharged to home care or a skilled nursing facility so the antibiotics can be given through a central venous access device (CVAD). CVADs are discussed in Chapter 17.

Treatment of chronic osteomyelitis includes surgical removal of the poorly perfused tissue and dead bone and extended use of antibiotics. In adults, oral therapy with a fluoroquinolone (e.g., ciprofloxacin) for 6 to 8 weeks may be prescribed instead of IV antibiotics. Oral antibiotics may be given for 4 to 8 weeks after acute IV therapy is done, to ensure the infection is resolved. We monitor the patient's response to drug therapy through bone scans and ESR testing.

Acrylic bead chains containing antibiotics may be implanted to help treat the infection. After debriding the dead, infected tissue, a suction irrigation system may be inserted and the wound closed. Intermittent or constant irrigation of the area with antibiotics may be used. Another option for wound management is negative-pressure wound therapy (discussed in Chapter 12). Casts or braces may be applied to protect the limb or the surgical site.

Hyperbaric O_2 may be given as an adjunct therapy in refractory cases of chronic osteomyelitis. It stimulates new blood growth and healing in the infected tissue.

If an orthopedic prosthetic device is the source of chronic infection, it must be removed. Muscle flaps or skin grafts provide wound coverage over the dead space in the bone. Bone grafts may help to restore blood flow. However, flaps or grafts should never be placed when there is an active or suspected infection.

Amputation may be needed if bone destruction is extensive. Amputation should improve quality of life and may save the patient's life if systemic complications are developing.

NURSING MANAGEMENT: OSTEOMYELITIS

Assessment

Subjective and objective data that you should obtain from a person with osteomyelitis are outlined in Table 68.2.

Clinical Problems

Clinical problems for the patient with osteomyelitis may include:

- Pain
- Musculoskeletal problems
- Infection

Additional information on nursing diagnoses and interventions for the patient with osteomyelitis can be found in eNursing Care Plan 68.1 (available on the website for this chapter).

Planning

The overall goals are that the patient with osteomyelitis will (1) have satisfactory pain and fever management, (2) be free from complications, (3) and adhere to the treatment plan.

TABLE 68.2 NURSING ASSESSMENT

Osteomyelitis

Subjective Data

Important Health Information

Health history: Bone trauma, open fracture, open or puncture wounds, other infections (e.g., streptococcal sore throat, bacterial pneumonia, sinusitis, skin or tooth infection, chronic urinary tract infection)
Medications: Analgesics or antibiotics
Surgery or other treatments: Bone surgery

Functional Health Patterns

Health perception–health management: IV drug and alcohol use. Malaise
Nutritional-metabolic: Anorexia, weight loss. Chills
Activity-exercise: Weakness, paralysis, muscle spasms around affected area
Cognitive-perceptual: Local tenderness over affected area, ↑ pain with movement of affected area
Coping–stress tolerance: Irritability, withdrawal, dependency, anger

Objective Data

General

Restlessness. High, spiking temperature. Night sweats

Musculoskeletal

Restricted movement; wound drainage. Spontaneous fracture

Skin

Diaphoresis. Redness, warmth, edema at site of infection

Possible Diagnostic Findings

Positive blood and/or wound cultures, ↑ ESR, ↑ WBC. Presence of sequestrum and involucrum on x-rays, radionuclide bone scans, CT, and MRI

Implementation

Health Promotion

Control of other current infections (e.g., urinary or respiratory tract, pressure injuries) is important in preventing osteomyelitis. Persons at risk for osteomyelitis are those who are immunocompromised or have diabetes, orthopedic prosthetic implants, or vascular insufficiency. Teach the at-risk patient about the signs of osteomyelitis. Encourage the patient to contact the HCP about bone pain, fever, swelling, and restricted limb movement so that they can start treatment. Teach caregivers about their role in monitoring the patient's health.

Acute Care

Nursing care of the patient with osteomyelitis is outlined in Table 68.3. Some immobilization of the affected limb (e.g., splint, traction) is usually needed to decrease pain and reduce risk for further injury. Carefully handle the limb. Avoid undue manipulation. This may increase pain and cause a pathologic fracture. Assess for pain. Muscle spasms may cause minor to severe pain. Nonsteroidal antiinflammatory drugs (NSAIDs), opioid analgesics, and muscle relaxants may be given.

Dressings are used to absorb drainage from wounds and debride dead tissue from the wound bed. These include dry, sterile dressings; dressings saturated in saline or antibiotic solution; wet-to-dry dressings; and dressings applied with negative-pressure wound therapy. Handle soiled dressings carefully

TABLE 68.3 NURSING MANAGEMENT

Caring for the Patient With Osteomyelitis

- Give IV antibiotics as ordered.
- Assess wound for signs of worsening infection.
- Teach patient and caregiver about antibiotic side effects and length of treatment, signs and symptoms of worsening infection, and use of hyperbaric O_2 if ordered.
- Assess for muscle spasms, and give muscle relaxants as ordered. Assess response.
- Assess pain, and give analgesics as ordered. Assess response.
- Handle affected limb carefully and avoid undue manipulation.
- Assess neurovascular condition of affected limb, and immediately inform HCP of significant changes.
- Encourage nondrug approaches to managing pain (e.g., guided imagery, relaxation breathing) (see Chapter 7).
- Change dressing as ordered using sterile technique.
- Implement contact precautions as needed.
- Supervise AP:
  - Handle affected limb carefully based on RN instruction.
  - Help patient with passive ROM of adjacent joints and active ROM exercises of unaffected limb.
  - Notify RN about reports of pain, tingling, or decreased sensation in the affected extremity.

Collaborate With Physical Therapist

- Assess current mobility and need for aid.
- Teach safe ambulation with assistive device based on weight-bearing restrictions.
- Establish exercise plan and teach patient to perform exercises safely.
- Coordinate PT so that patient can receive timely analgesia.
- Discuss home environment with patient and identify modifications needed (e.g., stair training, bed placement on first level).

Collaborate With Occupational Therapist

- Assess impact of condition on ability to perform ADLs.
- Teach use of assistive devices (e.g., long-handled reacher, shoe donner) to promote self-care while maintaining activity restrictions.

to prevent transfer of bacteria to other areas of the wound. Discard dressings appropriately to prevent spread of infection.

The patient is often placed on bed rest in the early stages of acute infection. Good body alignment and frequent position changes promote comfort and prevent complications related to immobility. Flexion contracture of the affected lower extremity is common. The patient often positions the leg in a flexed position to promote comfort. Footdrop can develop quickly due to Achilles tendon contracture if the foot is not supported in a neutral position by a splint or boot.

Teach the patient the possible adverse reactions from prolonged high-dose antibiotic therapy (see Table 15.8). These include hearing problems, impaired renal function, and neurotoxicity (e.g., limb weakness or numbness, cognitive changes, vision changes, headache, behavior problems). Monitor peak and trough blood levels of most antibiotics. Assess for the overgrowth of *Candida albicans* and *Clostridioides difficile* in the genitourinary (GU) and gastrointestinal (GI) tracts, especially in immunosuppressed and older adult patients. Teach the patient to report any changes in the oral cavity (e.g., whitish yellow, curd-like lesions) or the GU tract (e.g., perianal itching, discharge).

CHECK YOUR PRACTICE

Your patient on the orthopedic unit is a 22-year-old man who was in an all-terrain vehicle accident in a remote area 4 days ago. He is slowly recovering from his head injury and surgical repair of an open fracture of the femur. Yesterday, he was diagnosed with acute osteomyelitis. He is very angry and at times disoriented. When you try to assess his leg, he yells at you, "It hurts. Leave it alone!"

- What are your priorities of care?
- What signs and symptoms would suggest the patient's condition is worsening?

The patient and caregivers may be anxious and discouraged because of the serious nature of osteomyelitis, the uncertainty of the outcome, and the long, costly treatment. Continued emotional support is a key part of nursing management.

Ambulatory Care

Teach the patient and caregiver how to manage the CVAD if receiving IV antibiotics at home. Review how to administer the antibiotic. Reinforce the need for follow-up laboratory testing. Stress the importance of continuing to take the full course of antibiotics prescribed, even after symptoms have improved.

Dressing changes are often needed if the patient has an open wound. The patient and caregiver may need supplies and instruction for completing the dressing change. If the osteomyelitis becomes chronic, the patient needs continued physical and psychologic support.

Evaluation

The expected outcomes are that the patient with osteomyelitis will:

- Have satisfactory pain management
- Adhere to the recommended treatment plan
- Show a consistent increase in mobility and range of motion (ROM)

BONE TUMORS

Primary bone tumors, both benign and malignant, are rare in adults. They account for only around 3% of all tumors. Benign bone tumors are more common than primary malignant tumors. Metastatic bone cancer, in which cancer has spread from another site, is more common.

BENIGN BONE TUMORS

The main types of benign bone tumors are osteochondroma, osteoclastoma, and enchondroma (Table 68.4).

Osteochondroma

Osteochondroma is the most common benign bone tumor. It is characterized by an overgrowth of cartilage and bone near the

TABLE 68.4 Types of Primary Bone Tumors

Types	Description
Benign	
Enchondroma	• Intramedullary cartilage tumor usually found in cavity of a single hand or foot bone • Rarely transforms to cancer • If tumor becomes painful, surgical resection is done • Peak incidence in people ages 10–20 years
Osteochondroma	• Most common benign bone tumor • Often found in pelvis, scapula, or metaphyseal part of long bones • Occurs most often in people ages 10–25 years • May transform to cancer (chondrosarcoma)
Osteoclastoma (giant cell tumor)	• Arises in cancellous ends of arm and leg bones • Around 10% are locally aggressive and may spread to lungs • High rate of local recurrence after surgery and chemotherapy
Malignant	
Chondrosarcoma	• Most often occurs in cartilage in arm, leg, and pelvic bones of adults ages 50–70 years • Can arise from benign bone tumors (osteochondromas) • Wide surgical resection is typically done as tumor rarely responds to radiation and chemotherapy • Survival rate depends on stage, size, and grade of tumor
Ewing sarcoma	• Develops in medullary cavity of pelvis and long bones, especially femur, humerus, and tibia • Usually occurs in children and teenagers • Use of wide surgical resection, radiation, and chemotherapy has improved 5-year survival rate to 60%
Osteosarcoma	• Most common primary bone cancer • Occurs mostly in males ages 10–25 • Most often in pelvis or bones of arms, legs (Fig. 68.3)

end of the bone at the growth plate. They most often occur in the pelvis, scapula, or long bones of the leg.

Manifestations include a painless, hard, immobile mass; shorter-than-normal height for age; soreness of muscles close to the tumor; 1 leg or arm longer than the other; and pressure or irritation with exercise. Some may be asymptomatic. Diagnosis is confirmed using x-ray, CT scan, and MRI.

No treatment is needed for asymptomatic osteochondroma. Patients should have regular screenings to detect progression to cancer. If the tumor is causing pain or neurologic manifestations because of compression, surgical removal is usually done.

MALIGNANT BONE TUMORS

A **sarcoma** is a malignant tumor that develops in bone, muscle, fat, nerve, or cartilage. The most common types of sarcomas are osteosarcoma, chondrosarcoma, and Ewing sarcoma (Table 68.4). In 2020, 3600 new cases of bone and joint cancer are expected in the United States, with an estimated 1720 deaths.[4] Primary tumors occur most often during childhood and young adulthood. They cause bone destruction and have rapid metastasis.

Fig. 68.3 Osteosarcoma. (From Czerniak B: *Dorfman and Czerniak's bone tumors*, ed 2, Philadelphia, 2016, Elsevier.)

Osteosarcoma

Osteosarcoma is a very aggressive bone cancer. It rapidly spreads to distant sites. It often starts in the pelvis or metaphyseal region of the long bones of extremities, especially in the distal femur, proximal tibia, and proximal humerus (Fig. 68.3). Osteosarcoma is the most common bone cancer affecting children and young adults. It can occur in older adults, but not as often. It is most often associated with Paget disease and prior radiation.

The gradual onset of pain and swelling in the affected bone are the most common manifestations. The pain may be worse at night and increase with activity. A minor injury does not cause the cancer but may be how it is found. Metastasis is present in 10% to 20% of people at the time of diagnosis. Diagnosis is confirmed from tissue biopsy, increased serum alkaline phosphatase and calcium, x-ray, CT or PET scans, and MRI.

Chemotherapy (neoadjuvant) may be used before surgery to decrease tumor size. Limb salvage procedures are usually considered if a clear (no cancer present) 6- to 7-cm margin surrounds the lesion. Limb salvage is usually not possible if the patient has major nerve or blood vessel involvement, pathologic fracture, infection, or extensive muscle involvement.

Chemotherapy after amputation or limb salvage (adjuvant) has increased the 5-year survival rate to 70% in people without metastasis. Chemotherapy includes combinations of methotrexate, doxorubicin, cisplatin, ifosfamide, cyclophosphamide, and etoposide.[5]

Metastatic Bone Cancer

The most common type of cancerous bone tumor occurs because of spread *(metastasis)* from a primary tumor at another site. Common primary sites include breast, colon, prostate, lungs, kidney, and thyroid.[6] Metastatic cancer cells travel from the primary tumor to the bone via the lymph and blood supply. Metastatic bone lesions often occur in the spine, ribs, or

pelvis.[6] Pathologic fractures at the site of metastasis are common because the bone is weak. High serum calcium occurs as damaged bones release calcium.

Once a primary lesion has been found, bone scans are often done to detect metastatic lesions before they are visible on x-ray. Metastatic bone lesions may occur at any time (even years later) after diagnosis and treatment of the primary tumor. Bone metastasis should be suspected in any patient who has local bone pain and a history of cancer. Surgical stabilization of the bone may be indicated for fracture or to prevent fracture in a high-risk patient. Prognosis depends on the primary type of cancer and any other sites of metastasis. Possible palliative treatment consists of radiation and pain management (see Chapter 16).

❖ NURSING MANAGEMENT: BONE CANCER

Nursing care of the patient with bone cancer does not differ significantly from the general care of the patient with cancer (see Chapter 16). Monitor the tumor site for swelling, changes in circulation, and decreased movement, sensation, or joint function.

Use special care to prevent pathologic fractures and reduce the complications from them. Prevent fractures by careful handling and support of the affected extremity and logrolling the patient. Note weakness caused by anemia and decreased mobility.

Treatment for hypercalcemia may be started if bone decalcification occurs. The patient may be unwilling to exercise or take part in activities because of weakness from the disease and treatment, fear of falling and fracturing a bone, and fear of pain. Provide regular rest periods between activities.

Assess the patient for the location and severity of pain. The pain from bone cancer can be severe. It is often caused by the tumor pressing against nerves and other organs near the bone. New onset or changes in pain severity may indicate pathologic fracture. Ensure adequate pain medication is provided. Sometimes radiation therapy is used as a palliative treatment to shrink the tumor and decrease pain.

Assist the patient and caregiver in managing the diagnosis of bone cancer. Give special attention to managing pain and disability, side effects of chemotherapy, and postoperative care (e.g., after spinal cord decompression or amputation). As with all types of cancer, stress the importance of follow-up care.

MUSCULAR DYSTROPHY

Muscular dystrophy (MD) is a group of genetic diseases characterized by progressive symmetric wasting of skeletal muscles without neurologic involvement. A gradual loss of strength with increasing disability and deformity occurs with all forms of MD. Life expectancy is increasing due to advances in cardiac and respiratory care.

The types of MD differ in the groups of muscles affected, age of onset, rate of progression, and mode of genetic inheritance (Table 68.5). Duchenne MD is the most common type. Duchenne and Becker MDs are X-linked recessive disorders usually seen only in males (Box 68.1).[7]

TABLE 68.5 Select Types of MD

	Genetic Basis	Manifestations
Becker	• X-linked • Mutation of dystrophin gene	• Very similar but less severe than Duchenne MD • Onset ages 5–15 • Slower course of pelvic and shoulder muscle wasting than Duchenne • Cardiomyopathy • Respiratory failure • May survive into 50s
Duchenne	• X-linked • Mutation of dystrophin gene	• Most common form of MD • Primarily affects boys • Onset before age 5 • Progressive weakness of pelvic and shoulder muscles • Unable to walk by age 12 • Cardiomyopathy • Respiratory failure in 20s • Mental impairment
Facioscapulohumeral	• Autosomal dominant • Deletion of chromosome *4q35*	• Onset before age 20 • Slowly progressive weakness of face, shoulder muscles, and upper arms and lower legs • Can affect vision and hearing
Limb-girdle	• Autosomal recessive or autosomal dominant • Mutation in any of at least 15 genes affecting proteins needed for muscle function	• Group of disorders affecting voluntary muscles, especially those of hips and shoulders • Onset ranges from early childhood to early adulthood or later • Slow progressive weakness of hip and shoulder muscles

Other diagnostic studies include muscle serum enzymes (especially creatine kinase), electromyogram (EMG) testing, and muscle fiber biopsy. Classic findings on muscle biopsy include fat and connective tissue deposits, muscle fiber degeneration and necrosis, and a deficiency of dystrophin. An ECG may show abnormalities that suggest cardiomyopathy.

There is no cure for MD. Corticosteroids may slow disease progression for up to 2 years and improve survival.[8] Deflazacort (Emflaza) is the first corticosteroid approved to treat Duchenne MD. Eteplirsen (Exondys 51) is the first disease-modifying drug to treat patients with Duchenne MD who have a certain dystrophin gene mutation.[9]

The main treatment goals are to preserve mobility and independence through exercise, physical therapy, and use of assistive devices. Progressive muscle weakening around the trunk can cause spinal collapse. The patient may be fitted early with an orthotic jacket to give stability and prevent further deformity or injury.

Cardiomyopathy often occurs and causes heart failure.[8] Gradual decreases in pulmonary function often lead to the use of continuous positive airway pressure (CPAP). Eventually

BOX 68.1 GENETICS IN CLINICAL PRACTICE

Duchenne and Becker Muscular Dystrophy (MD)

Genetic Basis
- Caused by various mutations in the dystrophin *(DMD)* gene
- Gene provides instructions for making dystrophin, a protein that helps keep muscle fibers intact
- Dystrophin is found mainly in skeletal and cardiac muscle
- Abnormal dystrophin can cause defects in the muscle fiber and muscle fiber degeneration
- Inherited in an X-linked recessive pattern
- Females in affected families have a 50% chance of inheriting and passing the defective gene to their children

Incidence
- Between 400 and 600 boys are born with MD each year in the United States
- Together they affect 1 in 3500 to 5000 newborn males worldwide

Genetic Testing
- DNA testing can detect mutations in dystrophin gene
- Genetic testing and counseling should be considered for those with a family history of MD

Clinical Implications
- Because there are many types of MD with different genetic bases, knowing the type of MD is important to direct treatment and genetic counseling recommendations.

tracheostomy and mechanical ventilation are needed to support respiratory function.

Encourage communication between the patient and family to cope with the emotional and physical demands of MD. Teach the patient and caregiver range-of-motion (ROM) exercises, principles of good nutrition, and signs of disease progression.

Focus care on keeping the patient active as long as possible. Prolonged bed rest should be avoided because immobility can cause more muscle wasting. As the disease progresses, teach the patient to limit sedentary periods to prevent skin breakdown and respiratory complications. Ongoing medical and nursing care is needed throughout the patient's life.

The Muscular Dystrophy Association (www.mda.org) is an important resource with information about support services for the patient and caregivers. The website gives updates about the latest clinical trials and treatment advances.

LOW BACK PAIN

Low back pain is most often due to a musculoskeletal problem. It may be localized or diffuse. In *localized pain,* patients feel soreness or discomfort when a specific area of the lower back is palpated or pressed. *Diffuse pain* occurs over a larger area and comes from deep tissue.

Low back pain may be radicular or referred. *Radicular pain* is caused by irritation of a nerve root. Radicular pain is not isolated to a single location. Instead, it radiates or moves along a nerve distribution. Sciatica is an example of radicular pain. *Referred pain* is felt in the lower back, but the source of the pain is another location (e.g., kidneys, lower abdomen).

Low back pain affects about 80% of adults in the United States at least once during their lives. Backache is second to headache as the most common pain problem. It is the leading cause of job-related disability and a major contributor to missed work.[10]

Low back pain is common because the lumbar region (1) bears most of the weight of the body, (2) is the most flexible region of the spinal column, (3) has nerve roots that are at risk for injury or disease, and (4) has a naturally poor biomechanical structure. Risk factors include lack of muscle tone, obesity, trauma, poor posture, older age, smoking, pregnancy, prior compression fracture of the spine, spinal problems since birth, and a family history of back pain. Jobs that require repetitive heavy lifting, vibration (e.g., a jackhammer operator), and extended periods of sitting are associated with low back pain.

The causes of low back pain of musculoskeletal origin include (1) acute lumbosacral strain, (2) instability of the lumbosacral bony mechanism, (3) osteoarthritis (OA) of the lumbosacral vertebrae, (4) degenerative disc disease (DDD), and (5) herniation of an intervertebral disc.

ACUTE LOW BACK PAIN

Acute low back pain lasts 4 weeks or less. Most acute low back pain is caused by trauma or an activity that cause undue stress (often hyperflexion) on the lower back. Examples of trauma or activities that cause acute back pain are heavy lifting; overuse of back muscles during yard work; a sports injury; or a sudden jolt, as in a motor vehicle crash.

Often symptoms do not appear at the time of injury. They develop later (usually within 24 hours) because of a gradual increase in pressure on the nerve from an intervertebral disc and/or associated edema. Symptoms may range from muscle ache to shooting or stabbing pain, limited flexibility or ROM, or an inability to stand upright.

Few definitive diagnostic abnormalities are present with nerve irritation and muscle strain. One test is the straight-leg-raising test (see Chapter 66). MRI and CT scans are not done unless trauma or systemic disease (e.g., cancer, spinal infection) is suspected. MRI findings may be limited in the acute phase of an injury due to increased edema near the injury.

NURSING AND INTERPROFESSIONAL MANAGEMENT: ACUTE LOW BACK PAIN

Assessment

Subjective and objective data that you should obtain from the patient with low back pain are outlined in Table 68.6.

Implementation

Acute Care

If acute muscle spasms and accompanying pain are not severe and unbearable, the patient is treated as an outpatient with NSAIDs and muscle relaxants (e.g., cyclobenzaprine). Massage, back manipulation, acupuncture, and cold and hot compresses

TABLE 68.6 NURSING ASSESSMENT

Low Back Pain

Subjective Data

Important Health Information

Health history: Acute or chronic lumbosacral strain/trauma, osteoarthritis, degenerative disc disease, obesity

Medications: Opioid analgesics and NSAIDs, muscle relaxants, corticosteroids, over-the-counter remedies (e.g., topical ointments, patches)

Surgery or other treatments: Back surgery, epidural corticosteroid injections

Functional Health Patterns

Health perception–health management: Smoking, lack of exercise

Nutritional-metabolic: Obesity

Activity-exercise: Poor posture, muscle spasms, activity intolerance

Elimination: Constipation

Sleep-rest: Interrupted sleep

Cognitive-perceptual: Pain in back, buttocks, or leg associated with walking, turning, straining, coughing, leg raising. Numbness or tingling of legs, feet, toes

Role-relationship: Occupations requiring heavy lifting, vibrations, or extended driving. Change in role within family structure due to inability to work and provide income

Objective Data

General

Guarded movement

Musculoskeletal

Tense, tight paravertebral muscles on palpation, ↓ range of motion in spine

Neurologic

Depressed or absent Achilles tendon reflex or patellar tendon reflex. Positive straight-leg-raising test, positive crossover straight-leg-raising test, positive Trendelenburg test

Possible Diagnostic Findings

Localization of site of lesion or disorder on myelogram, CT scan, or MRI. Determination of nerve root impingement on EMG

TABLE 68.7 PATIENT & CAREGIVER TEACHING

Low Back Problems

Include the following instructions when teaching the patient and caregiver how to manage low back problems:

Do

- Maintain healthy body weight.
- Maintain a neutral pelvic position if standing. Place 1 foot on a low stool if standing for long periods.
- Choose a seat with good lower back support, armrests, and a swivel base. Place a pillow at the lumbar spine to maintain normal curvature. Keep knees and hips level.
- Sleep in a side-lying position with knees and hips bent, and a pillow between the knees for support.
- Sleep on back with a lift under knees and legs or on back with 10-in-high pillow under knees to flex hips and knees.
- Use proper body mechanics when lifting heavy objects. Bend at the knees, not at the waist, and stand up slowly while holding object close to your body.
- Take part in regular strength and flexibility training and low-impact aerobic exercise.
- Use local heat and cold application to relieve muscle tension.

Do Not

- Lean forward without bending knees.
- Lift anything above level of elbows.
- Stand unmoving for prolonged time.
- Sleep on abdomen or on back or side with legs out straight.
- Exercise without consulting HCP if having severe pain.
- Exceed prescribed amount and type of exercises without consulting HCP.
- Smoke or use tobacco products.

may help some patients. Severe pain may need a brief course of corticosteroids or opioid analgesics.

Some people may need a brief period (1 to 2 days) of rest at home. They should avoid prolonged bed rest. Most patients do better if they continue their regular activities. Patients should refrain from activities that increase the pain, including lifting, bending, twisting, and prolonged sitting. Symptoms of acute low back pain usually improve within 2 weeks. They often resolve without treatment.

Other nursing interventions for the patient with low back pain are detailed in eNursing Care Plan 68.2 (available on the website for this chapter).

◆ Ambulatory Care

The goal of care is to make an episode of acute low back pain an isolated incident. If the lumbosacral area is unstable, repeated episodes are likely. Teach the patient about the cause of the pain and ways to prevent further episodes. Exercise is aimed at strengthening the supporting muscles. Muscle stretching may be part of the management plan. Referral to a physical therapist or personal trainer to address posture and core and abdomen strength may be appropriate. Reinforce the type and frequency of prescribed exercise and the reason for the program.

Persistent use of poor body mechanics may result in repeated episodes of low back pain. Offer advice when the person does activities that could cause back strain. Some HCPs refer patients with back pain to a formal program called "Back School." Back School is usually taught by an HCP, nurse, or physical therapist. It is designed to teach the patient ways minimize back pain and avoid repeat episodes of pain.

Tips for prevention of back injury are listed in Table 68.7. Recommend flat shoes or shoes with low heels and shock-absorbing shoe inserts for women. Stress the importance of smoking cessation. Tobacco use impairs circulation to the intervertebral discs and contributes to low back pain.

Advise patients to maintain a healthy body weight. Excess body weight places more stress on the lower back. It weakens abdominal muscles that support the lower back. Sleeping position is important. Teach patients to avoid sleeping in a prone position. It causes excessive lumbar lordosis, placing stress on the lower back. Sleeping in a supine or side-lying position with knees and hips flexed prevents pressure on support muscles, ligaments, and lumbosacral joints. Recommend use of a firm mattress.

If the strain is work related, occupational counseling may be needed. Low back pain can cause frustration, pain, and

disability. Provide emotional support and understanding care of the patient.

Health care personnel who perform direct patient care activities are at high risk for developing low back pain.[11] Lifting and moving patients, excessive bending or leaning forward, and frequent twisting can result in low back pain. This causes lost productivity and disability. Safe patient handling devices to lift, transfer, and reposition patients are recommended for nurse and patient safety. Serve as a role model by always using proper body mechanics. This includes raising the patient's bed height, bending at the knees, and asking for help in lifting and moving patients.

CHRONIC LOW BACK PAIN

Chronic low back pain lasts more than 3 months or involves a repeated incapacitating episode. It is often progressive. The cause can be hard to determine. Causes include (1) degenerative conditions, such as arthritis or disc disease; (2) osteoporosis or other metabolic bone diseases; (3) weakness from the scar tissue of prior injury; (4) chronic strain on lower back muscles from obesity, pregnancy, or stressful postures on the job; and (5) congenital spine problems.

Spinal Stenosis

Spinal stenosis is a narrowing of the spinal canal, which holds the spinal cord. Stenosis in the lumbar spine is a common cause of chronic low back pain. Spinal stenosis can be acquired or inherited. A common acquired cause is OA. Arthritic changes (bone spurs, calcification of spinal ligaments, disc degeneration) narrow the space around the spinal canal and nerve roots, eventually leading to compression. Inflammation caused by the compression results in pain, weakness, and numbness.

Other acquired conditions that may cause spinal stenosis include rheumatoid arthritis, spinal tumors, Paget disease, and traumatic damage to the vertebral column. Inherited conditions that lead to spinal stenosis include congenital spinal stenosis and scoliosis.

The pain from lumbar spinal stenosis often starts in the lower back and then radiates to the buttock and leg. It is worse with walking or prolonged standing. Numbness, tingling, weakness, and heaviness in the legs and buttocks may be present. History of decreased pain when the patient bends forward or sits is often a sign of spinal stenosis. Cold, damp weather may worsen the pain. In most cases, stenosis slowly progresses.

Interprofessional and Nursing Care

The management and treatment of chronic low back pain are similar to those for acute low back pain. Manage the patient's pain and stiffness with mild analgesics, such as NSAIDs, for daily comfort. Antidepressants (e.g., duloxetine) may help with pain and sleep problems. The antiseizure drug gabapentin may improve walking and relieve leg symptoms.

Weight reduction, rest periods, and exercise and activity throughout the day help keep the muscles and joints mobilized. Physical therapy can significantly reduce pain and improve body posture. Rest and local heat application can decrease pain. Complementary and alternative therapies, such as biofeedback, acupuncture, and yoga, may help reduce pain.

Minimally invasive treatments, such as epidural corticosteroid injections and implanted devices that deliver pain medication, are options for those who do not respond to the usual therapies. Surgery may be done in patients with severe pain who received no benefit from conservative care and/or have continued neurologic deficits.

INTERVERTEBRAL DISC DISEASE

Intervertebral discs separate the vertebrae and help absorb shock for the spine. *Intervertebral disc disease* involves the deterioration, herniation, or other problem with the intervertebral discs. Disc problems can affect the cervical, thoracic, and lumbar spine.

Etiology and Pathophysiology

Degenerative disc disease (DDD) results from loss of fluid in the intervertebral discs with aging. The discs lose their elasticity, flexibility, and shock-absorbing abilities. Unless it is accompanied by pain, DDD is a normal process. The discs become thinner as the *nucleus pulposus* (gelatinous center of the disc) starts to dry out and shrink. This change limits the disc's ability to distribute pressure between vertebrae. The pressure is then transferred to the *annulus fibrosus* (strong outside part of the disc), causing progressive destruction. When the disc is damaged, the nucleus pulposus may seep through a torn or stretched annulus. This is called a **herniated disc** *(slipped disc),* a condition in which a spinal disc bulges outward between the vertebrae (Fig. 68.4).

A herniated disc can result from degeneration with age or repeated stress and trauma to the spine. The most common sites of herniation are the lumbosacral discs, specifically L4-5 and L5-S1. Disc herniation may also occur at C5-6 and C6-7. It may be the result of spinal stenosis. There is a narrowing of the spinal canal that forces the intervertebral disc to bulge.

The spinal nerves emerge from the spinal column through an opening *(intervertebral foramen)* between adjacent vertebrae. Herniated discs can press against these nerves ("pinched nerve"), causing *radiculopathy* (radiating pain, numbness, tingling, decreased strength and/or ROM).

OA of the spine is associated with DDD and the stresses placed on the vertebrae. As the poorly lubricated joints rub against each other, the protective cartilage is damaged and painful bone spurs occur.

Clinical Manifestations

In *lumbar disc disease,* the most common manifestation is low back pain. Radicular pain that radiates down the buttock and below the knee, along the distribution of the sciatic nerve, generally indicates disc herniation. Manifestations of lumbar disc herniation are outlined in Table 68.8. A positive straight-leg-raising test may indicate nerve root irritation (see Chapter 66). Back or leg pain may be reproduced by raising the leg.

Low back pain from other causes may not be accompanied by leg pain. Reflexes may be depressed or absent, depending on

the spinal nerve root involved. Numbness and tingling *(paresthesia)* or muscle weakness in the legs, feet, or toes may occur.

Multiple lumbar nerve root compressions *(cauda equina syndrome)* may occur from a herniated disc, tumor, or epidural abscess. Manifestations include severe low back pain, progressive weakness, increased pain, and bowel and bladder incontinence or retention. Saddle anesthesia (loss of or altered sensation of the perineum, buttocks, inner thighs and back of the legs [saddle area]) may be present. Symptoms of cauda equina syndrome may develop suddenly or evolve slowly over time. They may vary in intensity. Cauda equina is a medical emergency. It requires surgical decompression to reduce pressure on the nerves and prevent permanent paralysis.[12]

In *cervical disc disease,* pain radiates into the arms and hands, following the pattern of the involved nerve. Like lumbar disc disease, reflexes may or may not be present. The handgrip is often weak. Because manifestations of cervical disc disease may include shoulder pain and problems, the HCP must rule out shoulder problems as part of the diagnosis.

Diagnostic Studies

X-rays are done to detect any structural defects. A myelogram, MRI, or CT scan is helpful in localizing the damaged site. An epidural venogram or diskogram may be needed if other diagnostic studies are inconclusive. An EMG of the extremities can be done to determine the severity of nerve irritation or to rule out other conditions, such as peripheral neuropathy.

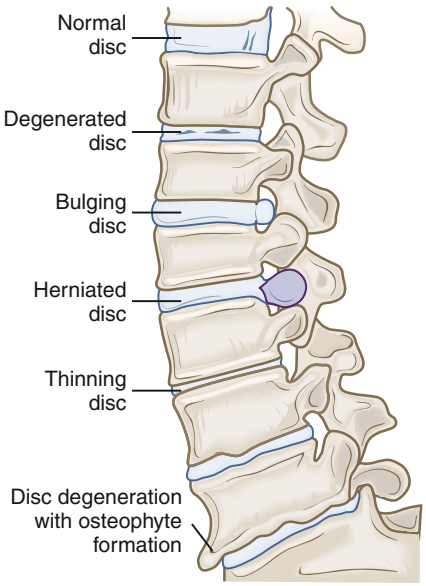

Fig. 68.4 Common causes of degenerative disc damage.

Interprofessional Care

The patient with suspected disc damage is usually managed with conservative therapy (Table 68.9). This includes limiting extremes of spinal movement (e.g., brace, corset, belt), local heat or ice, ultrasound and massage, traction, and transcutaneous electrical nerve stimulation (TENS). Drug therapy to manage pain includes NSAIDs, short-term oral corticosteroids, opioid analgesics, muscle relaxants, antiseizure drugs, and antidepressants.[13] Epidural corticosteroid injections may reduce inflammation and relieve acute pain. However, pain tends to recur if the underlying cause remains.

When symptoms subside, the patient should begin back-strengthening exercises twice a day and continue for life. Teach the patient the principles of good body mechanics. Discourage extremes of flexion and torsion. Most patients heal after 6 months with a conservative treatment plan.[13]

Surgical Therapy

If conservative treatment is unsuccessful, radiculopathy becomes worse, or loss of bowel or bladder control occurs, surgery may be considered. Surgery for a damaged disc is generally done if the patient is in constant pain and/or has a persistent neurologic deficit.

Intradiscal electrothermoplasty (IDET) is a minimally invasive outpatient procedure for treating back and sciatic pain. A needle is inserted into the affected disc with x-ray guidance. A wire is then threaded through the needle and into the disc. As the wire is heated, small nerve fibers that have invaded the degenerating disc are destroyed. The heat also partially melts the annulus fibrosus. This causes the body to make new reinforcing proteins in the fibers of the annulus.

Another outpatient technique is *radiofrequency discal nucleoplasty* (coablation nucleoplasty). Like IDET, a needle is inserted into the disc. Instead of a heated wire, a special radiofrequency probe is used. The probe generates energy that breaks the molecular bonds of the gel in the nucleus pulposus. Up to 20% of the nucleus is removed. This decompresses the disc, reducing pressure on the disc and surrounding nerve roots. Pain relief after varies.

A third minimally invasive procedure involves implanting a device made from titanium, elastomeric compounds, or other materials to decompress and/or stabilize the affected spinal

TABLE 68.8 Manifestations of Lumbar Disc Herniation

Intervertebral Level	Pain	Affected Reflex	Motor Function	Sensation
L3-4	Back to buttocks to posterior thigh to inner calf	Patellar	Quadriceps, anterior tibialis	Inner aspect of lower leg, anterior part of thigh
L4-5	Back to buttocks to dorsum of foot and big toe	None	Anterior tibialis, extensor hallucis longus, gluteus medius	Dorsum of foot and big toe
L5-S1	Back to buttocks to sole of foot and heel	Achilles	Gastrocnemius, hamstring, gluteus maximus	Heel and lateral foot

A disc herniation can involve pressure on more than 1 nerve root.

segment. *Interspinous devices* (ISDs) are implanted between the spinous processes to lift vertebrae off the pinched nerve. Newer ISDs include *interspinous dynamic stabilizers* (ISDSs) and *interspinous stabilizers* (ISSs). *ISSs* reduce the degree of extension of the vertebrae with no effect on spinal stability. *ISDSs* stabilize the spinal segment and provide some spacer properties.[14] Examples of devices include the Wallis, DIAM, X-Stop, and Coflex.

Laminotomy with discectomy (or lumbar discectomy) is the most common surgery. The HCP makes a small incision on the back over the involved disc. A small portion of the lamina is removed to expose the nerve root. Next, the herniated portion of the disc that is causing nerve root compression is removed. The goal is to relieve leg pain. It may or may not relieve back pain. A short hospital stay may be needed.[15]

Two minimally invasive procedures to decompress the nerve root are *microdiscectomy* and *endoscopic microdiscectomy.* In the first procedure, the HCP uses a microscope to see the disc and disc space in order to remove the herniated portion. *Percutaneous discectomy* uses instruments with a tiny camera with fluoroscopy guidance, then uses a laser on the damaged part of the disc.[15]

The goals of artificial disc replacement surgery are to restore movement and eliminate pain. The Charité disc is used in patients with lumbar disc damage from DDD. This disc has a high-density core between 2 cobalt-chromium end plates (Fig. 68.5). After removing the damaged disc, the device is surgically placed in the spine (usually through a small incision below the umbilicus). The disc restores movement at the level of the implant. The ProDisc-L and activL are 2 other types of artificial lumbar discs available.[16]

Options for treating DDD of the cervical spine include the Prestige cervical disc, Mobi-C disc, Secure-C, Simplify, and M6-C artificial cervical disc.

A *spinal fusion* may be needed if the spine is unstable. The spine is stabilized by creating *ankylosis* (fusion) of adjacent vertebrae with a bone graft from the patient's fibula or iliac crest *(autograft)* or from donated cadaver bone *(allograft).* Metal fixation with rods, plates, or screws may be placed to give more stability and decrease vertebral motion. Surgical procedures include posterior lumbar interbody fusion (PLIF), anterior lumbar interbody fusion (ALIF), transforaminal lumbar interbody fusion (TLIF), and extreme lateral interbody fusion (XLIF).[15]

Bone morphogenetic protein (BMP), a genetically engineered protein, may be used to stimulate bone growth of the graft in spinal fusions. A dissolvable sponge soaked with BMP is implanted into the spine. BMP on the sponge stimulates the body's cells to become active and produce bone, promoting fusion. The body absorbs the sponge, leaving living bone behind.

TABLE 68.9 Interprofessional Care

Intervertebral Disc Disease

Diagnostic Assessment
- History and physical assessment
- X-ray
- CT scan
- MRI
- Myelogram
- Diskogram
- EMG

Management

Conservative Therapy
- Restricted activity for several days, limited total bed rest
- Local ice or heat
- Physical therapy
- Analgesics (e.g., tramadol [Ultram])
- NSAIDs
- Muscle relaxants (e.g., cyclobenzaprine)
- Antiseizure drugs (e.g., gabapentin)
- Antidepressants
- Epidural corticosteroid injections

Surgical Therapy
- Intradiscal electrothermoplasty (IDET)
- Radiofrequency discal nucleoplasty
- Interspinous process decompression system (X-Stop)
- Laminectomy with or without spinal fusion
- Discectomy
- Percutaneous laser discectomy
- Artificial disc replacement (e.g., Charité disc)
- Spinal fusion with instrumentation (e.g., plates, screws) or without instrumentation

❖ NURSING MANAGEMENT: SPINE SURGERY

Nursing care after spine surgery is outlined in Table 68.10. A key nursing focus is maintaining proper spinal alignment until it has healed. Depending on the type and extent of surgery and the HCP's preference, the patient may be able to dangle the legs at the side of the bed, stand, or even ambulate the day of surgery.

After lumbar fusion, place pillows under the patient's thighs when supine and between the legs when in the side-lying position to provide comfort and ensure alignment. The patient often fears turning or any movement that may increase pain. Have

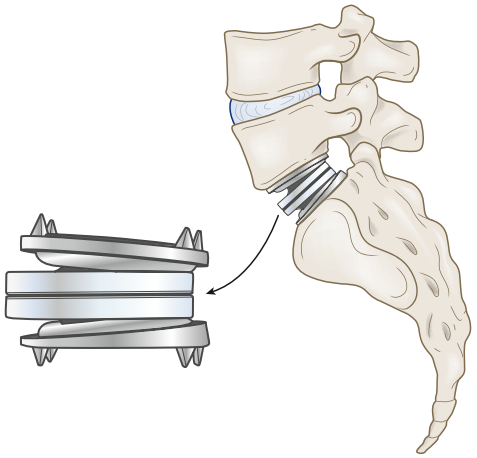

Fig. 68.5 The Charité artificial disc, used to replace a damaged intervertebral disc in degenerative disc disease of the lumbar spine. A movable high-density plastic core is placed between 2 cobalt-chromium alloy end plates. The disc's design helps realign the spine and preserve movement.

TABLE 68.10 NURSING MANAGEMENT

Care of the Patient After Spine Surgery

- Perform frequent peripheral neurologic and cardiovascular assessments.
- Monitor vital signs, intake and output.
- Maintaining proper spinal alignment:
  - Advance activity as ordered
  - Help patent with changing positions
  - Apply any immobilizers, braces, orthotics as ordered
- Assess for the presence of CSF leakage. If suspected, place the patient flat.
- Assess pain and give analgesics as ordered. Assess response.
- Administer IV fluids and antibiotics as prescribed.
- Provide wound care as ordered and assess for signs of infection.
- Assess for constipation and paralytic ileus. Give stool softeners or laxatives as ordered.
- Implement measures to promote elimination. Perform intermittent catheterization as needed.
- Implement prevention measure for VTE and CAUTI (if the patient has an indwelling catheter).
- Immediately report to the HCP:
  - Severe headache
  - Hypotension, tachycardia, fever
  - Suspected CSF leakage
  - Any new muscle weakness or paresthesia
  - Onset of bowel or bladder problems
  - Pain not responsive to analgesics
  - Signs of wound infection

Collaborate With Physical Therapist

- Assess patient's mobility and need for aid.
- Teach safe ambulation with assistive device based on patient's restrictions.
- Establish exercise plan, and teach patient to perform exercises safely.
- Coordinate PT so that patient can receive timely analgesia.

the patient logroll when changing position in bed. Have enough staff available to move the patient without undue pain or strain for the patient or staff. Reassure the patient that proper technique is being used to maintain body alignment.

After surgery, most patients need opioids, such as morphine IV, for 24 to 48 hours. Once the patient receives oral fluids, they can transition to oral drugs. Diazepam (Valium) may be prescribed for muscle relaxation.

Because the spinal canal may be entered during surgery, cerebrospinal fluid (CSF) leakage is possible. Immediately report leakage of CSF on the dressing or if the patient reports a severe headache. CSF appears as clear or slightly yellow drainage on the dressing. It has a high glucose concentration and tests positive for glucose with a dipstick. If suspected, place the patient flat.

Frequently assess peripheral neurologic condition and compare with the preoperative assessment. Movement of the arms and legs and assessment of sensation should at least equal the preoperative status. Repeat these assessments every 2 to 4 hours during the first 48 hours after surgery. Paresthesia may not be relieved right after surgery. Report any new muscle weakness or paresthesia at once. Assess extremity circulation using skin temperature, capillary refill, and pulses.

Paralytic ileus and interference with bowel function may occur for several days. Opioids can slow bowel elimination. Assess if the patient is passing gas, has bowel sounds, and has a flat, soft abdomen. Stool softeners (e.g., docusate) and laxatives may prevent and relieve constipation.

Emptying the bladder may be hard due to activity restrictions, opioids, or anesthesia. Encourage men to dangle the legs over the side of the bed or stand to urinate if allowed by the HCP. Urge patients to use a bedside commode or ambulate to the bathroom when allowed, to promote bladder emptying. Intermittent catheterization or an indwelling urinary catheter may be needed by patients with problems urinating. Loss of sphincter tone or bladder tone may indicate nerve damage. Monitor for incontinence or problems with bowel or bladder elimination. Immediately report problems to the HCP.

With cervical spine surgery, be alert for signs of spinal cord edema, such as respiratory distress and a worsening neurologic condition of the upper extremities. After surgery, the patient's neck may be immobilized in a soft or hard cervical collar.

If the patient also had a spinal fusion, a bone graft is usually involved. Healing time will be prolonged compared with a laminectomy. Activity limitations may be needed for an extended time. A rigid orthosis (thoracolumbar sacral orthosis [TLSO] or chairback brace) is often used during this period. Some HCPs want patients to learn to apply and remove the brace by logrolling in bed. Others allow their patients to apply the brace in a sitting or standing position. Verify the preferred method before starting this activity.

Regularly assess the bone graft donor site. The posterior iliac crest is the most often used donor site, although the fibula may be used. The donor site usually causes greater pain than the spinal fusion area. The donor site is bandaged with a pressure dressing to prevent excessive bleeding. If the donor site is the fibula, perform frequent neurovascular assessment of the extremity.

After spinal fusion, the patient may have some immobility of the spine at the fusion site. Teach the patient to use proper body mechanics and avoid sitting or standing for prolonged periods. Encourage activities such as walking and shifting weight from 1 foot to the other when standing. Review any lifting restrictions. Encourage the patient to think through an activity before starting a potentially injurious task, such as bending or stooping. Any twisting movement of the spine is contraindicated. Teach the patient to use the thighs and knees, rather than the back, to absorb the shock of activity and movement. A firm mattress or bed board is essential.

NECK PAIN

Neck pain can result from various cervical spine problems. It is common in both general and workers' compensation populations. Neck pain may result from benign *(cervical strains)* or more serious conditions (spondylosis, or degeneration; disc herniation; stenosis; or fractures) (Table 68.11).[17]

Cervical neck sprains and strains occur from hyperflexion and hyperextension injuries. Patients have stiffness and neck pain with possible radicular pain into the arm and hand. Pain may radiate to the head, anterior chest, thoracic spine region, and shoulders. Weakness or paresthesia of the arm and hand

TABLE 68.11 Causes of Neck Pain

- Degenerative disc disease, including herniation

- Osteomyelitis
- Osteoporosis
- Poor posture
- Rheumatoid arthritis
- Spondylosis
- Strain or sprain
- Trauma (e.g., fractures, subluxation)
- Tumor

suggests cervical nerve root compression from stenosis, DDD, or herniation.

The cause of neck pain is diagnosed by history, physical assessment, x-ray, MRI, CT scan, and myelogram. An EMG of the upper extremities may show cervical radiculopathy.

Conservative treatment for acute neck pain in patients without serious pathologies includes physical therapy followed by a home exercise program, gentle traction, and cautious manipulation due to possible worsening of symptoms. TENS and acupuncture may be helpful for short-term pain relief. There is no research to support the use of ultrasound. Drug therapy includes acetaminophen and NSAIDs. Opioids should be used only for intractable pain in the short term with close supervision by HCPs.[17] Multimodal strategies are more effective. Most neck pain resolves in about 2 months without surgical intervention.

Patient teaching should emphasize self-management and the importance of an active lifestyle. Preventing neck pain that occurs with everyday activities, such as prolonged sitting at a computer or television, sleeping in nonaligned spinal positions, or making jarring movements during exercise, is important. Cognitive behavioral therapy may assist with psychosocial risk factors.

FOOT PROBLEMS

The foot is the platform that supports the weight of the body and absorbs shock when the person ambulates. It is a complicated structure composed of bony structures, muscles, tendons, and ligaments. The foot can be affected by (1) congenital conditions; (2) structural weakness; (3) traumatic and stress injuries; and (4) systemic conditions, such as diabetes and rheumatoid arthritis. Table 68.12 outlines common foot problems.

Shoes may cause crowding and angulation of the toes and inhibit normal movement of foot muscles. Ill-fitting shoes that increase foot pain affect quality of life. They may increase the odds of falls in older adults.[18] Prolonged use of improper footwear can also cause a *Morton neuroma*. The neuroma compresses an intermetatarsal plantar nerve, resulting in paresthesia and burning. At first, patients may describe feeling as if a sock is rolled up under their toes. Neuromas usually occur between the third and fourth toes.

NURSING MANAGEMENT: FOOT PROBLEMS

Implementation

Health Promotion

Well-made and properly fitted shoes are essential for healthy, pain-free feet. Footwear should provide support, stability, protection, and shock absorption. Footwear provides a foundation for orthotics and can treat some foot problems.

Women's footwear is often influenced by current styles instead of comfort and support. Stress the importance of having a shoe that conforms to the foot rather than to fashion trends. The shoe must be long enough and wide enough to avoid crowding the toes and forcing the great toe into a position of **hallux valgus** (Fig. 68.6). At the metatarsal head, the shoe should be wide enough to allow foot muscles to move freely and toes to bend. The shank (narrow part of sole under the instep) of the shoe should be rigid enough to give good support. The height of the heel should be realistic in relation to the shoe's purpose. Ideally, the heel of the shoe should not rise more than 1 inch higher than the forefoot support. Wearing higher heeled shoes with a narrow toe box will cause hammertoes and corns over time.

Acute Care

Many foot problems require referral to a podiatrist. Depending on the problem, conservative therapies are tried first (Table 68.12). These include NSAIDs, ice, physical therapy, footwear changes, stretching, warm soaks, orthotics, ultrasound, and corticosteroid injections. If these methods do not help, surgery may be needed.

CHECK YOUR PRACTICE

A 53-year-old woman is scheduled for surgical correction of a bunion after a diagnosis of hallux valgus. You are doing her preoperative assessment. She says, "I love shoes and have a whole closet full of fancy ones. Now I have to wear this big ugly shoe. I hope I can wear my nice shoes after surgery."

- How will you respond to the patient?
- What are the priority learning needs related to her self-care after surgery?

Depending on the type of surgery, pins or wires may extend through the toes, or a protective splint may be placed over the end of the foot. The foot is usually immobilized by a bulky dressing (Fig. 68.7), short leg cast, slipper (plaster) cast, or a platform shoe that fits over the dressing and has a rigid sole (also known as a *bunion shoe*).

Elevate the foot with the heel off the bed to reduce discomfort and prevent edema. Assess neurovascular condition frequently during the immediate postoperative period. Inserted devices may interfere with assessment for movement. Be aware that evaluating sensation may be hard because the patient may be unable to distinguish surgical pain from pain caused by nerve pressure or circulatory impairment.

The type and extent of surgery determine the orders for ambulation. Crutches, a walker, or a cane may be needed. The patient may have pain or a throbbing sensation when lowering

TABLE 68.12 Common Foot Problems

Problem	Description	Treatment
Forefoot		
Hallux rigidus	Painful stiffness of first MTP joint caused by osteoarthritis or local trauma.	• Intraarticular corticosteroids, passive manual stretching of first MTP joint. • Shoe with a stiff sole decreases pain in the joint during walking. • Surgical treatment is joint fusion or arthroplasty with silicone rubber implant.
Hallux valgus (bunion)	Painful deformity of great toe with lateral angulation of great toe toward second toe, bony enlargement of medial side of first metatarsal head, swelling of bursa and formation of callus over bony enlargement (Fig. 68.6).	• Wearing shoes with wide forefoot or "bunion pocket" and use of bunion pads to relieve pressure on bursal sac. • Surgical treatment involves removal of bursal sac and bony enlargement and correction of lateral angulation of great toe. • May include temporary or permanent internal fixation.
Hammer and claw toes	Hammer toe is a deformity of PIP joint on 2nd to 5th toes causing toe to be permanently bent, resembling a hammer. Mallet toe is a similar condition affecting DIP joint. Claw toe is a similar deformity with dorsiflexion of proximal phalanx on MTP joint combined with flexion of both PIP and DIP joints. Symptoms include burning on bottom of foot and pain and difficulty walking when wearing shoes.	• Passive manual stretching of PIP joint, use of metatarsal arch support. • Surgical correction consists of resection of base of middle phalanx and head of proximal phalanx, bringing raw bone ends together. • Kirschner wire maintains straight position.
Morton neuroma (Morton toe or plantar neuroma)	Neuroma in web space between third and fourth metatarsal heads, causing sharp, sudden attacks of pain and burning sensations.	• Surgical excision.
Midfoot		
Pes cavus	Elevation of longitudinal arch of foot resulting from contracture of plantar fascia or bony deformity of arch.	• Surgical correction needed if condition interferes with ambulation.
Pes planus (flatfoot)	Loss of metatarsal arch causing pain in foot or leg.	• Use of resilient longitudinal arch supports. • Surgical treatment consists of triple arthrodesis or fusion of subtalar joint.
Hindfoot		
Calcaneus stress fracture	Heel pain after moderate walking. Common causes are overtraining, running on hard surfaces, osteoporosis.	• Rest, ice, shoe heel pad, NSAIDs. • See HCP to assess for osteoporosis.
Heel pain	Heel pain with weight bearing. Common causes are plantar bursitis, plantar fasciitis, bone spur.	• Corticosteroids injected locally into inflamed bursa. • Sponge-rubber heel cup. • Surgical excision of bursa or spur. • Stretching exercises, ice, shoe heel cup, shock-wave therapy, NSAIDs, corticosteroids for plantar fasciitis.
Other Problems		
Callus	Localized thickening of skin. Covers wide area and usually found on weight-bearing part of foot.	• Softened with warm water or preparations containing salicylic acid and trimmed with razor blade or scalpel. • Pressure on bony prominences caused by shoes is relieved.
Corn	Localized thickening of skin caused by continual pressure over bony prominences, especially metatarsal head, often causing localized pain.	• Same as with callus.
Plantar wart	Painful papillomatous growth caused by virus that may occur on any part of skin on sole of foot. Warts tend to cluster on pressure points.	• Remedies containing salicylic acid (e.g., Compound W), excision with electrocoagulation, or surgical removal. • Laser treatments. • May disappear without treatment.
Soft corn	Painful lesion caused by bony prominence of a toe pressing against adjacent toe. Usual location is web space between toes. Softness caused by secretions keeping web space relatively moist.	• Pain relieved by placing cotton or spacers between toes to separate them. • Surgical treatment is excision of projecting bone spur (if present).

DIP, Distal interphalangeal; *MTP,* metatarsophalangeal; *PIP,* proximal interphalangeal.

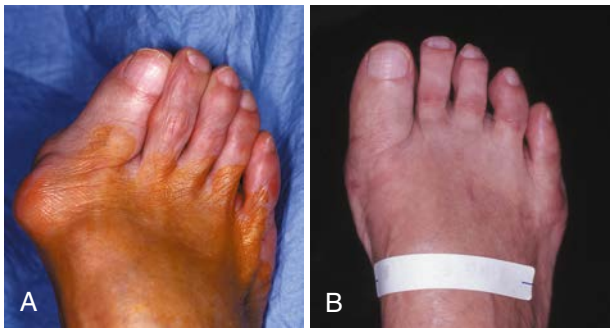

Fig. 68.6 (A) Severe hallux valgus with bursa formation. (B) Postoperative correction. (From Canale ST, Beaty JH: *Campbell's operative orthopaedics,* ed 12, Philadelphia, 2013, Mosby.)

the affected leg. Reinforce instructions from the physical therapist. Teach the patient the importance of walking with an erect posture with proper weight distribution. Report gait problems or continued pain to the HCP. Encourage frequent rest periods with the foot elevated.

Ambulatory Care

Teach the patient to perform daily hygienic foot care and wear clean stockings. Stockings should be long enough to avoid wrinkling and causing pressure areas. Trimming toenails straight across helps prevent ingrown toenails and reduces the risk for infection. Provide instruction to patients with impaired circulation or diabetes to prevent serious complications from blisters, pressure areas, and infection.

Gerontologic Considerations: Foot Problems

The older adult is prone to foot problems because of poor circulation, atherosclerosis, and decreased sensation in the lower extremities. This is especially true for those with diabetes. A patient may develop an open wound but not feel it because of altered sensation from peripheral vascular disease or diabetic neuropathy. Teach older adults to inspect their feet daily and report any open wounds or breaks in the skin to their HCP.

Untreated wounds may become infected, lead to osteomyelitis, and need surgical debridement. If the infection becomes widespread, lower limb amputation may be needed. Teach the caregiver of the older adult who needs help with hygiene practices to assess the feet at regular intervals.

METABOLIC BONE DISEASES

Normal bone metabolism is affected by hormones, nutrition, and genetics. When dysfunction occurs in any of these factors, generalized reduction in bone mass and strength may result. Metabolic bone diseases include osteomalacia, osteoporosis, and Paget disease.

OSTEOMALACIA

Osteomalacia is caused by a vitamin D deficiency that causes bone to lose calcium and become soft. The disease is uncommon in the United States. It is the same as rickets in children, except the epiphyseal growth plates are closed in adults. Vitamin

Fig. 68.7 Postoperative supportive dressing for treatment of moderate forefoot deformity. Dressing must be conforming and binding enough to hold toe in exact position. (From Canale ST, Beaty JH: *Campbell's operative orthopaedics,* ed 12, Philadelphia, 2013, Mosby.)

D is required for the absorption of calcium from the intestine. Insufficient vitamin D intake can interfere with normal bone mineralization. With little or no calcification, bones become soft.

Causes include limited sun exposure (ultraviolet rays needed for vitamin D synthesis), GI malabsorption (post weight loss surgery, celiac disease), chronic diarrhea, and pregnancy. Residents of long-term care settings may have inadequate sun exposure and thus poor synthesis of vitamin D. Chronic liver, kidney, and small intestine disease may contribute to vitamin D deficiency. Long-term use of antiseizure drugs (e.g., phenytoin) and phosphate-binding antacids (e.g., Maalox) may decrease calcium and vitamin D absorption.[19]

Common manifestations are bone pain and muscle weakness. The pain is often worse at night and affects the lower back, pelvis, hips, legs, and ribs.[19] Muscle weakness and progressive deformity of weight-bearing bones (e.g., spine, extremities) can lead to problems walking and a waddling gait. Fractures are common and indicate delayed bone healing.

Laboratory findings include decreased serum calcium or phosphorus, decreased serum 25-hydroxyvitamin D, and increased serum alkaline phosphatase. X-rays may show effects of generalized bone demineralization, especially loss of calcium in the bones of the pelvis and associated bone deformity. *Looser transformation zones* (ribbons of decalcification in bone found on x-ray) are diagnostic of osteomalacia. However, significant osteomalacia may exist without x-ray changes.

Treatment is directed toward correcting the vitamin D deficiency. The patient often has a dramatic response when vitamin D_3 (cholecalciferol) and vitamin D_2 (ergocalciferol) supplements are used. Calcium or phosphorus supplements may be prescribed. Encourage a diet rich in eggs, meat, and oily fish (e.g., salmon, tuna). Milk and breakfast cereals fortified with calcium and vitamin D should be part of the diet. Exposure to sunlight and weight-bearing exercise are valuable as well. Assess patients who had weight loss surgery to treat obesity for osteomalacia. Any vitamin D deficiencies should be corrected.[19]

OSTEOPOROSIS

Osteoporosis is a chronic, progressive metabolic bone disease marked by low bone mass and deterioration of bone tissue,

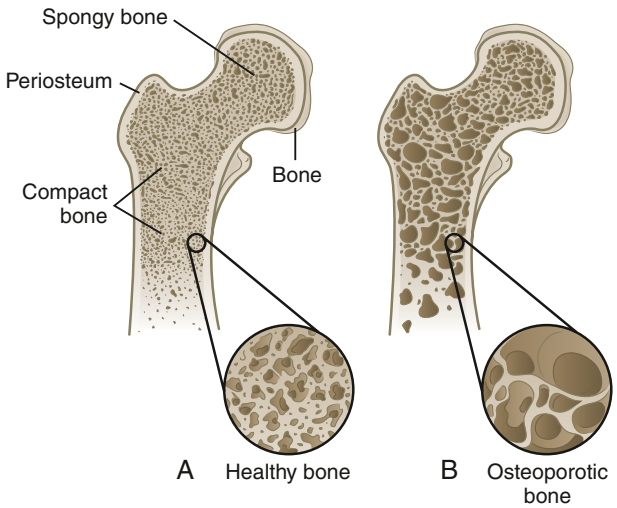

Fig. 68.8 (A) Normal bone. (B) Osteoporotic bone.

BOX 68.2 BIOLOGIC SEX CONSIDERATIONS

Osteoporosis

Men

- Men are underdiagnosed and undertreated for osteoporosis.
- 1 in men older than age 50 will have an osteoporosis-related fracture in his lifetime.

Women

- Osteoporosis is 8 times more common in women than in men.
- 1 in 2 women older than age 50 years will have an osteoporosis-related fracture in her lifetime.

leading to increased bone fragility (Fig. 68.8). More than 54 million persons in the United States have osteoporosis.[20] It is known as the "silent thief" because it slowly robs the skeleton of its banked resources. Bones eventually become so fragile that they cannot withstand normal mechanical stress.

Osteoporosis is more common in women (Box 68.2). There are several reasons why. Women tend to have lower calcium intake than men. Women have less bone mass because of their generally smaller frames. Bone resorption begins at an earlier age in women and becomes more rapid at menopause. Pregnancy and breastfeeding deplete a woman's skeletal reserve unless calcium intake is adequate. Women's longevity increases the risk for osteoporosis.

Current guidelines recommend an initial bone density test in all women older than age 65 years. If results are normal and the person is at low risk for osteoporosis, another test is not needed for 15 years. Women who are younger than 65 and at high risk (e.g., low body weight, smoker, prior fractures) should have a bone density test earlier. Testing should also start earlier and be done more often if a person is at high risk for fractures. Currently there is not enough evidence that shows any benefit for screening men.[21]

Etiology and Pathophysiology

Risk factors for osteoporosis are listed in Table 68.13. Regular weight-bearing exercise and adequate intake of fluoride, calcium, and vitamin D decrease risk. Low testosterone is a major risk factor in men.

TABLE 68.13 Risk Factors for Osteoporosis

- Advancing age (>65 years)
- Asian or White ethnicity
- Diet low in calcium or vitamin D deficiency
- Estrogen deficiency in women (surgical or age-related menopause)
- Excess use of alcohol (>2 drinks/day)
- Family history of osteoporosis
- Female gender
- Low body weight
- Low testosterone in men
- Medications: corticosteroids, thyroid replacement, heparin, long-acting sedatives, antiseizure drugs
- Sedentary lifestyle
- Smoking

Diseases associated with osteoporosis include inflammatory bowel disease, intestinal malabsorption, kidney disease, rheumatoid arthritis, hyperthyroidism, alcohol use disorder, cirrhosis, hypogonadism, and diabetes. Many drugs can interfere with bone metabolism. These include corticosteroids, antiseizure drugs (e.g., divalproex sodium, phenytoin), aluminum-containing antacids, heparin, some chemotherapy drugs, and excess thyroid hormones. When one of these drugs is prescribed, teach the patient about this possible side effect. Long-term corticosteroid use is a major contributor to osteoporosis.

Peak bone mass (maximum bone tissue) is typically achieved before age 20. It is largely determined by 4 factors: heredity, nutrition, exercise, and hormone function. Heredity may be responsible for up to 70% of a person's peak bone mass. Genetic factors also influence bone size, quality, and turnover. Bone loss from midlife (ages 35 to 40 years) onward is inevitable, but the rate of loss varies. At menopause, women have rapid bone loss when the decline in estrogen production is the greatest. The rate of loss then slows and eventually matches the rate of bone lost by men ages 65 to 70 years.

Bone is continuously being deposited by osteoblasts and resorbed by osteoclasts, a process called *remodeling*. Rates of bone deposition and resorption are normally equal, so total bone mass stays constant. In osteoporosis, bone resorption exceeds bone deposition.

Clinical Manifestations

Osteoporosis occurs most often in bones of the spine, hips, and wrists. Early manifestations include back pain and spontaneous fractures. The loss of bone mass causes the bone to become mechanically weaker and prone to spontaneous fractures or fractures from minimal trauma. A person who has a vertebral fracture due to osteoporosis has an increased risk for having a second vertebral fracture within 1 year. Over time, vertebral fractures and wedging cause gradual loss of height and a humped thoracic spine (*kyphosis,* or "dowager's hump") (Fig. 68.9).

Diagnostic Studies

Osteoporosis often goes unnoticed because it cannot be detected by conventional x-ray until 25% to 40% of calcium in the bone is

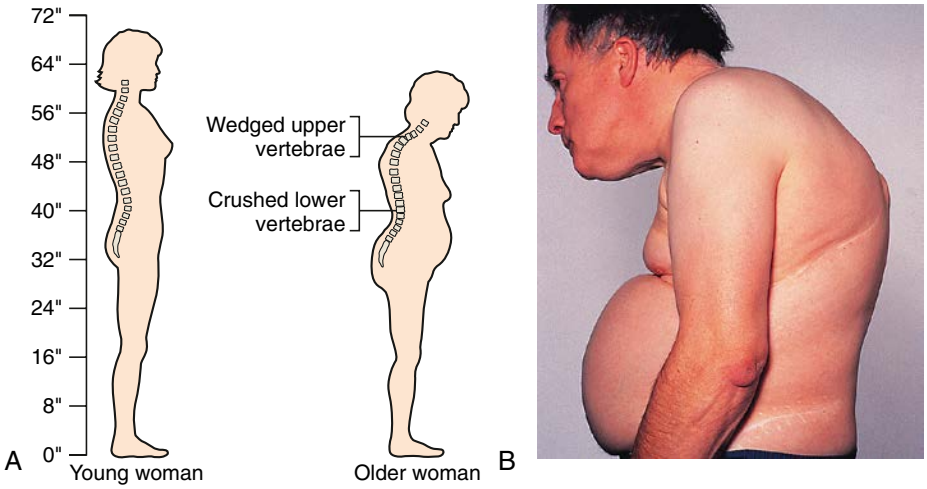

Fig. 68.9 The effects of osteoporosis. (A) Comparison of young woman with an older woman. (B) Severe fixed kyphosis producing a question-mark appearance. - History and physical assessment
- Serum calcium, phosphorus, alkaline phosphatase, vitamin D
- Bone mineral densitometry
- Dual energy x-ray absorptiometry (DEXA)

Management
- Adequate diet- calcium (Table 68.16)
- Calcium supplements
- Sun exposure or vitamin D supplements
- Exercise program
- Drug therapy (Table 68.17)
  - Bisphosphonates (recommended)
  - Monoclonal antibodies
  - Recombinant parathyroid hormone
- Minimally invasive procedures
  - Vertebroplasty
  - Kyphoplasty

lost. Serum calcium, phosphorus, and alkaline phosphatase levels usually are normal. Alkaline phosphatase may be increased after a fracture.

Bone mineral density (BMD) measurements are typically expressed as grams of mineral per unit volume. BMD is determined by peak bone mass and amount of bone loss (see Table 66.8). BMD may be measured by quantitative ultrasound (QUS) and dual-energy x-ray absorptiometry (DEXA). QUS uses sound waves to measure bone density in the heel, kneecap, or shin. DEXA measures bone density in the spine and hips. These are the most common sites of fragility fractures from osteoporosis. Most treatment guidelines use DEXA to guide the decision on when to start drug therapy to prevent osteoporotic fractures. DEXA studies evaluate changes in bone density over time and assess treatment effectiveness.

BMD test results are compared with the ideal or peak BMD of a healthy 30-year-old adult and reported as T-scores.[22] A T-score of 0 means the BMD is equal to the norm for a healthy young adult (Table 68.14). Differences between the BMD and that of the healthy young adult norm are measured in units called *standard deviations (SDs)*. The greater the negative number, the lower the BMD and the higher the risk for fracture.

Sometimes the HCP uses a Z-score instead of a T-score. In this case a person is compared with someone their own age, gender, and/or ethnic group instead of a healthy 30-year-old person. Among older adults, Z-scores can be misleading because decreased bone density is common. If the Z-score is –2 or lower, it may suggest that something other than aging is causing abnormal bone loss.

INTERPROFESSIONAL AND NURSING MANAGEMENT: OSTEOPOROSIS

Management focuses on proper nutrition, calcium and vitamin D supplementation, exercise, prevention of falls and fractures, and drugs (Table 68.15). The National Osteoporosis Foundation recommends treatment for osteoporosis for postmenopausal women with (1) a T-score of less than –2.5, (2) a T-score between –1 and –2.5 with other risk factors (Table 68.13), or (3) prior history of a hip or vertebral fracture.

We can also calculate a patient's risk for fracture from osteoporosis with the Fracture Risk Assessment (FRAX) tool. The

TABLE 68.16 NUTRITION THERAPY

Sources of Calcium

Food	Calcium (mg)
1 cup milk	
• Whole	279
• Skim	299
1 oz cheese	
• Mozzarella	222
• Cheddar	214
• Cottage	138
1/2 cup almonds	152
1 cup ice cream	168
6 oz calcium-fortified orange juice	261
3 oz seafood	
• Salmon	181
• Sardines	325
8 oz yogurt	313–384
Soft serve frozen yogurt	206

FRAX considers BMD and other clinical factors when assessing fracture risk.[23]

The recommended calcium intake is 1000 mg/day for women ages 19 to 50 years and men ages 19 to 70 years and 1200 mg/day in women age 51 years or older and men 71 years or older. Foods high in calcium include milk, yogurt, turnip greens, cottage cheese, ice cream, sardines, and spinach (Table 68.16). If diet intake of calcium is inadequate, calcium supplements calcium may be given.

It is hard to absorb calcium in single doses greater than 500 mg. Teach the patient to take calcium supplements as divided doses to increase absorption. The amount of elemental calcium varies in calcium preparations. Calcium carbonate has 40% elemental calcium. It should be taken with meals because stomach acid is needed to dissolve and absorb this supplement. Calcium citrate has around 20% elemental calcium but is less dependent on stomach acid for absorption. It is better absorbed by patients taking a proton pump inhibitor (e.g., esomeprazole) or histamine receptor blocker (e.g., cimetidine) for acid reflux. Calcium lactate and calcium gluconate are not recommended because they have small amounts of elemental calcium.

Vitamin D is important in calcium absorption and function and may have a role in bone formation. Most people get enough vitamin D from their diet or naturally through synthesis in the skin from exposure to sunlight. Being in the sun for 20 minutes a day is generally enough. However, supplemental vitamin D (800 IU) is recommended for postmenopausal women, older men, persons who are homebound or in long-term care settings, and those in northern climates, due to decreased sun exposure.

Regular physical activity is important to build and maintain bone mass. Exercise increases muscle strength, coordination, and balance. The best exercises are weight-bearing exercises that force a person to work against gravity. These include walking, hiking, weight training, stair climbing, tennis, and dancing. Walking is preferred to high-impact aerobics or running. Both may put too much stress on the bones and cause stress fractures. Encourage patients to walk 30 minutes 3 times a week. Teach patients to quit smoking and decrease alcohol use to lessen negative effects on bone mass.

Encourage patients to remain ambulatory to prevent further loss of bone density due to immobility. Treatment may involve the use of a gait aid to walk safely and protect areas of potential pathologic fractures. For example, a TLSO may be used to maintain the spine in proper alignment after fracture or treatment of a vertebral fracture.

Vertebroplasty and *kyphoplasty* are minimally invasive procedures used to treat osteoporotic vertebral fractures (see Chapter 62). In vertebroplasty, bone cement is injected into the collapsed vertebra to stabilize the spine and improve the patient's pain. This procedure does not restore vertebral height or correct deformity. In kyphoplasty, a small balloon is inserted into the collapsed vertebra and inflated to restore vertebral body height before injection of bone cement. Kyphoplasty is the preferred surgical treatment for vertebral compression fractures.

Drug Therapy

The recommended drug therapies for preventing and treating osteoporosis are the bisphosphonates alendronate, risedronate, zoledronic acid, or denosumab. Bisphosphonates inhibit osteoclast-mediated bone resorption and slow the cycle of bone remodeling. Although a modest increase in BMD is common, bone remodeling may be suppressed to the extent that normal bone formation is impaired and fracture risk increases. Treatment should continue for 5 years (Table 68.17).[24] A rare but serious side effect of bisphosphonates is *osteonecrosis* (bone death) of the jaw. Its cause is unknown. Those with dental disease, cancer, Paget disease, or renal disease are most at risk for this complication.

DRUG ALERT

Bisphosphonates

Teach patient to:
- Take with full glass of water.
- Take 30 min before food or other drugs.
- Stay upright for at least 30 min after taking.

Women no longer routinely use estrogen replacement therapy or estrogen with progesterone after menopause to prevent osteoporosis because of the increased risk for heart disease and breast and uterine cancer. A woman who takes short-term estrogen therapy to treat menopausal symptoms, such as hot flashes, may receive some protection against bone loss and hip and vertebrae fractures.[25] Estrogen may inhibit osteoclast activity, leading to decreased bone resorption.

Patients receiving corticosteroids should receive the lowest effective dose for the shortest possible time. Ensure an adequate intake of calcium and vitamin D, including supplements, when osteoporosis drugs are prescribed. If osteopenia is present in people who are taking corticosteroids, we may start a bisphosphonate.

PAGET DISEASE

Paget disease *(osteitis deformans)* is a chronic skeletal bone disorder in which excessive bone resorption is followed by replacement of normal marrow by vascular, fibrous connective tissue. The new bone is larger, disorganized, and weaker. Areas often affected include the pelvis, long bones, spine, ribs, sternum, and skull. Up to 5% of adults in the United States have

TABLE 68.17 Drug Therapy

Osteoporosis

Drug	Action	Side Effects	Considerations
Bisphosphonates			
alendronate (Fosamax, Binosto) etidronate (Didronel) ibandronate (Boniva) pamidronate (Aredia) risedronate (Actonel) zoledronic acid (Reclast, Zometa)	Inhibit osteoclast-mediated bone resorption and slows cycle of bone remodeling. Increases bone density.	Bone, joint, muscle pain Esophageal irritation Gastritis Osteonecrosis	When taking orally: Take with full glass of water. Take 30 min before food or other drugs. Stay upright for at least 30 min after. Zoledronic acid is once-yearly or every-other-year IV infusion. Monitor kidney function tests and serum calcium. Patients should see a dentist before beginning treatment and then annually.
Monoclonal antibodies			
denosumab (Prolia, Xgeva)	Binds to a protein (RANKL) involved in osteoclast function.	Back and extremity pain Dizziness Hypocalcemia Rash	Subcutaneous injection every 6 months. Give with calcium and vitamin D supplements. Monitor electrolytes.
romosozumab (Evenity)	Inhibits action of sclerostin, a regulatory factor in bone metabolism. Increases bone formation and, to a lesser extent, decreases bone resorption.	Femoral fractures Headache Hypocalcemia Muscle pain Osteonecrosis of jaw	Subcutaneous injection every month for a total of 12 doses. Give with calcium and vitamin D supplements. Monitor electrolytes.
Recombinant parathyroid hormone			
abaloparatide (Tymlos) teriparatide (Forteo)	Increases action of osteoblasts and stimulates new bone formation.	Dizziness GI distress Hypercalcemia Muscle cramps ↑ Uric acid levels	Self-administered daily by subcutaneous injection from preloaded pen. Monitor electrolytes and parathyroid hormone levels. Use for up to 2 years.
Selective Estrogen Receptor Modulator (SERM)			
raloxifene (Evista)	Mimics the effect of estrogen on bone by reducing bone resorption.	Flu-like symptoms Leg cramps VTE, including stroke, pulmonary embolism Weight gain	Reduces risk for vertebral, but not hip, fractures. Discontinue if immobilized; resume only after fully ambulatory. Avoid smoking. Teach symptoms to report to HCP.

Paget disease.[26] Men are affected twice as often. Paget disease is uncommon in people younger than age 40.

We do not know what causes Paget disease. The cause may be viral or genetic. Up to 40% of all patients with the disease have at least 1 relative with the disorder.

In milder forms of Paget disease, patients do not have any symptoms. The disease may be found incidentally through x-ray or serum chemistry findings of high alkaline phosphatase. Bone pain may develop gradually and progress to severe intractable pain. Other early manifestations include fatigue and progressive development of a waddling gait. Patients report becoming shorter or their heads are becoming larger. Headaches, dementia, vision problems, and hearing loss can result from an enlarged, thickened skull. Increased bone volume in the spine can cause spinal cord or nerve root compression.

Pathologic fracture is the most common complication and may be the first sign of Paget disease. Other complications include osteosarcoma, fibrosarcoma, and osteoclastoma (giant cell) tumors.

Serum alkaline phosphatase is very high in advanced disease, showing high bone turnover. X-rays may show curvature of an affected bone. The bone cortex becomes thicker and irregular, especially in weight-bearing bones and the cranium. Bone scans using a radiolabeled bisphosphonate show increased uptake in the affected skeletal areas.

Treatment is usually limited to symptomatic and supportive care, with correction of secondary deformities by surgical intervention or braces. Bisphosphonate drugs (Table 68.17) are used to slow bone resorption. Zoledronic acid is the therapy of choice. It is given specifically to build bone. Calcium and vitamin D can decrease hypocalcemia, a common side effect of drug therapy. Monitor drug effectiveness by regular assessment of alkaline phosphatase.

Calcitonin is an option for patients who cannot tolerate bisphosphonates. Its use is limited in duration as the body's response to this drug quickly decreases. Human calcitonin inhibits osteoclastic activity, prevents bone resorption, relieves acute symptoms, and lowers serum alkaline phosphatase.

Pain is usually managed with NSAIDs. Orthopedic surgery for fractures, hip and knee replacement, and knee realignment may be needed.

A firm mattress can provide back support and relieve pain. The patient may need to wear a corset or light brace to relieve back pain and give support when upright. Teach the patient to correctly apply the device and examine the skin for friction damage. Discourage lifting and twisting. Good body mechanics are essential. Physical therapy may increase muscle strength. A well-balanced diet is

important. Vitamin D, calcium, and protein ensure components are available for bone formation. To decrease risk for falls and related fractures, teach the patient to use an assistive device and make environmental changes (e.g., do not use throw rugs).

! SAFETY ALERT

Paget Disease

To reduce the risk for patient harm from falls:
- Assess environment for fall risk factors (e.g., poor lighting, clutter, pets).
- Identify personal risk factors for falls, including drugs and uncorrected vision.
- Take action to address identified risks.

Gerontologic Considerations: Metabolic Bone Diseases

Osteoporosis and Paget disease are common in older adults. Teach patients proper nutrition to decrease risk for further bone loss. Keep the patient as active as possible to slow demineralization of bone from disuse or extended immobilization.

Metabolic bone diseases increase the risk for pathologic fractures. Use caution when turning or moving the patient. Hip fractures, in particular, may decrease quality of life and lead to admission to a long-term care facility. A supervised exercise program is essential to osteoporosis treatment. Encourage ambulation if the patient's condition permits.

Case Study

Osteoporosis/Hip Fracture

(© azndc/iStock.com.)

Patient Profile

M.K. is a thin 70-year-old Asian woman admitted to the emergency department after falling in her driveway. X-ray shows a left femoral neck fracture. She has a history of hypertension and COPD.

Subjective Data

- Denies hitting her head or loss of consciousness
- Reports significant left hip pain, 9 on the 0–10 pain scale
- States she has never had a bone density test
- Former 2 pack a day smoker who quit 4 years ago
- Takes atenolol every morning and fluticasone propionate/salmeterol (Advair Diskus) inhaler twice a day

Objective Data

- Left lower extremity slightly shorter and externally rotated compared with right lower extremity
- Unable to bear weight on lower extremities
- Moderate edema with bruising on left hip
- 2+ dorsalis pedis and posterior tibialis pulses bilaterally
- Gross motor/sensation intact in affected extremity

Diagnostic Studies

- Normal CBC, metabolic panel, protime/INR and urinalysis
- Chest x-ray shows hyperinflated lung fields
- 12-lead ECG normal sinus rhythm

Interprofessional Care

- Hip arthroplasty for fracture
- Multimodal postoperative pain management
- Physical therapy evaluation and treatment
- Early postoperative mobilization
- Removal of urinary catheter (if applicable) early in postoperative period
- Ambulation using standard walker

Discussion Questions

1. ***Recognize***: Why did a relatively low-energy injury cause M.K.'s fracture?
2. ***Analyze:*** What factors could result in inadequate caloric intake after surgery?
3. ***Plan:*** What postoperative complications are M.K. at risk for developing?
4. ***Prioritize:*** What are M.K.'s priority learning needs?
5. ***Prioritize:*** What is the interprofessional team's top priority at this time for M.K.? What therapy do you expect?
6. ***Prioritize:*** Based on the assessment data, what are the priority clinical problems?
7. ***Act:*** Describe specific actions you would take to promote patient safety.
8. ***Evaluation:*** What outcomes would indicate that care was effective?

Answers available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A patient with acute osteomyelitis is being discharged on antibiotic therapy. What would the nurse include in the teaching plan? *(select all that apply)*
- **a.** It is important to finish all the antibiotics even if you feel better.
- **b.** You will need to schedule periodic through bone scans and ESR testing.
- **c.** If the infection comes back, you must contact the HCP to schedule surgery.
- **d.** Signs such as fever and night sweats may be present but are usually not severe.
- **e.** Contact the HCP if signs of infection such as pain and swelling at the site occur.

2. A patient with history of colon cancer is diagnosed with rib fractures, and the HCP orders a bone scan. The nurse determines the patient understands teaching about the purpose of the procedure when they state
- **a.** "The bone scan will cure my rib fractures."
- **b.** "The bone scan will see if my colon cancer may have spread."
- **c.** "My colon cancer was cured so I really don't think this is necessary."
- **d.** "The results of the bone scan will only just confirm that I have a rib fracture."

3. The nurse provides counseling to a family of a patient with Duchenne muscular dystrophy with the knowledge that
- **a.** patients are usually female.
- **b.** all daughters of a carrier will be carriers.

c. genetic testing can help determine treatment.
d. only males can pass the gene to their offspring.

4. Which persons are at high risk for chronic low back pain? *(select all that apply)*
a. A 63-year-old man who is a long-distance truck driver
b. A 30-year-old nurse who works on an orthopedic unit and smokes
c. A 55-year-old construction worker who is 6 ft, 2 in and weighs 250 lb
d. A 44-year-old female chef with prior compression fracture of the spine
e. A 28-year-old female yoga instructor who is 5 ft, 6 in and weighs 130 lb

5. When caring for a patient after lumbar spinal surgery, the nurse would immediately report which finding to the HCP?
a. The patient reports mild low back pain.
b. The patient has a single episode of emesis.
c. The patient is nauseated and has not voided in 4 hours.
d. The patient has loss of sensation to the perineum, buttocks, inner thighs, and back of the legs.

6. A patient who ran his first marathon had heel pain that would not resolve and was diagnosed with calcaneus stress fracture. The nurse will teach the patient to *(select all that apply)*
a. resume running in 1 week.
b. rest and refrain from running.
c. wear a shoe heel pad when ambulating.
d. walk barefoot to decrease pressure on the heel.
e. apply ice to the heel and take NSAIDs as directed by HCP.

7. A patient with osteoporosis shows an understanding of appropriate self-care when they state
a. "I should remove trip hazards such as throw rugs in my house to make it safer."
b. "I am not using the cane my HCP recommended. I don't want to look that old!"
c. "I can continue to go downhill skiing as long as I'm careful and don't ever fall."
d. "I need to take up running to help strengthen my bones. Walking is just not enough."

1. a, b, d, e; 2. b; 3. d; 4. a, b, c, d; 5. d; 6. b, c, e; 7. a.

CONCEPTUAL FOCUS

Coping
Fatigue
Functional Ability
Inflammation
Mobility
Pain
Self-Management

LEARNING OUTCOMES

1. Outline the sequence of events leading to joint destruction in osteoarthritis and rheumatoid arthritis.
2. Detail the clinical manifestations and interprofessional and nursing management of osteoarthritis and rheumatoid arthritis.
3. Describe the pathophysiology, clinical manifestations, and interprofessional care of gout, Lyme disease, and septic arthritis.
4. Discuss the pathophysiology, clinical manifestations, and interprofessional and nursing management of ankylosing spondylitis, psoriatic arthritis, and reactive arthritis.
5. Describe the pathophysiology, clinical manifestations, and interprofessional and nursing management of systemic lupus erythematosus, scleroderma, polymyositis, dermatomyositis, and Sjögren syndrome.
6. Explain the drug therapy and related nursing management associated with arthritis and connective tissue diseases.
7. Relate possible etiologies, clinical manifestations, and interprofessional and nursing management of fibromyalgia and systemic exertion tolerance disease.

KEY TERMS

ankylosing spondylitis (AS)
arthritis
dermatomyositis (DM)
fibromyalgia (FMS)
gout
Lyme disease
osteoarthritis (OA)
polymyositis (PM)
psoriatic arthritis (PsA)
Raynaud phenomenon
rheumatoid arthritis (RA)
septic arthritis
scleroderma
Sjögren syndrome
systemic exertion intolerance disease (SEID)
systemic lupus erythematosus (SLE)

This chapter discusses *rheumatic diseases,* which mainly affect body joints, tendons, ligaments, muscles, and bones. These diseases are often marked by inflammation, pain, and loss of function in 1 or more of the body's connecting or supporting structures. Limited function and fatigue, loss of self-esteem, altered body image, and fear of disability can challenge the patient's ability to cope. We have found more than 100 kinds of rheumatic diseases.[1] At least 54 million adults in the United States have rheumatic conditions.[2] By 2040, that number is expected to exceed 78 million.

ARTHRITIS

Arthritis involves inflammation of a joint or joints. Most forms of arthritis affect women more often in every age group.[2] Osteoarthritis is the most common chronic condition of the

TABLE 69.1 Causes of OA

Cause	Effects on Joint Cartilage
Drugs	Drugs, such as indomethacin and corticosteroids, may stimulate collagen-digesting enzymes in joint synovium.
Hematologic or endocrine problems	Chronic hemarthrosis (e.g., from hemophilia) may contribute to cartilage deterioration.
Inflammation	Release of enzymes in response to local inflammation may affect cartilage health.
Joint instability	Damage to supporting structures causes instability, placing uneven stress on joint cartilage.
Mechanical stress	Repetitive physical activities (e.g., sports) can cause cartilage deterioration.
Neurologic problems	Pain and loss of reflexes from neurologic disorders, such as diabetic neuropathy and Charcot joint, cause abnormal movements that may contribute to cartilage deterioration.
Skeletal deformities	Congenital or acquired conditions (e.g., dislocated hip) may contribute to cartilage deterioration.
Trauma	Dislocations or fractures may lead to avascular necrosis or uneven stress on cartilage.

joints.[3] Other forms include rheumatoid arthritis (RA), fibromyalgia (FMS), systemic lupus erythematosus (SLE), and gout.

OSTEOARTHRITIS

Osteoarthritis (OA) is a slowly progressive noninflammatory disorder of the diarthrodial *(synovial)* joints. OA affects over 30 million adults in the United States.[2] We expect this number to increase as the population ages.

Etiology and Pathophysiology

OA involves the gradual loss of articular cartilage with formation of bony outgrowths (spurs or osteophytes) at the joint margins. OA is not a normal part of the aging process, but aging is one risk factor for disease development. Cartilage destruction likely begins between ages 20 and 30. Most adults are affected by age 40. Few patients have symptoms until after age 50. By age 65, almost 50% of adults report having arthritis.[4]

OA may be caused by a known event or condition that directly damages cartilage or causes joint instability (Table 69.1). However, we cannot identify a single cause for many persons with OA. In these situations, various genetic traits may contribute to the development of cartilage defects.[5]

Decreased estrogen at menopause may contribute to the increased incidence of OA in aging women (Box 69.1). Obesity contributes to hip and knee OA. It increases mechanical stress on the joints. Regular moderate exercise, which helps with weight, decreases the risk for OA development and progression. Anterior cruciate ligament injury from quick stops and pivoting, as in football and soccer, increase risk for knee OA.[3] Work that requires frequent kneeling and stooping also increases the risk for knee OA.

The development of OA is complex. Genetic, metabolic, and local factors interact to cause cartilage deterioration from damage at the level of the chondrocytes (Fig. 69.1). The normally smooth, white, translucent articular cartilage becomes dull, yellow, and granular as OA progresses. Affected cartilage steadily becomes softer and less elastic. It is less able to resist wear with heavy use.

BOX 69.1 BIOLOGIC SEX CONSIDERATIONS

OA

Men
- Except for traumatic arthritis, men do not have OA as often as women until age 70 or 80 years.
- Hip OA is more common.

Women
- Affects women more often.
- More likely to have hand OA (interphalangeal joints and thumb base).
- Knee OA is more common and likely to be more severe, especially after menopause.

The body's attempts at cartilage repair cannot keep up with the destruction of OA. As the collagen structure in the cartilage changes, articular surfaces become cracked and worn. While central cartilage becomes thinner, cartilage at the joint edges becomes thicker and osteophytes form. Joint surfaces become uneven, affecting the distribution of stress across the joint and causing reduced motion.

Although inflammation is not typical of OA, secondary synovitis may occur when phagocytes try to rid the joint of small pieces of cartilage torn from the joint surface. These changes cause the early pain and stiffness of OA. Pain in later disease occurs when articular cartilage is lost, and bony joint surfaces rub each other.

Clinical Manifestations

Joints

Manifestations range from mild discomfort to significant disability. Joint pain is the main symptom and the typical reason the patient seeks medical care. Pain typically worsens with activity. In early stages of OA, rest relieves the joint pain. However, the patient with advanced OA may have pain at rest or have trouble sleeping due to increased joint pain. Pain may worsen when the barometric pressure falls before the onset of severe weather.

As OA progresses, increasing pain can contribute to disability and loss of function. Pain may be referred to the groin, buttock, or outside of the thigh or knee. It can be hard to sit down or get up from a chair when the hips are lower than the knees. As OA develops in the intervertebral *(apophyseal)* joints of the spine, local pain and stiffness are common.

Joint stiffness occurs after periods of rest or an unchanged position *(gelling phenomenon)*. Early morning stiffness is common. It often resolves within 30 minutes. This distinguishes OA from inflammatory joint disorders, such as RA. Excess activity can cause a mild joint swelling that temporarily increases stiffness. *Crepitation,* a grating sensation caused by loose cartilage particles in the joint cavity, can cause stiffness. Crepitation is common in patients with knee OA.

OA usually affects joints on 1 side of the body *(asymmetric)* rather than in pairs. For example, the left knee may be affected

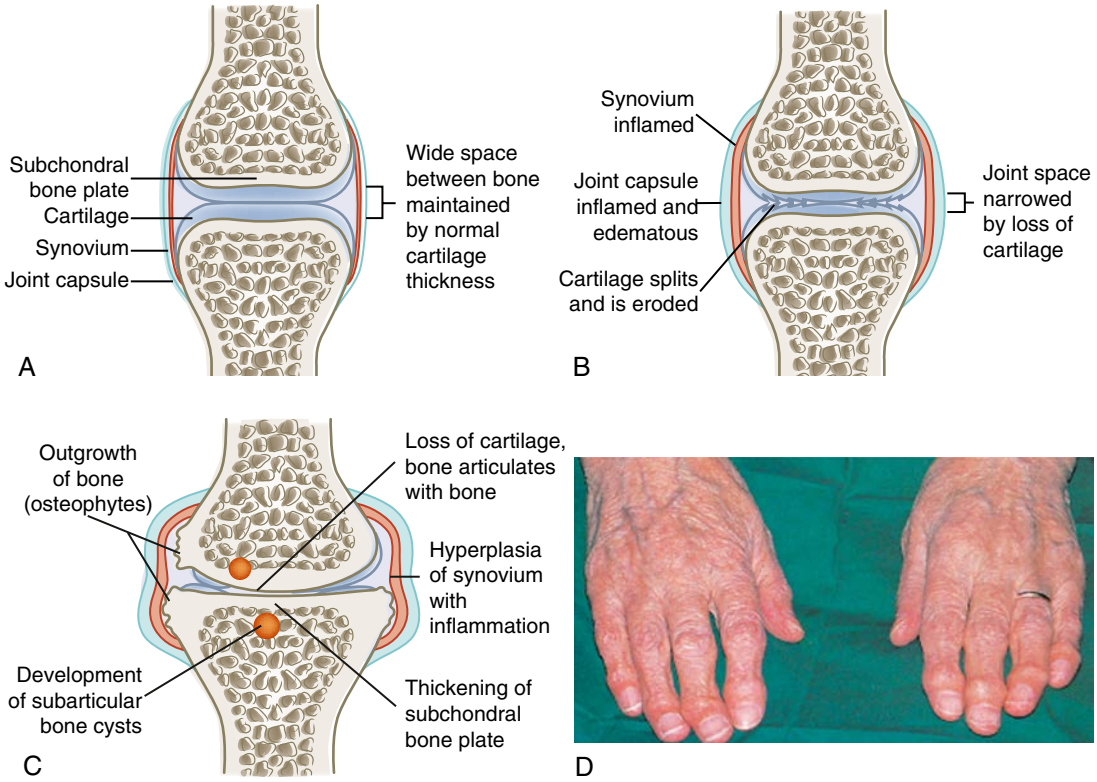

Fig. 69.1 Pathologic changes in OA. (A) Normal synovial joint. (B) Early change in OA is destruction of articular cartilage and narrowing of the joint space. There is inflammation and thickening of the joint capsule and synovium. (C) With time, thickening of subarticular bone occurs, caused by constant friction of the 2 bone surfaces. Osteophytes form around the periphery of the joint by irregular overgrowths of bone. (D) Heberden nodes *(red arrows)* and Bouchard nodes *(yellow areas)* in a patient with OA. (From Forbes CD, Jackson WF: *Color atlas and text of clinical medicine,* ed 3, London, 2003, Mosby.)

and the right knee unchanged. Weight-bearing joints (hips, knees), the metatarsophalangeal (MTP) joint of the foot, and the cervical and lower lumbar vertebrae are often involved (Fig. 69.2). Other affected joints include the distal interphalangeal (DIP) and proximal interphalangeal (PIP) joints of the fingers, and the metacarpophalangeal (MCP) joint of the thumb.

Deformity

Deformity or instability from OA is specific to the involved joint. For example, *Heberden nodes* occur on the DIP joints due to osteophyte formation and loss of joint space (Fig. 69.1D). They can appear as early as age 40. *Bouchard nodes* on the PIP joints indicate similar disease involvement. Heberden and Bouchard nodes are often red, swollen, and tender. They usually do not cause significant loss of function, but the visible deformity may bother the patient.

Knee OA often leads to obvious joint deformity due to cartilage loss in 1 joint compartment. For example, the patient becomes bowlegged *(varus deformity)* from medial joint arthritis. Lateral joint arthritis causes a knock-kneed appearance *(valgus deformity)*. In advanced hip OA, 1 leg may become shorter as the joint space narrows.

Systemic

Fatigue, fever, and organ involvement are not present in OA. This is an important distinction between OA and inflammatory joint disorders, such as RA.

Diagnostic Studies

X-rays help confirm disease and stage joint damage. As OA progresses, x-rays often show joint space narrowing and increasingly dense bone. Osteophytes may be visible. However, these changes do not always reflect the degree of pain the patient has. Despite strong x-ray evidence of disease, the patient may have few symptoms. Another patient may have severe pain with only slight x-ray changes. A bone scan, CT scan, or MRI can detect early joint change. They are not typically used for diagnosis due to cost.

Synovial fluid analysis helps distinguish OA from other types of inflammatory arthritis. In OA, the fluid is clear yellow with little or no sign of inflammation. No laboratory tests or biomarkers can be used to diagnose OA. The erythrocyte sedimentation rate (ESR) is normal except for slight increases during acute inflammation. Other routine blood tests (e.g., CBC, liver function tests) are useful only in screening for related conditions or establishing baseline values before starting treatment.

Interprofessional Care

OA has no cure. Care focuses on managing pain and inflammation, preventing disability, and maintaining and improving joint function (Table 69.2). A comprehensive treatment plan may include education and behavioral, psychosocial, and physical interventions. Drug therapy can include topical, oral, and intraarticular agents.[6]

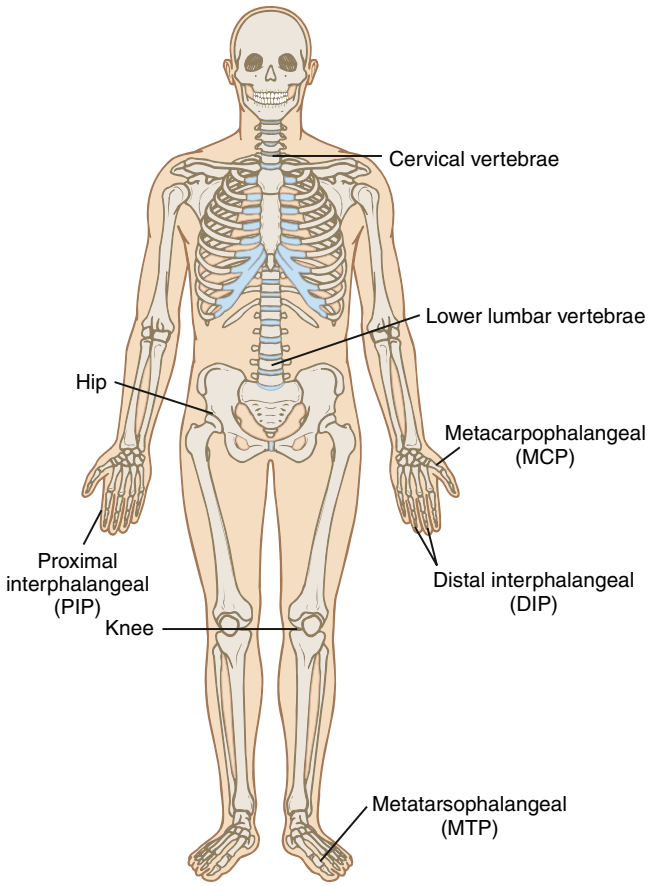

Fig. 69.2 Joints most often involved in OA.

Drugs thought to slow the progression of OA or support joint healing are known as *disease-modifying osteoarthritis drugs (DMOADs)*. To date, no drugs have been approved to modify OA progression despite much research.

Drug Therapy

Drug therapy is based on the joint affected and symptom severity (Table 69.3). Nonsteroidal antiinflammatory drugs (NSAID) are first-line treatment for OA. NSAIDs inhibit the production of cyclooxygenase. When given in equivalent doses, all NSAIDs are comparably effective. They vary widely in cost. Individual responses to NSAIDs also vary. Most NSAIDs are nonspecific, affecting both COX-1 and COX-2.[7] These 2 enzymes convert arachidonic acid into prostaglandins (see Fig. 9.5). COX-2 plays a role in inflammation. COX-1 helps protect the stomach lining. Inhibiting COX-1 causes many of the negative effects of oral NSAIDs, including bleeding and gastrointestinal (GI) irritation.[7]

Some patients start with a topical agent, such as capsaicin cream. It blocks pain by locally interfering with substance P. It is responsible for the transmission of pain impulses. A concentrated product is available by prescription. Creams of 0.025% to 0.075% capsaicin are available over the counter (OTC). Diclofenac gel is another option. OTC products that contain camphor, eucalyptus oil, and menthol (e.g., Bengay, Arthricare) may provide temporary pain relief. Topical salicylates (e.g., Aspercreme) may be an option for some patients. Several applications may be needed daily because topical agents have short-acting effects.

Oral NSAID therapy typically is started in low-dose OTC strengths (e.g., ibuprofen 200 mg up to 4 times daily). The dose may be increased if needed. If the patient is at risk for or develops GI side effects with an NSAID, adding a protective agent, such as misoprostol (Cytotec), may be needed. Arthrotec, a combination of misoprostol and the NSAID diclofenac, is available.

Teach the patient who is taking an oral NSAID to avoid use of a topical NSAID because of increased risk for adverse effects. Patients taking an anticoagulant (e.g., warfarin) and an oral NSAID are at high risk for bleeding. Long-term NSAID treatment may affect cartilage metabolism, especially in older patients who may have poor cartilage integrity. As an alternative to traditional NSAIDs, the COX-2 selective inhibitor celecoxib (Celebrex) may be considered in selected patients.

Some patients still prefer aspirin, but it is no longer a common treatment. It should be used cautiously with NSAIDs because both inhibit platelet function and prolong bleeding time.

Intraarticular corticosteroid injections may be needed for those with local inflammation and swelling. Four or more injections without relief suggest the need for more intervention. Systemic corticosteroids are not used as they may hasten the disease process. Hyaluronic acid injection *(viscosupplementation)* has been a common treatment for knee OA. Neither the American College of Rheumatology (ACR) nor the American Academy of Orthopaedic Surgeons (AAOS) recommends using hyaluronates.[6]

Surgical Therapy

Symptoms are often managed conservatively for many years. Loss of joint function, unmanaged pain, and increased dependence in self-care may lead to consideration of surgery. Reconstructive surgeries (e.g., hip and knee replacements) are discussed in Chapter 67.

TABLE 69.2 Interprofessional Care

OA

Diagnostic Assessment
- History and physical assessment
- Radiologic studies of involved joints (e.g., x-ray, CT scan, MRI, bone scan)
- Possible synovial fluid analysis

Management
- Nutrition and weight management counseling
- Rest and joint protection, use of assistive devices
- Therapeutic exercise
- Heat and cold applications
- TENS
- Reconstructive joint surgery

Drug Therapy **(Table 69.3)**
- NSAIDs
- Intraarticular corticosteroids

TABLE 69.3 Drug Therapy

OA

Drug	Mechanism of Action	Nursing Considerations
Corticosteroids		
Intraarticular Injections		
methylprednisolone acetate (Depo-Medrol) triamcinolone (Aristospan)	Analgesic Antiinflammatory Inhibit synthesis and/or release of inflammatory mediators	Use strict aseptic technique for corticosteroid injection. Tell patient that joint may temporarily feel worse right after injection. Teach patient to avoid overusing affected joint right after injection. Improvement lasts weeks to months after injection.
Systemic		
dexamethasone hydrocortisone (Solu-Cortef) methylprednisolone (Solu-Medrol) prednisone triamcinolone	Analgesic Antiinflammatory Inhibit synthesis and/or release of inflammatory mediators	Use only in life-threatening exacerbation or when symptoms persist after treatment with less potent antiinflammatory drugs. Give for short time only, taper dose slowly. Abrupt withdrawal of drug worsens symptoms. Monitor BP, weight, CBC, potassium. Limit sodium intake. Report signs of infection.
Nonsteroidal Antiinflammatory Drugs (NSAIDs)		
celecoxib (Celebrex) diclofenac (Voltaren) ibuprofen (Advil) indomethacin (Indocin) ketoprofen meclofenamate meloxicam (Mobic) nabumetone naproxen (Aleve) oxaprozin (Daypro) piroxicam (Feldene) sulindac tolmetin	Antiinflammatory Analgesic Antiinflammatory Inhibit prostaglandin synthesis	Give drug with food, milk, or antacids (as prescribed). Report signs of bleeding, edema, skin rashes, persistent headaches, visual problems. Monitor BP for increases from fluid retention. Use regularly for maximum effect. Monitor for kidney toxicity in older adults.
Salicylate		
aspirin, salicylate	Analgesic Antiinflammatory Inhibit prostaglandin synthesis	Give with food, milk, antacids (as prescribed), or full glass of water. May use enteric-coated aspirin. Report signs of bleeding.
Topical Analgesics		
capsaicin cream	Depletes substance P from nerve endings, interrupting pain signals to the brain	Must be used at regular intervals for maximal effect. Aloe vera cream may decrease burning sensation. Do not use with external heat source (heating pad) because of burn risk. Available in OTC and prescriptive strengths.
diclofenac sodium (Voltaren gel)	Analgesic Antiinflammatory	Avoid sun and ultraviolet (UV) light exposure. Do not use with oral NSAIDs or aspirin due to risk for increased side effects.

Complementary and Alternative Therapies

Complementary and alternative therapies for OA symptom management are popular with patients who have not found relief through traditional medical care. Teach the patient to carefully research any alternative therapies and avoid replacing conventional OA treatments with unproven complementary approaches. Acupuncture may reduce arthritis pain and improve joint mobility.

Some nutrition supplements may have antiinflammatory effects (e.g., fish oil, ginger, SAM-e). However, results of studies on glucosamine and chondroitin are mixed. The ACR and AAOS do not recommend their use.[6] Teach patients to discuss any supplement use with their HCP to identify possible drug interactions.

❖ NURSING MANAGEMENT: OSTEOARTHRITIS

◆ Assessment

Assess and document the type, location, severity, frequency, and duration of the joint pain and stiffness. What makes the pain better or worse? Ask how these symptoms affect the ability to perform activities of daily living (ADLs). Review pain management practices. Ask about success of each treatment. Assess

BOX 69.2 PROMOTING POPULATION HEALTH

Preventing OA

- Avoid smoking.
- Promptly treat any joint injury.
- Maintain healthy weight and eat a balanced diet.
- Use safety measures to protect and decrease risk for joint injury.
- Exercise regularly, including strength and endurance training.

tenderness, swelling, limitation of movement, and crepitation of affected joints. Compare an involved joint with the opposite joint if it is not affected.

Health assessment questionnaires can pinpoint areas of decreased function. They are completed at regular intervals to document disease and treatment progression. Treatment goals can be based on data from the questionnaires and physical assessment, with specific interventions for identified problems.

Clinical Problems

Clinical problems for the patient with OA may include:

- Pain
- Musculoskeletal problems
- Impaired role performance

Planning

Overall goals are that the patient with OA will (1) maintain or improve joint function through a balance of rest and activity, (2) use joint protection measures to improve activity tolerance, (3) achieve independence in self-care and maintain optimal role function, and (4) use drug and nondrug strategies to manage pain satisfactorily.

Implementation

Health Promotion

Prevention of OA is possible in some cases. Focus community education on altering modifiable risk factors (Box 69.2). For example, encourage the patient to lose weight and reduce occupational or recreational hazards. For athletic instruction and physical fitness programs, include safety measures that protect and reduce trauma to the joints.

Ambulatory Care

The patient with OA usually receives treatment as an outpatient. The interprofessional team may include an internal medicine physician or family HCP, a rheumatologist, a nurse, an occupational therapist, and a physical therapist. The patient is usually hospitalized only if having joint surgery (see Chapter 67).

Patient and caregiver teaching related to OA is important. Provide information about the nature and treatment of OA, pain management, body mechanics, correct use of assistive devices (e.g., cane, walker), principles of joint protection and energy conservation (Table 69.4), nutrition choices, weight and stress management, and an exercise program.

Assure the patient that OA is a localized disease and severe deforming arthritis is not the usual course. The patient may gain support and understanding through community resources, such as the Arthritis Foundation's self-help course (www.arthritis.org).

TABLE 69.4 PATIENT & CAREGIVER TEACHING

Joint Protection and Energy Conservation

Include the following instructions when teaching patients with arthritis to protect joints and conserve energy:

- Maintain healthy weight.
- Use assistive devices, if needed.
- Avoid forceful repetitive joint movements.
- Avoid awkward positions that stress joints.
- Use good posture and body mechanics.
- Seek help with needed tasks that may cause pain.
- Organize routine tasks and pace yourself to decrease fatigue and joint pain.
- Modify home and work environment to perform tasks in less stressful ways.

CHECK YOUR PRACTICE

A 54-year-old woman has OA of the left knee. She received an intraarticular corticosteroid injection in the left knee and a prescription for meloxicam 7.5 mg once daily. She has a prescription for physical therapy.

- What self-care information will you reinforce immediately after the injection?
- What information will you provide about meloxicam to ensure safe, effective use?
- What type of exercises would be appropriate?

Heat and Cold Applications

Use of heat or cold is based on symptoms. Ice is not used as often as heat in OA treatment. Ice can help reduce swelling if the patient has acute inflammation. Heat therapy is especially useful for stiffness. It increases flexibility and improves blood flow to the area. Treatments include hot packs, whirlpool baths, ultrasound, and paraffin wax baths.

Nutrition Therapy

If the patient is overweight, a weight-reduction program is a critical part of the treatment plan. Help the patient evaluate the current diet to make needed changes. Chapter 45 discusses ways to help the patient attain and maintain a healthy body weight.

Exercise

Aerobic conditioning, range-of-motion (ROM) exercises, and programs to strengthen muscles around the affected joint help many patients. A physical therapist can help plan an exercise program. Stress the importance of warming up before any exercise to decrease risk for injury. Balance exercises improve the ability to control and stabilize body position. The therapist may recommend an exercise like Tai Chi, which focuses on strength and balance. Tai Chi can be done by patients of all ages and may be done in a wheelchair.

Rest and Joint Protection

Teach the patient to balance rest and activity. Encourage rest of the affected joint during periods of acute inflammation. Keep

joints in a functional position with splints or braces if needed. Splints can rest and stabilize painful or inflamed joints. Review ways to modify usual activities to decrease stress on affected joints. Teach the patient with knee OA to avoid standing, kneeling, or squatting for long periods. Work with the physical therapist about the use of assistive devices, such as a cane, walker, or crutches, to decrease joint stress.

Role Performance

Adjust home management goals to meet the patient's needs. Include the caregiver, family members, and significant others in goal setting and teaching. Discuss home and work environment modification for patient safety, accessibility, and self-care. Measures include removing throw rugs, placing rails at the stairs and bathtub, using night-lights, and wearing well-fitting supportive shoes. Assistive devices, such as canes, walkers, elevated toilet seats, and grab bars, reduce the load on an affected joint and promote safety. Urge the patient to continue all prescribed therapies at home and be open to new approaches to symptom management.

Sexual counseling may help the patient and significant other enjoy physical closeness by introducing the idea of alternative positions and timing for sexual activity. Discussion also increases awareness of each partner's needs. Encourage the patient to take analgesics or a warm bath to decrease joint stiffness before sexual activity.

Evaluation

The expected outcomes are that the patient with OA will:

- Have adequate rest and activity
- Achieve acceptable pain management
- Maintain joint flexibility and muscle strength through joint protection and therapeutic exercise

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a chronic, systemic autoimmune disease characterized by inflammation of connective tissue in the diarthrodial (synovial) joints. RA is typically marked by periods of remission and exacerbation. RA often has extraarticular manifestations. It is considered one of the most disabling forms of arthritis. Symptoms and outcomes vary greatly. Without adequate treatment, patients may need mobility aids or joint reconstruction. They may have loss of independence and self-care ability.

RA occurs globally, affecting all ethnic groups. It can occur at any time of life. RA most often begins in women between ages 30 and 60 years. It is rare in men under age 45 years. RA affects around 1.5 million adult Americans. Almost 3 times as many women have RA as men.[8]

Etiology and Pathophysiology

We do not know the exact cause of RA. It likely results from a combination of genetics and environmental triggers. An autoimmune cause is the most widely accepted theory. This theory suggests RA begins when a genetically susceptible person has an initial immune response to an antigen. While a bacteria or virus could be the possible antigen, we have not found a specific infection or organism to date.

The antigen, which is probably not the same in all patients, triggers formation of an abnormal immunoglobulin G (IgG). RA is marked by autoantibodies to this abnormal IgG. The autoantibodies are known as *rheumatoid factor (RF).* They combine with IgG to form immune complexes. At first, the complexes deposit on synovial membranes or superficial articular cartilage in the joints. Complex formation leads to complement activation and an inflammatory response (see Chapter 12).

Neutrophils are attracted to the site of inflammation. They release proteolytic enzymes that damage articular cartilage and cause the synovial lining to thicken (Fig. 69.3). Other inflammatory cells include T helper (CD4) cells, which stimulate cell-mediated immune responses. Activated CD4 cells cause monocytes, macrophages, and synovial fibroblasts to secrete the proinflammatory cytokines interleukin-1 (IL-1), IL-6, and tumor necrosis factor (TNF). These cytokines drive the inflammatory response in RA.

Some patients report a precipitating stressful event, such as infection, work stress, physical exertion, childbirth, surgery, or emotional upset. However, research has not been able to correlate such events with RA onset. Smoking increases the risk for RA. People who smoke are less likely to have disease remission if they have RA. Smoking cessation can reduce the risk of developing RA. The strongest evidence for a genetic predisposition is the role of human leukocyte antigens (HLA), especially the HLA-DR4 and HLA-DR1 antigens. HLA is discussed in Chapter 14.

Clinical Manifestations

Joints

The onset of RA is often subtle. Nonspecific manifestations, such as fatigue, anorexia, weight loss, and general stiffness, may precede the onset of joint symptoms. Stiffness becomes more localized in the following weeks to months.

Specific joint involvement is marked by pain, stiffness, limited motion, and signs of inflammation (e.g., warmth, swelling, pain). Joint symptoms occur symmetrically and often affect the small joints of the hands (PIP, MCP) and feet (MTP). Larger peripheral joints such as wrists, elbows, shoulders, knees, hips, ankles, and jaw may be involved. The cervical spine may be affected. The axial skeleton (spine and bones connected to it) is generally spared. Table 69.5 compares RA and OA.

The patient typically has joint stiffness after periods of inactivity. Morning stiffness may last from 60 minutes to several hours or more, depending on disease activity. MCP and PIP joints are typically swollen. In early disease, the fingers may become spindle shaped from synovial hypertrophy and thickening of the joint capsule. Joints are tender, painful, and warm to the touch. Joint pain increases with motion. It varies in intensity. It may not be related to the degree of inflammation. Tenosynovitis often affects the extensor and flexor tendons around the wrists. This causes symptoms of carpal tunnel syndrome and makes it hard for the patient to grasp objects.

As RA progresses, inflammation and fibrosis of the joint capsule and supporting structures may cause deformity and

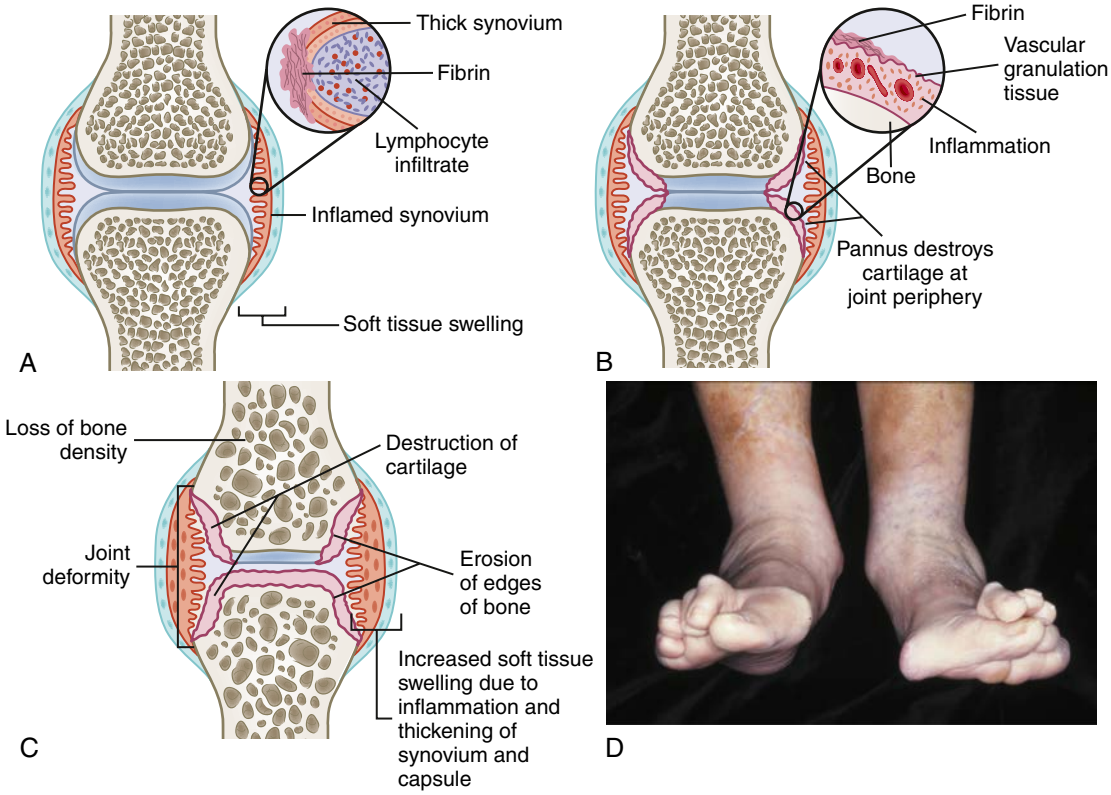

Fig. 69.3 RA. (A) Early pathologic change is rheumatoid synovitis. Synovium becomes inflamed. Lymphocytes and plasma cells increase. (B) Over time, articular cartilage destruction occurs, and vascular granulation tissue grows across the cartilage surface (pannus) from the edges of the joint. Joint surface shows loss of cartilage beneath the extending pannus, most marked at joint margins. (C) Inflammatory pannus causes focal destruction of bone. Osteolytic destruction of bone occurs at joint edges, causing erosions seen on x-rays. This phase is associated with joint deformity. (D) Multiple deformities of the foot from RA. (D, From Canale ST, Beaty JH: *Campbell's operative orthopaedics,* ed 12, Philadelphia, 2013, Mosby.)

TABLE 69.5 Comparison of RA and OA

Parameter	RA	OA
Age at onset	Young to middle age.	Usually older than 40 years.
Gender	Female-to-male ratio is 3:1. Less marked difference after age 60.	Females 2:1 after age 60; except for traumatic arthritis, men less affected until age 70 or 80.
Weight	Lost or maintained weight.	Often overweight or obese.
Disease	Systemic disease with exacerbations and remissions.	Localized disease with variable, progressive course.
Affected joints	Small joints typically affected first (PIPs, MCPs, MTPs), wrists, elbows, shoulders, knees. Usually bilateral, symmetric joint involvement.	Weight-bearing joints of knees and hips, small joints (MCPs, DIPs, PIPs), cervical and lumbar spine. Often asymmetric.
Pain characteristics	Stiffness lasts 1 h to all day and may ↓ with joint use. Pain is variable, may disrupt sleep.	Stiffness occurs on arising but usually subsides after 30 min. Pain gradually worsens with joint use and disease progression, relieved with joint rest but may disrupt sleep.
Effusions	Common.	Uncommon.
Nodules	Present, especially on extensor surfaces.	Heberden (DIPs) and Bouchard (PIPs) nodes.
Synovial fluid	WBC count 5000–60,000/μL with mostly neutrophils; ↓ viscosity.	WBC count < 2000/μL (mild leukocytosis); normal viscosity.
X-rays	Joint space narrowing and erosion with bony overgrowths, subluxation with advanced disease. Osteoporosis related to decreased activity, corticosteroid use.	Joint space narrowing, osteophytes, subchondral cysts, sclerosis.
Laboratory findings	Rheumatoid factor positive in about 80% of patients; negative titers in early disease for about 25%.	Rheumatoid factor negative.
	↑ Antinuclear antibodies (ANAs) titer likely.	ANA negative.
	Positive anti-CCP (anti-citrullinated peptide) in 60%–80%.	Anti-CCP negative.
	↑ ESR, CRP indicative of active inflammation, used to test disease activity. Not specific to RA.	Transient elevation in ESR related to synovitis.

DIPs, Distal interphalangeal joints; *MCPs,* metacarpophalangeal joints; *MTPs,* metatarsophalangeal joints; *PIPs,* proximal interphalangeal joints.

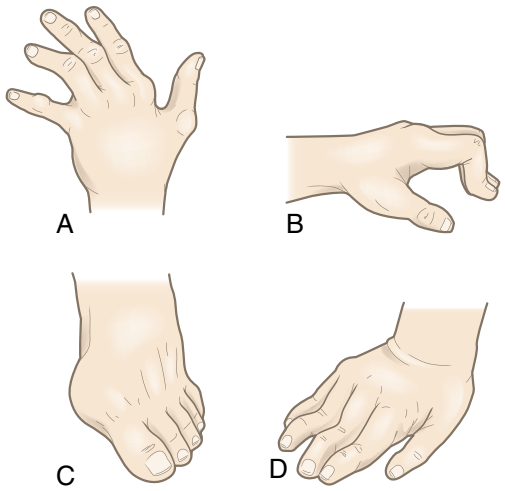

Fig. 69.4 Typical deformities of RA. (A) Ulnar drift. (B) Boutonnière deformity. (C) Hallux valgus. (D) Swan neck deformity.

disability. Muscle atrophy and tendon destruction cause 1 joint surface to slip past the other *(subluxation)*. Metatarsal head dislocation and subluxation in the feet may cause pain and walking disability (Fig. 69.3D). Ulnar drift ("zig-zag deformity"), swan neck, and boutonnière deformities are common in the hands (Fig. 69.4).

Extraarticular Manifestations

RA can affect nearly every body system (Fig. 69.5). Extraarticular manifestations are more likely to occur in the person with high levels of biomarkers, such as RF.

Atherosclerosis can result from chronic inflammation that damages endothelial cells within blood vessels. More cholesterol plaques may be formed. When plaques break loose, they can lead to heart attack or stroke. Risk of heart attack in people with RA is 60% higher than in persons without RA.[9]

Rheumatoid nodules develop in about half the patients with RA.[9] The nodules appear under the skin as firm, nontender masses. They are often found on bony areas exposed to pressure, such as the fingers and elbows. Treatment is usually not needed. However, these nodules can break down, like pressure injuries. Rheumatoid nodules may form in the lungs but are usually harmless.

The patient may develop *Sjögren syndrome*. The inflammation of RA can damage the tear-producing (lacrimal) glands, making the eyes feel dry and gritty.[9] Medications may be needed to prevent damage related to dryness.

Felty syndrome is rare but can occur in those with long-standing RA. It is characterized by an enlarged spleen and low white blood cell (WBC) count. Patients with Felty syndrome are at increased risk for infection and lymphoma.

Flexion contractures and hand deformities cause decreased grasp strength and affect the ability to perform self-care. Depression may occur. However, it is unclear if the patient becomes depressed from struggling with chronic pain and disability or if depression is part of the autoimmune disease process. Levels of C-reactive protein (CRP), a marker of inflammation, are higher in patients with depression compared to those with no symptoms of depression.[10]

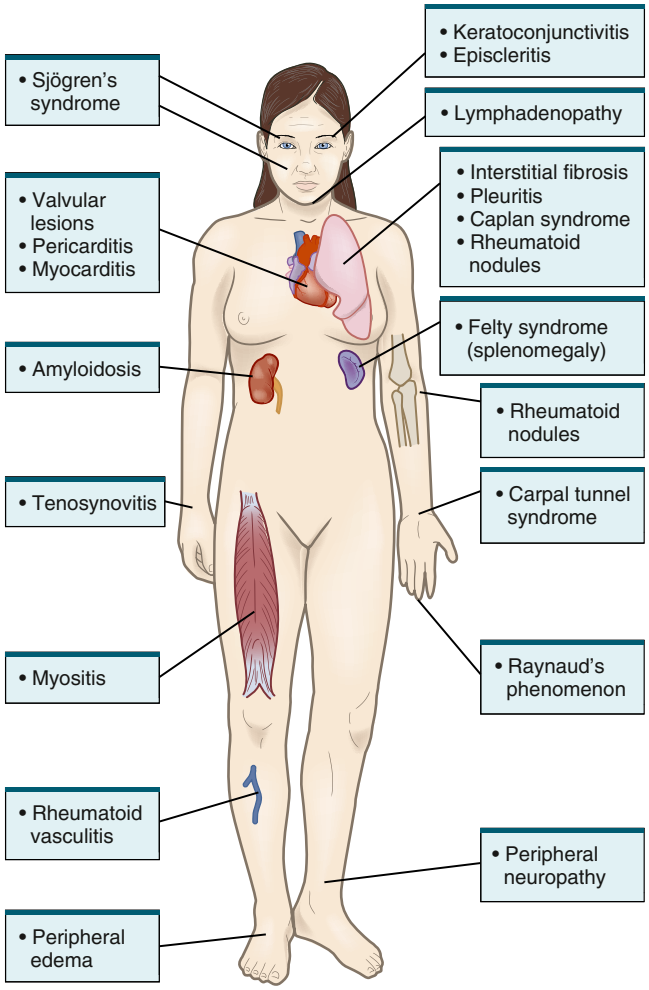

Fig. 69.5 Extraarticular manifestations of RA.

Diagnostic Studies

Accurate diagnosis is important so we can start treatment promptly. A diagnosis is often made based on history and physical findings. Criteria for diagnosis of RA in a newly presenting patient are shown in Table 69.6. Laboratory tests are used to confirm diagnosis and monitor disease progression (Tables 69.7 and 69.8).

Positive RF occurs in about 80% of adults with RA. Negative RF results do not exclude disease. Positive results do not guarantee diagnosis. Titers may rise during active disease. Testing for antibodies to citrullinated peptide (anti-CCP) is more specific than RF for RA. Anti-CCP is present in about 80% of patients with RA. If the patient's symptoms are consistent with RA, the presence of anti-CCP and RF makes a strong case for early, accurate diagnosis. An increase in antinuclear antibody (ANA) titers is a general indicator of autoimmune activity. It is not diagnostic of RA. ESR and CRP are increased as general indicators of active inflammation. Periodic testing can be used to monitor RA activity.

Synovial fluid analysis in early disease often shows slightly cloudy, straw-colored fluid with many fibrin flecks. The WBC count and the enzyme MMP-3 are increased in the synovial fluid. MMP-3 may be a marker of progressive joint damage.

TABLE 69.6 Diagnostic Criteria

Newly Diagnosed Patients With RA

Patients should be tested for RA who initially are seen with:
- At least 1 joint with definite clinical synovitis
- Synovitis not better explained by another disease

Joint Involvement	Score
1 large joint	0
2–10 large joints	1
1–3 small joints (with or without large joint involvement)	2
4–10 small joints (with or without large joint involvement)	3
>10 joints (at least 1 small joint)	5

Serology (at least 1 test result needed for classification)	
Negative RF *and* negative anti-CCP	0
Low-positive RF *or* low-positive anti-CCP	2
High-positive RF *or* high-positive anti-CCP	3

Acute Phase Reactants (at least 1 test needed)	
Normal CRP *and* normal ESR	0
Abnormal CRP *or* abnormal ESR	1

Duration of Symptoms	
<6 weeks	0
≥6 weeks	1

Scoring: Add score of categories A–D. Scores range from 0 to 10. A score of ≥6 indicates the definitive presence of RA.

From Aletaha D, Neogi T, Silman AJ, et al.: 2010 Rheumatoid arthritis classification criteria: an American College of Rheumatology/European League Against Rheumatism Collaborative Initiative, *Arthr Rheum* 62:2569, 2010. Retrieved from https://www.rheumatology.org/Portals/0/Files/2010_revised_criteria_classification_ra.pdf.

TABLE 69.7 Stages of RA

Stage	Characteristics
I	• No destructive change on x-ray • X-ray evidence of osteoporosis possible
II	• X-ray evidence of osteoporosis at joint, with or without slight subchondral bone destruction • Slight cartilage destruction possible • Joint mobility may be limited, but no joint deformities noted • Muscle atrophy near joints • Soft tissue lesions (nodules, tenosynovitis) possible near joints
III	• X-ray evidence of cartilage and bone destruction, osteoporosis at joint • Joint deformity without joint fusion • Extensive muscle atrophy near joints • Soft tissue lesions possible near joints
IV	• Criteria from stage III, plus • Fibrous or bony joint fusion

Tissue biopsy can confirm early inflammatory changes in the synovial membrane.

X-rays alone are not diagnostic of RA. They may show only soft tissue swelling and bone demineralization in early disease. A narrowed joint space, articular cartilage destruction, erosion, subluxation, and deformity are seen in later disease. Poor alignment and fusion may be seen in advanced disease. Baseline x-rays may be used to monitor disease progression and treatment effectiveness. Bone scans are more useful in detecting early joint changes and confirming diagnosis so RA treatment can be started.

TABLE 69.8 Interprofessional Care

RA

Diagnostic Assessment
- History and physical assessment
- CBC
- ESR
- C-reactive protein (CRP)
- Rheumatoid factor (RF)
- Antibodies to citrullinated peptide (anti-CCP)
- Antinuclear antibody (ANA)
- X-rays of involved joints
- Synovial fluid analysis, synovial biopsy

Management
- Nutrition and weight management counseling
- Therapeutic exercise
- Psychologic support
- Rest and joint protection, use of assistive devices
- Heat and cold applications
- Reconstructive surgery

Drug Therapy
- Disease-modifying antirheumatic drugs (DMARDs) (Table 69.9)
- Biologic response modifiers (BRMs) (Table 69.9)
- NSAIDs (Table 69.3)
- Intraarticular or systemic corticosteroids (Table 69.3)

Interprofessional Care

A patient-specific treatment plan considers disease activity, joint function, age, sex, family and social roles, and response to previous treatment (Table 69.8). Treatment advances have improved the prognosis for patients with newly diagnosed RA. The progression of joint damage can be decreased and disease activity reduced with aggressive, early treatment.[11] A caring, long-term relationship with the health care team can promote the patient's self-esteem and positive coping.

Drug Therapy

Disease-modifying antirheumatic drugs. Drugs are the cornerstone of RA treatment (Table 69.9). Because irreversible joint changes can occur as early as the first year of RA, HCPs aggressively prescribe disease-modifying antirheumatic drugs (DMARDs). These drugs may slow disease progression and decrease risk for joint erosion and deformity. The choice of drug is based on disease activity, the patient's functional level, and lifestyle considerations, such as the wish to become pregnant.

Methotrexate is preferred for early treatment.[11] It has a lower risk for toxicity than other drugs. Rare but serious side effects include bone marrow suppression and liver toxicity. Therapy requires frequent laboratory monitoring, including CBC and blood chemistry. The patient begins to see therapeutic effects within 4 to 6 weeks. However, not everyone gets adequate relief

TABLE 69.9 Drug Therapy

RA

Drug	Mechanism of Action	Nursing Considerations
Disease-Modifying Antirheumatic Drugs (DMARDs)		
leflunomide (Arava)	Antiinflammatory Immunomodulatory agent that inhibits proliferation of lymphocytes	Monitor liver function. Avoid pregnancy.
methotrexate (Trexall)	Antimetabolite Inhibits DNA, RNA, protein synthesis	Monitor CBC, liver and renal function. Teach patient to report signs of anemia (fatigue, weakness). Keep patient well hydrated. Avoid pregnancy.
sulfasalazine (Azulfidine)	Sulfonamide Antiinflammatory Blocks prostaglandin synthesis	Monitor CBC. Tell patient drug may cause orange-yellow discoloration of urine or skin. Space doses evenly around the clock, taking drug after food with 8 oz water. Treatment may be continued even after symptoms are relieved. Encourage oral fluid intake. Wear sunscreen with sun exposure.
hydroxychloroquine (Plaquenil)	Exact mechanism of action unknown May suppress formation of antigens	Monitor CBC, liver function. Response may not occur for up to 6 months. Teach patient to report vision changes, muscle weakness, ↓ hearing, tinnitus. Have a baseline eye examination with follow-up every 6–12 months because of risk for vision loss. Avoid pregnancy.
Biologic Response Modifiers (Biologics, Immunotherapy)		
B-Cell Depleting Agent		
rituximab (Rituxan)	Monoclonal antibody Binds to CD20, an antigen on B cells, destroying B cells and suppressing immune response	Monitor for infection and bleeding. No live virus vaccines during treatment. Monitor for low BP if taking BP medication. Fatigue is common.
Interleukin-1 Receptor Antagonist		
anakinra (Kineret) canakinumab (Ilaris)	Blocks the action of interleukin-1, ↓ inflammatory response	Do not use with TNF inhibitors. Injection site reaction generally occurs in first month of treatment and decreases with continued therapy. Monitor renal function. Monitor for infection.
Interleukin-6 Receptor Antagonist		
sarilumab (Kevzara) tocilizumab (Actemra)	Blocks action of interleukin-6, thus ↓ inflammatory response	Given to patients for whom other therapies have failed. Monitor BP and for infection. Tell patient of GI effects (e.g., perforation). Monitor liver function, low-density lipoprotein (LDL). Monitor for infection.
JAK (Janus Kinase) Inhibitors		
baricitinib (Olumiant) tofacitinib (Xeljanz) upadacitinib (Rinvoq)	Inhibits action of JAK enzymes, signaling pathways inside the cell with a key role in inflammation of RA	Avoid use in patient with severe liver impairment. Monitor CBC and liver function. Monitor for infection. Avoid pregnancy.
T-Cell Activation Inhibitor		
abatacept (Orencia)	Inhibits T-cell activation, thus suppressing immune response	Do not use with TNF inhibitors. Monitor for infusion reaction if given IV. Assess injection site for reaction. Monitor for infection.
Tumor Necrosis Factor (TNF) Inhibitors		
adalimumab (Humira) certolizumab (Cimzia) etanercept (Enbrel) golimumab (Simponi) infliximab (Remicade)	Bind to TNF, blocking its interaction with cell surface receptors. Decrease inflammatory and immune responses	Monitor CBC, liver function. ↑ Risk for tuberculosis. Teach patient to have yearly PPD. Monitor for infection, bleeding, cancers. No live virus vaccines during treatment. For infliximab: Monitor for infusion reaction. For other TNF inhibitors: SC injection site reaction generally occurs in first month of treatment and ↓ with continued therapy.

from methotrexate alone. It can be given with other DMARDs or biologic response modifiers (BRMs).

Sulfasalazine (Azulfidine) and the antimalarial drug hydroxychloroquine (Plaquenil) may be effective DMARDs for mild to moderate disease. They are rapidly absorbed, relatively safe, and well-tolerated. The synthetic DMARD leflunomide (Arava) blocks immune cell overproduction. Its efficacy and side effects are similar to those of methotrexate and sulfasalazine. Because these drugs are teratogenic, pregnancy must be excluded before starting therapy.

Biologic response modifiers. *Biologic response modifiers* (also called *biologics* or *immunotherapy*) are used to slow disease progression. They can be used alone or in combination therapy with a DMARD, such as methotrexate. BRMs can be used to treat patients with moderate to severe RA who have not responded to DMARDs.

We classify BRMs by their mechanism of action (Table 69.9). These drugs all inhibit the inflammatory response. TNFs bind to TNF in circulation before TNF can bind to the cell surface receptor. Interleukin receptor antagonists block the action of cytokines (IL-1, IL-6) that contribute to inflammation. JAK inhibitors interfere with JAK enzymes involved in joint inflammation in RA. Abatacept (Orencia) blocks T-cell activation. Rituximab (Rituxan) is a monoclonal antibody that targets B cells.

DRUG ALERT

BRM Therapies

- Perform tuberculin test and chest x-ray before starting therapy.
- Monitor for signs of infection. Notify HCP if acute infection develops as therapy may be stopped temporarily.
- Live vaccines should be taken at least 4 weeks before starting drug.
- Report bruising or bleeding.

Other drug therapy. The antibiotics doxycycline (Vibramycin) and minocycline (Minocin) continue to be researched. Any current use of these drugs for RA treatment is not FDA approved. Immunosuppressants (azathioprine) and gold salts are rarely used because they are weak treatments compared to DMARDs and BRMs.

Corticosteroid therapy can be used to manage symptoms during disease flares. Intraarticular injections may temporarily reduce acute pain and inflammation. Low-dose oral corticosteroids may be used for a limited time to decrease disease activity until we see the effects of DMARDs or BRMs. However, they are not used as a sole therapy because they do not affect disease progression. Their long-term use should not be a mainstay of RA treatment. Complications include osteoporosis and avascular necrosis.

Patients use various NSAIDs and salicylates to treat pain and inflammation. They do not alter the course of RA. Aspirin may be used in dosages of 3 to 4 g/day in 3 to 4 doses. We monitor salicylate levels if the patient takes more than 3600 mg daily.[12] NSAIDs have antiinflammatory and analgesic effects. Some relief may be seen within days of starting treatment with NSAIDs. Full effect may take 2 to 3 weeks. The patient may be able to better follow the treatment plan if using an antiinflammatory drug that can be taken only once or twice a day (Table 69.3). Celecoxib (Celebrex), the only available COX-2 inhibitor, is effective in RA. All nonaspirin NSAIDs increase the risk for blood clots, heart attack, and stroke.

Surgical Therapy

Surgery may be needed to relieve severe pain and improve the function of severely deformed joints. Removal of the joint lining *(synovectomy)* is one type of surgery. Total joint replacement *(arthroplasty)* can be done for many different joints in the body. Joint surgery is discussed in Chapter 67.

NURSING MANAGEMENT: RHEUMATOID ARTHRITIS

Assessment

Subjective and objective data you should obtain from the patient with RA are outlined in Table 69.10. Begin with the physical assessment (e.g., joint pain, swelling, ROM, general health status). Assess psychosocial needs (e.g., family support, sexual satisfaction, emotional stress, financial constraints, vocational and career limitations). Are there environmental concerns (e.g., transportation, home or work modifications)? After identifying the patient's problems, plan a program for rehabilitation and education with the interprofessional care team (Table 69.11).

Clinical Problems

Clinical problems for the patient with RA may include:

- Impaired musculoskeletal function
- Pain
- Impaired role performance

Additional information on clinical problems and interventions for the patient with RA is provided in eNursing Care Plan 69.1 (available on the website for this chapter).

Planning

The overall goals are that the patient with RA will (1) have acceptable pain management, (2) have minimal loss of function of affected joints, (3) take part in planning and implementing the treatment plan, (4) maintain a positive self-image, and (5) perform self-care to the maximum amount possible.

Implementation

Care of the patient with RA includes a broad program of drug therapy, self-management strategies, exercise, and patient and caregiver teaching. Nondrug management may include the use of therapeutic heat and cold, rest, relaxation techniques, joint protection (Tables 69.4 and 69.12), biofeedback, transcutaneous electrical nerve stimulation (see Chapter 9), and hypnosis. Allow the patient and caregiver to choose therapies that promote optimal comfort and fit their lifestyle. The Arthritis Foundation offers many publications, classes, and support activities to help persons with RA.

TABLE 69.10 NURSING ASSESSMENT

RA

Subjective Data

Important Health Information

Health history: Recent infections. Precipitating factors, such as emotional upset, infections, overwork, childbirth, surgery. Pattern of remissions and exacerbations

Medications: Aspirin, NSAIDs, corticosteroids, DMARDs, BRMs

Surgery or other treatments: Any joint surgery

Functional Health Patterns

Health perception–health management: Positive family history for RA or other autoimmune disorders. Malaise, ability to take part in treatment plan. Impact of disease on functional ability

Nutritional-metabolic: Anorexia, weight loss, dry mucous membranes

Activity-exercise: Stiffness and joint swelling, muscle weakness, difficulty walking, fatigue

Cognitive-perceptual: Paresthesia of hands and feet, loss of sensation; symmetric joint pain and aching that ↑ with motion or stress on joint, may interfere with rest

Objective Data

Cardiovascular

Symmetric pallor and cyanosis of fingers (Raynaud phenomenon). Distant heart sounds, murmurs, dysrhythmias

General

Lymphadenopathy, fever

GI

Splenomegaly (Felty syndrome)

Musculoskeletal

Symmetric joint involvement with swelling, redness, warmth, tenderness. Deformities (with later disease). Enlargement of PIP and MCP joints. Limitation of joint movement, muscle contractures, muscle atrophy

Respiratory

Bronchiectasis, pleural effusion, tuberculosis, interstitial lung disease

Skin

Scleritis, uveitis, Sjögren syndrome. Subcutaneous rheumatoid nodules on forearms, elbows. Skin ulcers. Shiny, taut skin over involved joints. Peripheral edema

Possible Diagnostic Findings

Positive rheumatoid factor (RF), Antinuclear antibody (ANA), Anti-CCP. ↑ ESR; anemia. ↑ WBCs in synovial fluid. On x-ray evidence of joint space narrowing, bony erosion, deformity, possible osteoporosis

TABLE 69.11 NURSING MANAGEMENT

Caring for the Patient With RA

- Give drug therapy as ordered.
- Teach patient and caregiver about drug therapy, including increased risk for infection with DMARDs and BRMs.
- Assess disease impact on quality of life and joint function.
- Assess pain intensity and give analgesics as ordered. Assess response.
- Develop program for rehabilitation and education with the interprofessional team.
- Teach patient about need for balance of rest and activity, with use of joint protective strategies.
- Supervise AP
  - Aid with passive ROM of affected joints.
  - Help with self-care needs.

Collaborate With Interprofessional Team Members

Physical Therapist

- Assess current mobility and need for help (e.g., walker).
- Develop exercise plan and teach patient to perform exercises safely.
- Coordinate PT with RN so that patient can receive timely analgesia.
- Recommend and apply thermal therapies.

Occupational Therapist

- Assess impact of condition on ability to perform.
- Teach use of assistive devices (e.g., long-handled reacher, long-handled shoehorn) to improve self-care ability without increasing stress on joints.
- Identify modifications to improve role performance (e.g., kitchen modifications for meal preparation).

Social Worker

- Help with obtaining durable medical equipment (e.g., walker).
- Assess psychosocial and financial impact of disease. Arrange vocational retraining if needed.

The patient is usually treated on an outpatient basis. The patient who has systemic complications or needs surgery for decreased functional ability may be hospitalized. Work closely with the HCP, physical and occupational therapists, and social worker to help the patient regain function and adjust to chronic illness.

Teach the patient and caregiver about the disease process and treatment plan. Inflammation may be managed with NSAIDs, DMARDs, and BRMs. Careful timing of drug administration is critical to maintain a therapeutic drug level and reduce early morning stiffness. Discuss the action and side effects of each drug and any needed laboratory monitoring. Many patients take several different drugs, so make the drug regimen as understandable as possible. Encourage patients to develop a way to remember to take their medications (e.g., pill containers).

◆ Rest

Energy conservation requires careful planning. Alternating scheduled rest periods with activity throughout the day (pacing) helps relieve fatigue and pain. The amount of rest needed varies based on disease severity and the patient's limitations. The patient should rest before becoming exhausted. Total bed rest is rarely necessary. It should be avoided to prevent stiffness and other effects of immobility. A patient with mild disease may need daytime rest plus 8 to 10 hours of sleep at night.

Help the patient find ways to change daily activities to avoid overexertion and fatigue, which can worsen disease activity. For example, the patient may be able to prepare meals more easily while sitting on a high stool in front of the sink.

Teach the patient to maintain good body alignment during rest through use of a firm mattress or bed board. Encourage

TABLE 69.12 PATIENT & CAREGIVER TEACHING

Protecting Small Joints

Include the following instructions when teaching the patient with arthritis how to protect small joints:

1. Maintain joint in neutral position to minimize deformity.
   - Press water from a sponge instead of wringing.
2. Use strongest joint available for any task.
   - When rising from chair, push with palms rather than fingers.
   - Carry laundry basket in both arms rather than with fingers.
3. Distribute weight over many joints instead of stressing a few.
   - Slide objects instead of lifting them.
   - Hold packages close to body for support.
4. Change positions often.
   - Do not hold book or grip steering wheel for long periods without resting.
   - Avoid grasping pencil or cutting vegetables with knife for extended periods.
5. Avoid repetitious movements.
   - Do not knit or sew for long periods.
   - Rest between rooms when vacuuming.
   - Use faucets and doorknobs that push rather than turn.
6. Modify chores to avoid stress on joints.
   - Avoid heavy lifting.
   - Sit on stool instead of standing during meal preparation.

positions of extension. Teach the patient to avoid positions of flexion. To decrease the risk for joint contracture, never place pillows under the knees. Use a small, flat pillow under the head and shoulders if needed.

Joint Protection

Protecting joints from stress is important. Help the patient find ways to alter routine tasks to put less stress on joints (Table 69.12). The emphasis is on work simplification. Organize activities to avoid going up and down stairs repeatedly. Use carts to carry supplies. Store frequently used materials in a convenient, easy-to-reach area. Use joint-protective devices (e.g., electric can opener) whenever possible. Teach patients to delegate tasks to other family members.

An occupational therapist helps the patient maintain upper extremity function and encourages use of splints or other assistive devices for joint protection. Lightweight splints can rest an inflamed joint and prevent deformity from muscle spasms and contractures. Remove the splints regularly to assess skin and perform ROM exercises. After assessment and supportive care, reapply splints as prescribed.

Occupational therapy may increase independence with assistive devices that simplify tasks (e.g., built-up utensils, buttonhooks, modified drawer handles, lightweight plastic dishes, raised toilet seats). Encourage the patient to make dressing easier by wearing shoes with Velcro fasteners and clothing with buttons or a zipper in the front instead of the back. Use a cane or a walker for support and decreased pain when walking.

Cold and Heat Therapy

Cold and heat applications can help relieve stiffness, pain, and muscle spasm. They can be used several times a day as needed. Ice is especially helpful during periods of increased disease activity. Cold application should not exceed 10 to 15 minutes at a time. Plastic bags of small frozen vegetables (peas or kernel corn) can easily mold around the shoulder, wrists, or knees to be an effective home treatment. The patient can use ice cubes or small paper cups of frozen water to massage areas on either side of a painful joint.

Moist heat offers better relief for chronic stiffness. Heating pads, moist hot packs, paraffin baths, warm baths, or sitting or standing in a warm shower can relieve stiffness and allow the patient to take part in therapeutic exercise. Heat application should not exceed 20 minutes at a time. Alert the patient to the risk for a burn and the need to avoid using a heat-producing cream (e.g., capsaicin) with an external heat device. Sitting or standing in a warm shower, sitting in a tub with warm towels around the shoulders, or simply soaking the hands in a basin of warm water may allow the patient to perform ADLs more comfortably.

Exercise

Exercise is an important part of the treatment plan. A physical therapist may develop a therapeutic exercise program to improve flexibility and strength of affected joints and increase endurance. Encourage program participation and reinforce correct performance of the exercises. Progressive joint immobility and muscle weakness can occur if the patient does not move the joints. Overaggressive exercise can cause increased pain, inflammation, and joint damage. Emphasize that taking part in a recreational exercise program (e.g., walking, swimming) or doing usual daily activities does not take the place of therapeutic exercise to maintain adequate joint motion.

Gentle ROM exercises daily can help to keep joints functional. The patient should practice exercises with supervision. Exercising in warm water (78° F to 86° F [25° C to 30° C]) allows easier joint movement because of the buoyancy and warmth of the water. Although movement seems easier, water provides 2-way resistance that makes muscles work harder than they would on land. During acute inflammation, limit exercise to 1 or 2 repetitions.

Nutrition

Balanced nutrition is important. Fatigue, pain, and depression may cause a loss of appetite. Limited endurance and mobility may make it hard to shop for and prepare food. Weight loss may result. The occupational therapist can help the patient modify the home environment and use assistive devices for easier food preparation.

Corticosteroid therapy and decreased mobility due to pain may cause unwanted weight gain. Corticosteroids increase the appetite, leading to higher caloric intake. A sensible weight loss program with balanced nutrition and exercise reduces stress on affected joints. The patient taking corticosteroids may become distressed as signs and symptoms of Cushing syndrome (e.g., moon face, redistribution of fatty tissue to the trunk) changes their appearance. Encourage the patient not to change the dose or stop therapy abruptly. Weight will return to normal several months after treatment ends. Remind the patient to continue to eat a balanced diet.

Psychologic Support

For effective self-management, help the patient understand the nature and course of RA and the goals of therapy. Discuss changes in sexuality. Consider the patient's value system and perception of the disease.

Evaluate their support system. Financial planning may be needed. Consider community resources, such as a home care nurse, homemaker services, and vocational rehabilitation. Self-help groups are helpful for some patients.

Chronic pain or loss of function may make the patient vulnerable to claims of false advertising about unproven or even dangerous remedies. Help the patient recognize fears and concerns faced by all people who live with chronic illness.

Living with chronic pain may lead to depression. To decrease depressive symptoms, suggest activities such as listening to music, reading, exercising, and counseling. Hypnosis and biofeedback may be useful.

Gerontologic Considerations: Arthritis

The prevalence of arthritis in older adults is high. The disease is accompanied by problems unique to this age group. Areas of concern for older adults include:

- The high incidence of OA may keep the HCP from considering other types of arthritis.
- Age alone causes changes that make interpretation of laboratory values, such as RF and ESR, more difficult. Drugs taken for comorbid conditions can affect laboratory values.
- Musculoskeletal pain syndromes and weakness may have no physical cause. They may be related to depression and physical inactivity.
- Diseases such as SLE, which often occur in younger adults, can develop in a milder form in older adults.

Physical and metabolic changes of aging may increase the older patient's sensitivity to both therapeutic and toxic effects of some drugs. The older adult who takes NSAIDs has an increased risk for side effects, especially GI bleeding and renal toxicity. Using NSAIDs with a shorter half-life may need more frequent dosing and have fewer side effects in the older patient with altered drug metabolism.

Polypharmacy is a concern. Use of drugs in RA treatment may increase the chance of drug interactions. The drug regimen should be as simple as possible to increase adherence. This is especially important for those who lack regular assistance.

Osteopenia from corticosteroid use can worsen the problem of decreased bone density from aging and inactivity. The risk for pathologic fractures is increased, especially vertebral compression fractures. An age-appropriate exercise program can minimize myopathy from corticosteroid use. The support system for the older adult is critical to the ability to follow a treatment plan.

GOUT

Gout is a type of arthritis characterized by elevation of uric acid *(hyperuricemia)* and the deposit of uric acid crystals in 1 or more joints. Sodium urate crystals may be found in articular, periarticular, and subcutaneous tissues. Unlike other forms of arthritis, gout is marked by painful flares lasting days to weeks followed by long periods without symptoms. More than 9 million Americans have gout. Blacks have a higher incidence compared to Whites.[13] Gout usually develops in men ages 30 to 50. Women rarely develop gout before menopause because estrogen promotes renal excretion of uric acid.

TABLE 69.13 Causes of High Uric Acid Levels

- Acidosis or ketosis
- Alcohol use, especially beer and red wine
- Cancer
- Chemotherapy drugs
- Diabetes
- Drug-induced renal impairment
- Hyperlipidemia
- Hypertension
- Lead exposure
- Metabolic syndrome
- Myeloproliferative disorders
- Obesity
- Renal insufficiency
- Sickle cell anemia
- Starvation
- Use of certain common drugs (aspirin, ACE inhibitors, β-blockers, loop or thiazide diuretics, niacin)

Etiology and Pathophysiology

Uric acid is the major end product of purine catabolism. It is excreted by the kidneys. Gout occurs when either the kidneys cannot excrete enough uric acid or there is too much being made for the kidneys to handle effectively.

We classify hyperuricemia as primary or secondary. *Primary hyperuricemia* is genetic. Accumulation of uric acid may be due to a lack of uricase. Uricase breaks down uric acid into water-soluble products for elimination in urine. A lack of uricase then leads to uric acid retention. *Secondary hyperuricemia* may be caused by conditions that increase uric acid production or decrease uric acid excretion or drugs that inhibit uric acid excretion (e.g., loop diuretics, β-blockers). About 10% of gout cases are due to overproduction of uric acid.[14] Organ transplant recipients receiving immunosuppressive agents are at risk (Table 69.13).

Gout is likely caused by the interaction of several factors. The most important is metabolic syndrome (obesity, insulin resistance, hypertension, hyperlipidemia). Increased intake of foods containing purines (e.g., red and organ meat, shellfish, fructose drinks) can trigger gout. High uric acid may result from prolonged fasting or excess alcohol use because they increase the production of keto acids, which inhibit uric acid excretion. Persons with other forms of inflammatory arthritis (e.g., RA, PsA) are more likely to develop gout.

Not everyone with high uric acid levels develops gout. Two processes are essential for a person to develop gout: crystallization and inflammation. As urate levels increase and saturate the synovial fluid or soft tissues, the excess urate coalesces into crystals. These trigger inflammation. Monocytes and macrophages try to remove the crystals through phagocytosis. This causes the

Fig. 69.6 Tophi from chronic gout. Painless nodules are filled with uric acid crystals. (From Barajas-Ochoa A, Castaneda-Sanchez JJ, Ramos-Remus C: Is gout an easy-to-treat disease? *Reumatol Clin* 14:59, 2017.)

release of inflammatory mediators into the surrounding area, causing more inflammation and tissue damage.

Clinical Manifestations and Complications

Gout may occur acutely in 1 or more joints (usually less than 4). Inflammation of the great toe *(podagra)* is the most common initial problem. Other affected joints may include wrists, knees, ankles, and the midfoot. Olecranon bursae may be involved. Affected joints may appear dusky or cyanotic. They are very tender. Acute gout arthritis may be triggered by events such as trauma, surgery, alcohol use, or systemic infection. Symptom onset typically occurs at night with sudden swelling and severe pain peaking within several hours. The painful area is highly sensitive to light touch. Low-grade fever is common.

An attack usually ends in 2 to 10 days with or without treatment. The affected joint returns to normal. Patients have no symptoms between attacks.

Chronic gout is characterized by multiple joint involvement and visible deposits of sodium urate crystals called tophi. Tophi are hard white nodules. They are typically seen in subcutaneous tissue, synovial membranes, tendons, and soft tissues (Fig. 69.6). Tophi often occur many years after the onset of disease.

The severity of gout arthritis varies. The clinical course may involve infrequent mild attacks or multiple severe episodes (up to 12 per year) marked by slowly progressive disability. In general, tophi appear earlier, and the patient has more frequent, severe episodes of gout if serum uric acid is high. Chronic inflammation may cause joint deformity. Cartilage destruction may lead to secondary OA. Large urate crystal deposits may pierce overlying skin, causing draining sinuses that often become infected.

Excess uric acid excretion may lead to stone formation in the kidneys or urinary tract. Pyelonephritis related to sodium urate deposits and obstruction contributes to kidney disease.

Diagnostic Studies

Normal uric acid levels range from 2.7 to 8.5 mg/dL based on gender.[14] The higher the value, the greater the risk for uric acid deposits in joints and future gout attacks. However, hyperuricemia is not specifically diagnostic of gout because serum values may be normal during an acute gout attack. A 24-hour urine uric acid can determine if gout is caused by decreased renal excretion or overproduction of uric acid.

The gold standard for diagnosis of gout is synovial fluid aspiration. Affected fluid contains needle-like monosodium urate crystals. This procedure is done in only a small number of patients because diagnosis can often be made on symptoms alone. However, it is the only reliable way to tell gout from septic arthritis or *pseudogout* (calcium phosphate crystal formation). Aspiration may decrease pain by relieving pressure in a swollen joint capsule.

X-rays appear normal in the early stages of gout. In chronic disease, tophi may appear as eroded areas in the bone.

❖ INTERPROFESSIONAL AND NURSING MANAGEMENT: GOUT

Goals for the care of the patient with acute gout (Table 69.14) include ending an attack with an antiinflammatory agent, such as colchicine. Hyperuricemia and gout are chronic problems that can be controlled with effective patient education and careful adherence to a treatment program. Drug therapy is the primary way to treat acute and chronic gout.

◆ Drug Therapy

Acute gout is treated with oral colchicine (Colcrys, Mitigare) and NSAIDs. Because colchicine has antiinflammatory effects but is not an analgesic, an NSAID is added for pain management. Colchicine often results in pain relief when given within 12 hours of an attack. This helps in diagnosis because good response to this drug is further evidence of gout.

TABLE 69.14 Interprofessional Care

Gout

Diagnostic Assessment

- History and physical assessment
- Family history of gout or other inflammatory arthritis
- Sodium urate crystals in synovial fluid
- ↑ Serum uric acid
- ↑ Uric acid in 24-hr urine
- X-ray of affected joints

Management

- Joint immobilization
- Local application of cold
- Joint aspiration and intraarticular corticosteroids
- Avoid food and fluids with high purine content (e.g., anchovies, liver, wine, beer)

Drug Therapy

- colchicine
- NSAIDs (e.g., naproxen)
- Xanthine oxidase inhibitors: allopurinol (Zyloprim), febuxostat (Uloric)
- Uricosurics: probenecid
- pegloticase (Krystexxa)
- Corticosteroids (e.g., prednisone)
- Intraarticular corticosteroids (methylprednisolone)
- Adrenocorticotropic hormone (ACTH)

Corticosteroids (intraarticular injection or orally by tapered dosing) can be helpful in treating an acute attack. Systemic corticosteroids may be used only if routine therapies are contraindicated or ineffective. Adrenocorticotropic hormone (ACTH) is an option for acute treatment of patients for whom NSAIDs, colchicine, or steroids may be problematic.

Future gout attacks are prevented in part by a maintenance dose of a xanthine oxidase inhibitor. These drugs decrease the production of uric acid. Allopurinol is the drug used most often and the first choice for therapy. It can be used for patients with uric acid kidney stones or renal impairment. Serious adverse effects limit the use of febuxostat (Uloric) to those not treated effectively or having severe side effects with allopurinol.

DRUG ALERT

Febuxostat

- May cause heart-related death and liver failure.
- Encourage patient with cardiovascular disease to take low-dose aspirin therapy.
- Monitor liver function tests before starting therapy and during treatment.
- Teach patient to notify HCP if symptoms of liver or heart problems occur.

A uricosuric agent, which increases uric acid excretion in the urine, may be added with a xanthine oxidase inhibitor if uric acid levels do not decrease. Probenecid is the most common agent. Aspirin inactivates its effect, resulting in urate retention, and must be avoided during treatment. Acetaminophen can be used safely if analgesia is needed.

Uricosurics can cause renal impairment. They are ineffective when creatinine clearance is reduced, as can occur in patients over age 60 years or with renal impairment. They should be taken in the morning with food and water. Teach patients to stay well hydrated and to drink about 2 L of liquid a day when taking the drug.

Patients who cannot take or do not respond to drugs that lower serum uric acid may receive pegloticase (Krystexxa). It is an enzyme that metabolizes uric acid into a harmless chemical excreted in the urine. It is given IV, every 2 weeks, for at least 6 months. Life-threatening anaphylactic and infusion reactions can occur.

The angiotensin II receptor antagonist losartan (Cozaar) may be effective for treating older patients with gout and hypertension. Losartan promotes urate excretion and may normalize serum urate. Combination therapy with losartan and allopurinol may be used.

Serum uric acid is checked regularly to monitor treatment effectiveness. Explain the importance of drug therapy and the need for regular assessment of serum uric acid. Limiting alcohol and foods high in purine help minimize uric acid production. Adequate urine volume with normal renal function (2 to 3 L/day) must be maintained to prevent uric acid precipitation in the renal tubules. Teach obese patients to follow a planned weight-reduction program (see Chapter 45). Teach the patient about other factors that may cause an attack, including fasting, drug use (e.g., diuretics), and major medical events (e.g., surgery, heart attack).

Nursing interventions for the patient with acute gout include supportive care of the inflamed joints. Avoid causing pain by careless handling of an inflamed joint. Bed rest may be needed to immobilize affected joints. Use a cradle or footboard to protect a painful lower extremity from the weight of bed linens. Assess motion limitations and degree of pain.

CHECK YOUR PRACTICE

A patient comes to the primary care office with acute gout. The right great toe is swollen, red, and painful. He is prescribed colchicine.

- What nursing interventions will you teach the patient to protect the foot and decrease pain?
- What will you discuss with the patient about diet changes to decrease risk for future attacks?

LYME DISEASE

Lyme disease is an infection caused by the spirochete *Borrelia burgdorferi*. It is transmitted by the bite of an infected deer tick. The tick typically feeds on mice, dogs, cats, cows, horses, deer, and humans. Person-to-person transmission does not occur. It is the most common vector-borne disease in the United States, with about 35,000 cases annually.[15]

Human infection peaks in summer months. Most U.S. cases occur in the northeastern states from Virginia to northern Maine, and in Wisconsin and Minnesota.[15] Reinfection is common.

Symptoms mimic those of other diseases, such as multiple sclerosis, mononucleosis, and meningitis. The most characteristic symptom of early disease is *erythema migrans* (EM). This

Fig. 69.7 Erythema migrans. Typical skin lesion of Lyme disease occurs at the site of tick bite. (From Marx J, Hockberger R, Walls R: *Rosen's emergency medicine*, ed 7, Philadelphia, 2009, Mosby.)

"bull's-eye rash" occurs in about 80% of infected persons.[15] It appears at the site of the tick bite within 1 month after exposure (Fig. 69.7). It may occur anywhere else on the body as the disease progresses. The EM lesion begins as a central red macule or papule that slowly expands to include a red outer ring of up to 12 in, resembling a bull's eye. It may be warm to the touch but is not itchy or painful. The rash often occurs with acute flu-like symptoms. These include low-grade fever, headache, neck stiffness, fatigue, loss of appetite, and joint and muscle pain. These symptoms generally resolve over weeks or months, even if untreated.

If not treated, the spirochete can spread within several weeks or months to the heart, joints, and central nervous system (CNS). Arthritis is the second most common manifestation of Lyme disease. Many persons with untreated infection develop chronic arthritic pain and swelling in the large joints, mainly the knee. Cardiac symptoms, such as palpitations or irregular heartbeat *(Lyme carditis)*, may require hospitalization.[15] Bell palsy is the most common neurologic effect. Other problems include brain and spinal cord inflammation, dizziness, shortness of breath, and numbness and tingling in the feet.

Diagnosis is often based on the manifestations, especially EM, and a history of exposure in an at-risk area. The CDC recommends a 2-step laboratory testing process to confirm the diagnosis.[15] The first step is the enzyme immunoassay (EIA). It will be positive for most people with Lyme disease. If the EIA is positive or inconclusive, then a Western blot test is done. Results are diagnostic of Lyme disease only if both tests are positive. The CDC does not recommend the Western blot test alone. False-positive results lead to incorrect diagnosis and treatment. Cerebrospinal fluid should be tested in those with neurologic involvement.

Active lesions are treated with oral antibiotics. Doxycycline, cefuroxime, and amoxicillin are often effective in treating early-stage infection and preventing later stages of the disease (see Table 15.8). Short-term therapy of 10 to 14 days of doxycycline is preferred.[15] It treats both Lyme disease and human granulocytic anaplasmosis, which can be transmitted as a co-infection with a single tick bite. While other antibiotics can be used for those who cannot tolerate these drugs, they all are less effective. Patients treated with macrolide antibiotics need close monitoring to ensure symptoms resolve.

A small number of persons treated with antibiotics have lingering fatigue or joint and muscle pain. Antibiotic treatment is extended as needed because the risks of untreated Lyme disease outweigh those of long-term antibiotic therapy.

Reducing exposure to ticks is the best way to prevent Lyme disease. Patient and caregiver teaching for people living in endemic areas is outlined in Table 69.15. No vaccine is available for Lyme disease.

TABLE 69.15 PATIENT & CAREGIVER TEACHING

Prevention and Early Treatment of Lyme Disease

Include the following instructions when teaching patients how to prevent Lyme disease:

- Do not walk through tall grasses and low brush or sit on logs.
- Mow grass frequently. Remove brush around paths, buildings, and campsites to create tick-safe zones.
- Move woodpiles and bird feeders away from your house. Discourage deer (main source of food for adult ticks) from being in the area.
- Keep playground equipment and decks away from yard edges, and in a sunny location if possible.
- Wear long pants or nylon tights of tightly woven, light-colored fabric so that you can easily see ticks.
- Tuck pants into boots or long socks, wear long-sleeved shirts tucked into pants, and wear closed toed shoes when hiking.
- Check often for ticks crawling from pant legs to open skin.
- Thoroughly inspect and wash clothes. Placing clothing in dryer on high heat kills ticks.
- Spray insect repellent containing DEET sparingly on skin or clothing. Apply permethrin to clothing and camping gear; protects for several hours.
- Have pets wear tick collars and inspect them often. Do not allow pets on furniture or beds.

Include the following instructions when teaching patients and caregivers living in endemic areas:

- Remove attached ticks with fine-tipped tweezers (not fingers). Grasp tick's mouth parts as close to skin as possible and pull straight out with steady, even pressure. Do not twist or jerk. Avoid folk solutions, such as painting the tick with nail polish or petroleum jelly.
- Save the tick in a bottle of alcohol (if you need it later for identification). Never crush a tick with your fingers.
- Wash bitten area with soap and water, iodine scrub, or rubbing alcohol. Apply antiseptic. Wash hands.
- See an HCP if flu-like symptoms or a bull's-eye rash appears within 2–30 days after removal of tick.

DEET, N, N-diethyl-m-toluamide.
Adapted from Centers for Disease Control and Prevention: Preventing tick bites on people. Retrieved from https://www.cdc.gov/lyme/prev/on_people.html; and Centers for Disease Control and Prevention: Tick removal. Retrieved from https://www.cdc.gov/lyme/removal/index.html.

SEPTIC ARTHRITIS

Septic arthritis (infectious or bacterial arthritis) is caused by microorganisms invading the joint cavity. These organisms can travel through the bloodstream from another site of active infection, resulting in seeding of the joint. Organisms can be introduced directly through trauma or surgical incision.

Any infectious agent can cause septic arthritis, especially in the immunocompromised patient. *Staphylococcus aureus* is the most common causative organism.[16] Factors that increase

infection risk include (1) diseases with decreased host resistance (e.g., RA, SLE), (2) treatment with corticosteroids or immunosuppressive drugs, (3) debilitating chronic illness (e.g., diabetes), (4) joint trauma or an artificial joint, (5) skin conditions (e.g., psoriasis, eczema), and (6) IV drug use.[16]

Large joints, such as the knee and hip, are most often affected. Inflammation of the joint cavity causes severe pain, redness, and swelling. Septic arthritis of the hip can cause avascular necrosis. Because infection has often spread from a primary site elsewhere in the body, fever or shaking chills are often present. Diagnosis may be made by joint aspiration *(arthrocentesis)* and synovial fluid culture. WBC count may be low early in the infectious process, especially in those who are immunosuppressed, so diagnosis is not possible solely based on WBC count. Blood cultures for aerobic and anaerobic organisms should be obtained. X-rays or other imaging tests can assess joint damage or loosening of an artificial joint.

Emergent aspiration or surgical drainage is a cornerstone of treatment. Permanent joint damage can occur without rapid treatment. Sometimes, damage occurs despite treatment. Broad-spectrum antibiotics are often started before we have culture results. Once we identify the organism, more specific treatment can be determined. IV antibiotics are typically transitioned to oral antibiotics, with total treatment of 2 to 6 weeks. If an artificial joint is infected, treatment may involve removing the joint and replacing it temporarily with a joint spacer. The spacer is made with antibiotic cement. If the artificial joint cannot be removed, several months of oral antibiotics will be needed to avoid return of infection.

Assess and monitor joint inflammation, pain, and fever. To manage pain, use resting splints or traction to immobilize affected joints. Local hot compresses can decrease pain. Start gentle ROM exercises as soon as tolerated to prevent muscle atrophy and joint contractures. Explain the need for antibiotics and the importance of their continued use until the infection is resolved (see Table 15.8). Support the patient who needs joint drainage. Use strict aseptic technique when assisting with joint aspiration.

SPONDYLOARTHROPATHIES

The *spondyloarthropathies* are a group of multisystem inflammatory disorders that affect the spine, peripheral joints, and periarticular structures. These disorders include ankylosing spondylitis, psoriatic arthritis, and reactive arthritis. They are all negative for RF, so we call them *seronegative arthropathies.*

Inheriting HLA B27 is strongly associated with these diseases. Both genetic and environmental factors play a role in their development. HLAs and their relationship to autoimmune diseases are discussed in Chapter 14.

Pain in the lower back *(sacroiliitis)* and hips, especially in the morning or after periods of inactivity, is the primary symptom of all spondyloarthropathies. These general symptoms may make it hard to discern among them in early disease. Other related conditions may include peripheral joint involvement (mainly of the lower extremities), pain and redness of the eyes *(uveitis),* intestinal inflammation, and psoriasis.

BOX 69.3 GENETICS IN CLINICAL PRACTICE

Ankylosing Spondylitis (AS)

Genetic Basis
- Inheritance of HLA-B27 increases susceptibility to developing AS.
- We do not know how HLA-B27 increases the risk for AS.

Incidence
- HLA-B27 antigen is found in about 90% of people with AS.
- Inheriting HLA-B27 does not mean a person will develop AS.
- About 80% of those who inherit HLA-B27 do not develop AS.

Genetic Testing
- Testing for HLA-B27 antigen is available.
- Presence of HLA-B27 is not diagnostic for AS.

Clinical Implications
- Diagnosis of AS usually occurs in the third and fourth decades of life.
- Multiple genetic and environmental factors play a role in pathogenesis of disease.

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis (AS) *(axial spondyloarthritis)* is a chronic inflammatory disease that primarily affects the axial skeleton, including the sacroiliac joints, intervertebral disc spaces, and costovertebral articulations. Onset of AS is usually in the third and fourth decades of life, but onset in adolescence is fairly common. Men are more likely to develop radiographic AS, with spine damage that we can see on x-ray. With the nonradiographic form of AS, changes show on MRI rather than x-ray. This form is as common in women as in men. Whites, Asians, and Hispanics are more likely to have AS.

Etiology and Pathophysiology

We do not know the exact cause of AS. HLA-B27 antigen is found in about 90% of all patients with AS, but only 8% of the general population.[17] This suggests genes play a key role in AS (Box 69.3). Families with other diagnosed HLA-B27–positive rheumatic diseases (e.g., psoriatic arthritis, juvenile spondyloarthritis) should be alert to signs of low back pain for early identification of AS.

Inflammation in the joints and adjacent tissue causes the formation of granulation tissue *(pannus)* and dense fibrous scars that can cause joint fusion. Inflammation can affect the eyes, lungs, heart, kidneys, and peripheral nervous system.

Clinical Manifestations and Complications

AS is characterized by symmetric sacroiliitis and progressive inflammatory arthritis of the axial skeleton. Symptoms of inflammatory spine pain are the first clues to AS. The patient often has low back pain, stiffness, and limited motion that is worse during the night and in the morning but improves with mild activity. In women, early symptoms may include pain and stiffness in the neck rather than the lower back. Uveitis is the most common nonskeletal symptom. It can appear as an initial presentation years before arthritic symptoms develop.

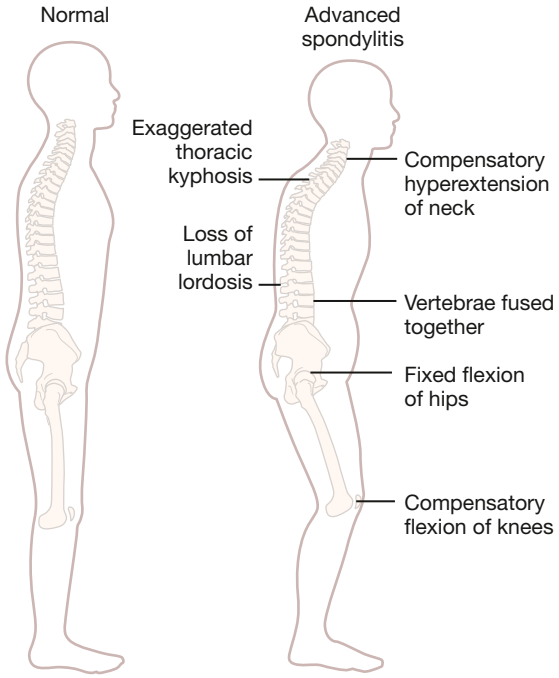

Fig. 69.8 Posture changes in patient with ankylosing spondylitis.

Patients with AS may have chest pain and sternal/costal cartilage tenderness.

Most people with AS stay fully independent or become minimally disabled. Postural abnormalities and deformity can cause disability (Fig. 69.8). Impaired spinal ROM and fusion, along with vision problems, raise concerns about safe ambulation. The patient is at increased risk for aortic insufficiency and pulmonary fibrosis. Cauda equina syndrome (compression of the nerves at the end of the spinal cord) can occur. This contributes to lower extremity weakness and bladder problems. The patient is at risk for spinal fracture from osteoporosis.[17]

Diagnostic Studies

X-rays are the most important technique for the diagnosis and follow up of AS. However, they are limited in detecting early sacroiliitis or subtle changes in posterior vertebrae. MRI is useful in assessing early cartilage changes. CT scan is appropriate in specific situations (e.g., cases with subtle x-ray changes). Changes on later spinal films include the appearance of "bamboo spine," the result of calcifications *(syndesmophytes)* that bridge from one vertebra to another. An increased ESR and mild anemia may be seen. When the suspicion for AS is high, the presence of the HLA-B27 antigen improves the likelihood of the diagnosis.

Interprofessional and Nursing Care

Care goals are aimed at maintaining maximal skeletal mobility while decreasing pain and inflammation. Heat applications can help relieve local symptoms. NSAIDs and salicylates are often prescribed. DMARDs, such as sulfasalazine or methotrexate, have little effect on spinal disease but may help with peripheral joint disease. Local corticosteroid injections may help relieve symptoms.

TNF, which promotes inflammation, is increased in the blood and certain tissues of patients with AS. Etanercept, a BRM, binds TNF and inhibits its action. Etanercept reduces active inflammation and improves spinal mobility. Other anti-TNF inhibitors (infliximab, adalimumab, golimumab) may be effective.

Once pain and stiffness are managed, exercise is essential. Good posture is important to minimize spinal deformity. The exercise plan should include back, neck, and chest stretches. Hydrotherapy (e.g., sauna, steam bath) can decrease pain and facilitate spinal extension. Most patients will not need surgery. Surgery may be done to improve pain and mobility in a severely damaged joint. Spinal osteotomy and total joint replacement are the most common procedures (see Chapter 67).

Teach the patient about the disease and principles of therapy. The home management program should include regular exercise and attention to posture, local moist heat applications, and drug therapy.

Assess chest expansion (using breathing exercises) as part of baseline ROM assessment. Encourage smoking cessation to decrease the risk for lung complications in persons with reduced chest expansion. Ongoing PT includes gentle, graded stretching and strengthening exercises. These preserve ROM and improve thoracolumbar flexion and extension.

Discourage physical exertion during periods of increased disease activity. Proper positioning at rest is essential. Encourage the patient to use a firm mattress. They should sleep on the back with a flat pillow, avoiding positions that encourage flexion deformity. Emphasize the need to avoid spinal flexion (e.g., leaning over a desk); heavy lifting; and prolonged walking, standing, or sitting. Encourage sports that involve natural stretching, such as swimming and racquet games. Family counseling and vocational rehabilitation are important.

PSORIATIC ARTHRITIS

Psoriatic arthritis (PsA) is a progressive inflammatory disease that affects about one-third of people with psoriasis.[18] *Psoriasis* is a common, benign, inflammatory skin disorder characterized by red, irritated, and scaly patches. Although we do not know the exact cause of PsA, we suspect a combination of immune, genetic, and environmental factors. PsA appears to have a genetic link with HLA antigens in many patients.

PsA can occur in different forms. *Asymmetric oligoarthritis* involves different joints on each side of the body. *Symmetric polyarthritis* resembles RA. It affects joints on both sides of the body at the same time. These 2 forms are the most common types of PsA. *Distal interphalangeal predominant PsA* involves the ends of the fingers and toes. The patient often has pitting and color changes in the fingernails and toenails. *Spondylitis* is marked by pain and stiffness in the spine and neck. *Arthritis mutilans* affects less than 5% of people with PsA. It is the most severe form of the disease, causing complete destruction of small joints.

On x-ray, the cartilage loss and erosion are similar to RA. Advanced cases often show widened joint spaces. A "pencil in cup" deformity is common in the DIP joints due to thinning, weakened bone. In this deformity, the narrowed ends of the metacarpals or phalanges insert into the expanded end of the

other bone sharing the joint. Some patients have increased ESR and uric acid levels with mild anemia. So, the diagnosis of gout must be excluded.

Treatment includes splinting, joint protection, and PT. Starting NSAIDs early in the course of the disease may help with inflammation. Drug therapy includes DMARDs, such as methotrexate. They are effective for both articular and skin manifestations. Sulfasalazine, cyclosporine, and BRMs (e.g., etanercept, golimumab, adalimumab, infliximab) may be used. Apremilast (Otezla), a phosphodiesterase-4 inhibitor, can treat adults with active PsA.

REACTIVE ARTHRITIS

Reactive arthritis (Reiter syndrome) is associated with a symptom complex that includes urethritis, conjunctivitis, and mucocutaneous lesions. We do not know the exact cause. It appears to be a reaction triggered in the body after exposure to specific genitourinary or GI tract infections. *Chlamydia trachomatis* spreads by sexual contact. Associated GI infections include *Shigella, Salmonella, Campylobacter,* or *Yersinia* species and other pathogens.[19] It occurs more often in young men.

Those who are positive for HLA-B27 are at increased risk for developing reactive arthritis after sexual contact or exposure to certain GI pathogens. This finding supports a genetic predisposition.

Urethritis develops within 1 to 2 weeks after sexual contact or GI infection. Women may have cervicitis. Low-grade fever, conjunctivitis, and arthritis may occur over the next several weeks. Arthritis is usually the last symptom to appear. It tends to be asymmetric. It often involves the toes and the large joints of the lower extremities. Lower back pain may occur with severe disease. Lesions involving the skin and mucous membranes often occur as small, painless, superficial ulcerations on the tongue, oral mucosa, and glans penis. Soft tissue manifestations include Achilles tendinitis or plantar fasciitis. Few laboratory abnormalities occur, although the ESR may be increased.

Most patients recover within a few months of initial symptoms. Because *C. trachomatis* infection can cause reactive arthritis, treatment with doxycycline is recommended for patients and their sexual partners. Antibiotics have no effect on arthritis or other symptoms. NSAIDs are given to treat inflammation. DMARDs may be used if joint symptoms do not resolve. Topical ophthalmic corticosteroids are helpful for uveitis. Conjunctivitis and skin lesions generally do not need treatment. PT may help during recovery.

Most patients have complete remission with return of full joint function. A few develop chronic arthritis, but the condition is often mild. X-ray changes in chronic reactive arthritis closely resemble those of AS. Treatment is based on symptoms.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is a multisystem inflammatory autoimmune disease. It is a complex disorder of multifactorial origin resulting from interactions among genetic, hormonal, environmental, and immune factors. SLE typically affects the skin, joints, and serous membranes (pleura, pericardium). Renal, hematologic, and neurologic systems are often affected. SLE has a chronic unpredictable course with alternating periods of remission and exacerbation.

About 1.5 million people in the United States have SLE. Blacks, Asian Americans, Hispanics, Native Americans, and Pacific Islanders are more likely than Whites to develop SLE. 90% of those with SLE are women. Most people with lupus develop the disease between ages 15 to 45 years.[20]

Etiology and Pathophysiology

We do not know the cause of the abnormal immune response in SLE. Based on the high prevalence of SLE among family members, we suspect a genetic influence. Multiple genes from the HLA complex, including *HLA-DR2* and *HLA-DR3,* are associated with SLE.

Hormones play a role in SLE. Onset or worsening of disease symptoms may occur after the start of menses, with oral contraceptive use, and during and after pregnancy. SLE tends to become worse in the immediate postpartum period. Infections, including the Epstein Barr virus, may stimulate immune hyperactivity.

Environmental factors can contribute to SLE. These include sun or ultraviolet light exposure, stress, and exposure to some chemicals and toxins. Exposure to silica dust in agricultural or industrial settings can be a factor. Drug triggers include those that make a person more sensitive to the sun (e.g., sulfa drugs, diuretics, tetracycline) and penicillin or similar antibiotics. Drug-induced SLE should not be confused with drug side effects, which typically occur within a few hours or days of short-term drug use. SLE generally occurs months to years after continuous therapy with a causative drug.

In SLE, the body makes various autoantibodies against nucleic acids (e.g., single- and double-stranded DNA), erythrocytes, coagulation proteins, lymphocytes, platelets, and many other self-proteins. Autoimmune reactions (antinuclear antibodies [ANA]) are directed against elements of the cell nucleus, especially DNA.

Circulating immune complexes with antibodies against DNA are deposited in the basement membranes of capillaries in the kidneys, heart, skin, brain, and joints. These complexes trigger inflammation that causes tissue destruction. Overaggressive autoimmune responses are related to activation of B and T cells. Specific disease effects depend on the involved cell types or organs. SLE is a type III hypersensitivity response (see Chapter 14).

Clinical Manifestations and Complications

Severity of SLE varies widely. It ranges from a mild disorder to a rapidly progressive disease affecting many body systems (Fig. 69.9). No characteristic pattern occurs in the progression of SLE. The circulating immune complexes can affect any organ. Common tissues involved are the skin and muscle, lining of the lungs, heart, nervous tissue, and kidneys. General problems, such as fever, weight loss, joint pain, and fatigue, may precede worsened disease activity.

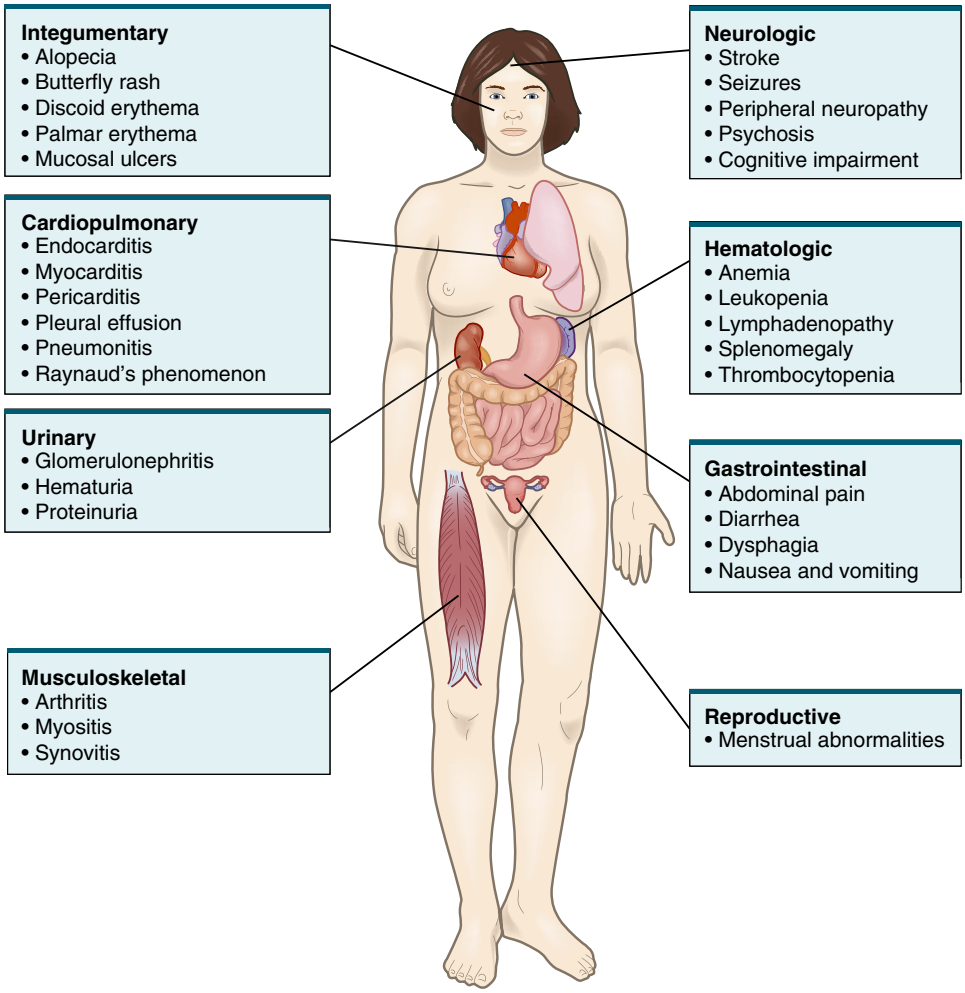

Fig. 69.9 Multisystem involvement in SLE.

Skin Problems

Vascular skin lesions can appear anywhere. Skin lesions are most likely to develop on sun-exposed areas. Severe skin reactions can occur in people who are sensitive to sunlight *(photosensitivity)*. For some, the skin rash is the first symptom.

Some patients have a form of lupus limited to the skin. People with *chronic cutaneous lupus erythematosus* (CCLE) have discoid (round, coin-shaped) lesions, usually on the scalp and face. About 10% of patients with CCLE later develop lupus in other organ systems. *Subacute cutaneous lupus erythematosus* (SCLE) is marked by areas of red, ring-shaped lesions. The lesions of *acute cutaneous lupus* appear when the disease is active. The most common form is the classic butterfly rash over the cheeks and bridge of the nose *(malar rash)* that looks like a sunburn (Fig. 69.10). Lesions in SCLE usually do not scar or itch. They are not thick and scaly.[20]

Oral or nasopharyngeal ulcers occur in one-third of patients with SLE. Alopecia is common. The hair may grow back during remission. Hair loss may be permanent over lesions. The scalp becomes dry, scaly, and atrophied.

Fig. 69.10 Butterfly rash of SLE. (From Yale Dermatology Residents' Slide Collection. In Bolognia JL, Schaffer JV, Duncan KO, Ko CJ: *Dermatology essentials*, Philadelphia, 2014, Elsevier.)

Musculoskeletal Problems

Arthritis occurs in many patients with SLE. Pain in multiple joints *(polyarthralgia)* with morning stiffness is often the first symptom. It may precede the onset of multisystem disease by many years. Diffuse swelling occurs with joint and muscle pain and some stiffness. SLE-related arthritis is often nonerosive. It may cause deformities (e.g., swan neck deformity of the fingers [Fig. 69.4D], ulnar deviation, subluxation with joint laxity). Patients have increased risk for bone loss and fracture.

Cardiopulmonary Problems

Tachypnea and cough suggest the presence of lung disease. Pleurisy is possible. Cardiac involvement may include

dysrhythmias due to fibrosis of the sinoatrial and atrioventricular nodes. This shows advanced disease and is the leading cause of death among patients with SLE. Inflammation can lead to pericarditis, myocarditis, and endocarditis. Hypertension and hypercholesterolemia from steroid use need aggressive treatment and careful monitoring. People with SLE are at risk for secondary *antiphospholipid syndrome* (APS). This coagulation disorder causes clots in the arteries and veins. It increases the risk for stroke, gangrene, and heart attack.

Renal Problems

About 40% of persons with SLE develop kidney problems that need medical evaluation and treatment. Renal involvement is usually present within the first 5 years after diagnosis. Manifestations vary from mild proteinuria to rapidly progressive glomerulonephritis. Scarring and permanent damage can lead to end-stage renal disease (ESRD).

The main goal is to slow the progression of nephropathy and preserve renal function by managing the underlying disease. The need for a renal biopsy is controversial, but findings can help guide treatment. Treatments include corticosteroids and immunosuppressive agents (e.g., azathioprine, cyclosporine). Oral prednisone or pulsed IV methylprednisolone may be used, especially in the initial treatment period when cytotoxic agents have not yet taken effect. Newer treatments for lupus nephritis include belimumab (Benlysta), a human monoclonal antibody. It reduces autoantibody levels and controls autoimmune disease activity. Voclosporin (Lupkynis) binds to the protein calcineurin, stopping T cells from triggering an autoimmune response.[21]

Nervous System Problems

Neuropsychiatric manifestations are common. They range from headache to cerebrovascular disease. They may be related to the stress of having a major illness or associated drug therapies. We think that neuropsychiatric SLE (NPSLE) occurs in 1 of 2 ways. *Focal NPSLE* is caused by clots, especially in the presence of antiphospholipid antibodies. A stroke or aseptic meningitis may occur. Headaches are common and can become severe during a disease flare. Small vessel injury in chronic disease may cause vasculopathy. *Diffuse NPSLE* is caused by an inflammatory process. The patient may have psychosis, anxiety, depression, acute confusion, or cognitive problems.

Hematologic Problems

Blood problems are common due to formation of antibodies against blood cells. Anemia, leukopenia, thrombocytopenia, and coagulation disorders (excess bleeding or clotting) are often present. People with SLE are likely to be resistant to the blood-thinning effects of aspirin. Hydroxychloroquine may decrease risk of clots.[22]

Infection

Patients have increased susceptibility to infection. This may be due to impaired ability to destroy invading bacteria, deficient antibody production, and immunosuppressive effects of many antiinflammatory drugs. Pneumonia is the most common infection. Vaccinations are safe for patients with SLE. Patients receiving corticosteroids or cytotoxic drugs must avoid live virus vaccines.

TABLE 69.16 Diagnostic Criteria

SLE

A person is classified as having SLE if 4 or more of the criteria are present, serially or simultaneously, during any interval of observation:

- Antinuclear antibody (ANA): abnormal titer
- Discoid rash: raised patches with scaling follicular plugging; scarring in older lesions
- Hematologic disorder: hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia
- Immunologic disorder: anti-DNA antibody or antibody to Sm (Smith) nuclear antigen or positive antiphospholipid antibodies
- Malar rash: fixed redness, flat or raised (butterfly rash)
- Oral ulcers: usually painless
- Neurologic disorder: seizures or psychosis (in the absence of causative drugs or known metabolic disorders)
- Nonerosive arthritis: 2 or more peripheral joints with tenderness, swelling, effusion
- Pleuritis or pericarditis
- Photosensitivity
- Renal disorder: persistent proteinuria, cellular casts in urine

American College of Rheumatology: 1997 Update of the 1982 American College of Rheumatology revised criteria for classification of SLE. Retrieved from https://www.rheumatology.org/Portals/0/Files/1997%20Update%20of%201982%20Revised.pdf.

Diagnostic Studies

Diagnosis of SLE is based on distinct criteria (Table 69.16). No specific test is diagnostic for SLE, but a variety of abnormalities may be present in the blood. 97% of persons with SLE have ANA present.[23]

Testing for anti-DNA antibodies, anti-Smith (Sm) antibodies, and antiphospholipid antibodies is expected to identify immunologic disorders typical of SLE. Increased ESR and CRP indicate inflammation but are not diagnostic of SLE. They may be used to monitor disease activity and treatment effectiveness.

Interprofessional Care

A major challenge in the treatment of SLE is managing active disease while preventing complications of treatment. Age, sex, social health determinants, having other problems, and severity influence survival. Prognosis can be improved with early diagnosis, ongoing assessment and prompt recognition of organ involvement, and effective treatment plans.

Drug Therapy

NSAIDs continue to be an important intervention, especially for patients with mild joint pain. The patient may need to try several different NSAIDs to find the most effective one. Monitor the patient on long-term NSAID therapy for GI and renal effects.

Antimalarial agents, such as hydroxychloroquine and chloroquine, are often used to treat fatigue and skin and joint problems. They repress the immune system but do not cause immunosuppression. These drugs may reduce flares. Patients taking hydroxychloroquine should have eye examinations every

TABLE 69.17 Interprofessional Care

SLE

Diagnostic Assessment
- History and physical assessment
- Antibodies (ANA, anti-DNA, anti-Sm, antiphospholipid)
- CBC
- Serum complement
- Urinalysis
- X-ray of affected joints
- Chest x-ray
- ECG to assess cardiac involvement

Management

Drug Therapy
- NSAIDs or acetaminophen for mild disease
- Steroid-sparing drugs (e.g., methotrexate)
- Antimalarials (e.g., hydroxychloroquine)
- Corticosteroids for flares and severe disease
- Immunosuppressive drugs (e.g., cyclophosphamide, azathioprine)

6 to 12 months. Retinopathy can develop over time and with high doses of these drugs. It generally reverses when they are stopped. If the patient cannot tolerate an antimalarial agent, an antileprosy drug, such as dapsone, may be used.

Corticosteroids should be limited to the lowest dose for the shortest possible time. For example, steroids can be used for a few weeks until a slower acting drug becomes effective. Taper the dose of steroid slowly rather than stopping therapy abruptly. High doses of corticosteroids may be appropriate for the patient with severe cutaneous SLE.

Immunosuppressive drugs, such as azathioprine and cyclophosphamide, can suppress the immune system and reduce end-organ damage. Monitor closely to decrease the risk for toxicity and side effects. Because blood clots can be a life-threatening complication of SLE, anticoagulants, such as warfarin or low-dose heparin, may be prescribed.

Topical immunomodulators can be used instead of corticosteroids to treat serious skin conditions. Tacrolimus (Protopic, Prograf) and pimecrolimus (Elidel) suppress immune activity in the skin, affecting the butterfly rash and discoid lesions.

Serial anti-DNA titers and serum complement help us monitor disease management (Table 69.17). ESR or CRP may be helpful.

❖ NURSING MANAGEMENT: SLE

◆ Assessment

Subjective and objective data you should obtain from the patient with SLE are outlined in Table 69.18. Assess the effect of pain and fatigue on ability to perform ADLs.

During a disease flare, the patient may quickly become very ill. Assess fever pattern, joint inflammation, limitation of motion, location and degree of discomfort, and fatigue. Monitor weight, fluid intake, and output. This is especially important if corticosteroids are prescribed because of related fluid retention and possible renal failure. Collect 24-hour urine samples for protein and creatinine clearance as ordered. Observe for signs of bleeding due to drug therapy (e.g., pallor, skin bruising, petechiae, tarry stools).

Carefully assess neurologic function. Observe for vision problems, headaches, personality changes, seizures, and memory loss. Psychosis may result from CNS disease or be an effect of corticosteroid therapy. Nerve irritation of the extremities *(peripheral neuropathy)* may cause numbness, tingling, and weakness of the hands and feet.

◆ Clinical Problems

Clinical problems for the patient with SLE may include:
- Musculoskeletal problems
- Impaired role performance
- Impaired tissue integrity

Additional information on clinical problems and interventions for the patient with SLE is presented in eNursing Care Plan 69.2 (available on the website for this chapter).

◆ Planning

Overall goals are that the patient with SLE will (1) have acceptable pain management, (2) show awareness of and avoid activities that worsen the disease, and (3) maintain optimal role function and positive self-image.

◆ Implementation

The unpredictable nature of SLE presents many challenges for the patient and caregiver. Physical, psychologic, and sociocultural problems linked to long-term management require varied approaches and skills from health care team members. Tell the patient and caregiver that SLE has a good prognosis for most people.

Patient involvement is important for successful self-management. Help the patient understand that adherence to the treatment plan is no guarantee against flares in this unpredictable disease. Several factors may increase disease activity. These include fatigue, sun exposure, emotional stress, infection, drugs, and surgery. Help the patient and caregiver eliminate or reduce exposure to such factors (Table 69.19).

Explain the nature of SLE, treatments, and all diagnostic procedures. Teach patients about their drug therapy. Include indications for use, proper administration, and side effects. Help patients understand that abruptly stopping a drug may worsen disease activity.

◆ Role Performance

The patient with SLE may face many psychosocial issues. Supportive therapies may be as important as medical treatment in helping the patient cope with the disease. Provide emotional support for the patient and caregiver, especially during a disease flare.

Stress the importance of planning recreational and work activities. The young adult may find sun restrictions and physical limitations hard to follow. Help the patient develop and achieve reasonable goals for improving or maintaining mobility, energy, and self-esteem. Those making decisions about marriage and careers worry how SLE will interfere with their plans. Discuss how to approach employers, teachers, and coworkers about the impact of SLE.

TABLE 69.18 NURSING ASSESSMENT

SLE

Subjective Data

Important Health Information

Health history: Exposure to ultraviolet light, drugs, chemicals, viral infections. Physical or psychologic stress. States of ↑ estrogen activity, including early onset of menses, pregnancy, and postpartum period. Pattern of remissions and flares

Medications: Oral contraceptives, procainamide, hydralazine, isoniazid, antiseizure drugs, antibiotics, corticosteroids, NSAIDs

Functional Health Patterns

Health perception–health management: Family history of autoimmune disorders, frequent infections, malaise, impact of disease on functional ability

Nutritional-metabolic: Weight loss, oral and nasal ulcers, nausea and vomiting, dry mouth *(xerostomia),* dysphagia, photosensitivity with rash, frequent infections

Elimination: ↑ Urine output, diarrhea or constipation

Activity-exercise: Morning stiffness, joint swelling and deformity, shortness of breath *(dyspnea),* excessive fatigue

Sleep-rest: Insomnia

Cognitive-perceptual: Vision problems, vertigo, headache, arthralgia, chest pain (pericardial, pleuritic), abdominal pain. Painful, throbbing, cold fingers with numbness and tingling

Sexuality-reproductive: Amenorrhea, irregular menstrual periods

Coping–stress tolerance: Depression, withdrawal

Objective Data

Cardiovascular

Vasculitis, pericardial friction rub, hypertension, edema, dysrhythmias, murmurs. Bilateral, symmetric pallor and cyanosis of fingers (Raynaud phenomenon)

General

Fever, lymphadenopathy, periorbital edema

GI

Oral and pharyngeal ulcers; splenomegaly

Musculoskeletal

Myopathy, myositis, arthritis

Neurologic

Facial weakness, peripheral neuropathies, papilledema, dysarthria, confusion, hallucination, disorientation, psychosis, seizures, aphasia, hemiparesis

Respiratory

Pleural friction rub, ↓ breath sounds

Skin

Alopecia. Dry, scaly scalp. Keratoconjunctivitis, butterfly (malar) rash, palmar or discoid redness, hives, redness at fingernails or toenails, purpura, or petechiae. Leg ulcers

Possible Diagnostic Findings

Presence of anti-DNA, anti-Sm, or antinuclear antibodies. Anemia, leukopenia, thrombocytopenia. ↑ ESR, ↑ serum creatinine. Microscopic hematuria, proteinuria, cellular casts in urine. Pericarditis or pleural effusion on chest x-ray

TABLE 69.19 PATIENT & CAREGIVER TEACHING

SLE

Include the following information in the teaching plan for a patient with SLE and the caregiver:

- Disease process
- Names of drugs, actions, side effects, dosage, administration
- Pain management strategies
- Energy conservation and pacing techniques
- Therapeutic exercise, heat therapy for arthralgia
- Relaxation therapy
- Avoid physical and emotional stress
- Avoid exposure to people with infection
- Avoid drying soaps, powders, household chemicals
- Use sunscreen protection (at least SPF 15) and protective clothing, with minimal sun exposure from 11:00 AM to 3:00 PM
- Need for regular medical and laboratory follow-up
- Marital and pregnancy counseling as needed
- Community resources and health care agencies

◆ SLE and Pregnancy

Because SLE is most common in women of childbearing age, we must consider treatment during pregnancy. Many couples need pregnancy and sexual counseling. They may worry about hereditary aspects and want to know if their children will have SLE.

The HCP and obstetrician should discuss with the woman her desire to become pregnant. For the best outcome, pregnancy should be planned when disease activity is minimal. Some drugs should be stopped (e.g., methotrexate) or switched up to 3 months before the patient tries to become pregnant. Hydroxychloroquine can be safely continued in pregnancy. Infertility may have resulted from renal involvement and use of high-dose corticosteroids and immunosuppressive drugs. The patient should understand spontaneous abortion, stillbirth, and intrauterine growth restriction are common problems. They occur because immune complexes are deposited in the placenta and inflammation occurs in placental blood vessels.

Renal, lung, CNS, and cardiovascular systems may be affected during pregnancy. Women who already show serious effects in these systems should be counseled against pregnancy. Flares are common during the postpartum period. Therapeutic abortion offers the same risk for postdelivery exacerbation as carrying the fetus to term.

◆ Evaluation

The expected outcomes are that the patient with SLE will:

- Use energy-conservation techniques
- Adapt lifestyle to current energy

- Maintain skin integrity with use of topical treatments
- Prevent disease flare with use of sunscreens and limited sun exposure

SCLERODERMA

Scleroderma is a disorder of connective tissue characterized by fibrotic, degenerative, and, sometimes, inflammatory changes in the skin, blood vessels, synovium, skeletal muscle, and internal organs. *Localized scleroderma* mainly affects the skin. It is more common in children. Skin changes of localized disease are usually limited to a few places on the skin or muscle. The prognosis of patients with limited disease is better than for those with systemic disease. *Systemic scleroderma* (or *systemic sclerosis*) is more common in adults.[24] Skin and connective tissue changes progress rapidly during the first months of systemic scleroderma. It is associated with internal organ involvement.

Scleroderma is more common in Blacks, Native Americans, and persons of Japanese descent. The usual age at onset is between 30 and 50 years. Only about 300,000 Americans have the disease.[24] It is more common in women.

Etiology and Pathophysiology

We do not know the cause of scleroderma. We think immunologic and vascular abnormalities play a role in the development of systemic disease. Risk factors include environmental or occupational exposure to coal, plastics, and silica dust.

In scleroderma, the body makes too much collagen (protein that gives normal skin its strength and elasticity) (Fig. 69.11). This leads to progressive tissue fibrosis and occlusion of blood vessels. Collagen overproduction disrupts normal function of internal organs, such as the lungs, kidney, heart, and GI tract. Vascular problems, which involve the small arteries and arterioles, are almost always present. These changes are some of the earliest changes in scleroderma.

Clinical Manifestations

Manifestations range from benign limited skin disease to diffuse skin thickening with rapidly progressive and widespread organ involvement. *Diffuse scleroderma* involves widespread thickening of the skin. This especially occurs in the hands, arms, thighs, chest, abdomen, and face. Blood vessels, heart and lungs, joints and muscles, esophagus, and intestines may be damaged. *Limited scleroderma* affects the face, fingers, hands, and lower arms and legs.

Some patients with limited scleroderma have *CREST syndrome*:

Calcinosis: painful deposits of calcium in skin of fingers, forearms, pressure points

Raynaud phenomenon: intermittent vasospasm of fingertips in response to cold or stress

Esophageal dysfunction: difficulty swallowing due to internal scarring

Sclerodactyly: tightening of skin on fingers and toes

Telangiectasia: red spots on skin from capillary dilation

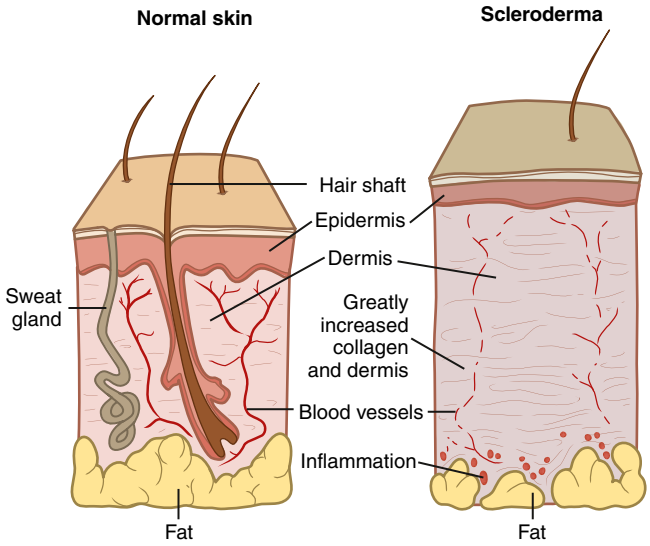

Fig. 69.11 Skin changes in scleroderma.

Raynaud Phenomenon

Raynaud phenomenon (sudden vasospasm of the digits) is the most common first sign in limited scleroderma. Patients have decreased blood flow to the fingers and toes when exposed to cold *(blanching or white phase).* This is followed by cyanosis as hemoglobin releases O_2 to the tissues *(blue phase),* then redness during rewarming *(red phase).* Numbness and tingling often occur. Raynaud phenomenon may precede the onset of systemic disease by months, years, or even decades. Raynaud phenomenon is described in Chapter 41.

Skin and Joint Changes

Symmetric painless swelling or thickening of the skin of the fingers and hands may progress to diffuse scleroderma of the trunk. In limited scleroderma, skin thickening often does not extend above the elbow or knee. The face may be affected. In diffuse disease, the skin loses elasticity and becomes taut and shiny. This causes the typical expressionless face with tightly pursed lips. Skin changes in the face may contribute to reduced ROM in the temporomandibular joint. The fingers may stay in a semiflexed position *(sclerodactyly),* with tightened skin to the wrist (Fig. 69.12). Reduced peripheral joint function may be an early symptom of arthritis.

Internal Organ Involvement

About 20% of people with systemic scleroderma and a few with localized disease develop secondary Sjögren syndrome, a condition associated with dry eyes and dry mouth.[24] Dysphagia, gum disease, and dental decay can result. Frequent reflux of gastric acid can occur due to esophageal fibrosis. If swallowing becomes difficult, the patient is likely to decrease food intake and lose weight. GI effects include constipation from colonic hypomotility and diarrhea due to malabsorption from bacterial overgrowth.

Lung problems include pleural thickening, pulmonary fibrosis, and abnormal pulmonary function. The patient develops a cough and dyspnea. Pulmonary arterial hypertension and

Fig. 69.12 Sclerodactyly in the hands of a patient with scleroderma. (From Bolognia JL, Schaffer JV, Duncan KO, Ko CJ: *Dermatology essentials*, ed 2, Philadelphia, 2021, Elsevier.)

interstitial lung disease may occur. Lung disease is the main cause of death.

Heart disease includes pericarditis, pericardial effusion, and dysrhythmias. Heart failure from myocardial fibrosis occurs most often in patients with systemic disease.

Because malignant hypertension with rapidly progressive, irreversible renal insufficiency can occur, early recognition of renal involvement and initiation of therapy are critical. Dialysis, bilateral nephrectomy in patients with uncontrollable hypertension, and kidney transplant have offered hope to patients with renal failure. Angiotensin-converting enzyme (ACE) inhibitors (e.g., lisinopril) have a marked effect on renal disease.

Diagnostic Studies

Diagnosis is based on the manifestations. No laboratory testing is diagnostic. However, testing is done to rule out other diseases, assess organ involvement, and monitor disease progress. Common tests include CBC, serum muscle enzymes, and ESR. CBC may show mild hemolytic anemia from RBC damage in diseased small vessels. If renal involvement is present, urinalysis may show proteinuria, microscopic hematuria, and casts. Serum creatinine may be increased. Numerous antibodies are related to this condition. Anticentromere antibodies occur in patients with CREST syndrome. Antibodies to topoisomerase-1 are present in about 30% of people with diffuse disease. X-rays may show subcutaneous calcification, distal esophageal hypomotility, or bibasilar pulmonary fibrosis. Pulmonary function studies show decreased vital capacity and lung compliance. Thermography can detect temperature differences between affected and normal tissue. Soft tissue can be assessed with ultrasound and MRI.

Interprofessional Care

There is no specific treatment (Table 69.20). Supportive care is directed toward preventing or treating complications of involved organs. PT helps to maintain joint mobility and preserve muscle strength. Occupational therapy assists the patient in maintaining functional abilities.

TABLE 69.20 Interprofessional Care

Scleroderma

Diagnostic Assessment
- History and physical assessment
- Antibodies to topoisomerase-1
- Anticentromere antibody
- Nail bed capillary microscopy
- Chest x-ray
- Skin or organ biopsy
- Urinalysis (proteinuria, hematuria, casts)
- Pulmonary function tests
- ECG

Management
- Physical therapy
- Occupational therapy

Drug Therapy
- Vasoactive agents: reserpine, bosentan, epoprostenol
- Calcium channel blockers: diltiazem, nifedipine
- ACE inhibitors: lisinopril (Prinivil)
- PDE5 inhibitors: sildenafil, tadalafil
- Immunosuppressive drugs: cyclophosphamide, mycophenolate mofetil

Drug Therapy

Vasoactive agents are often prescribed in early disease.[25] Calcium channel blockers (e.g., nifedipine, diltiazem) and the angiotensin II blocker losartan are common treatments for Raynaud phenomenon. Reserpine, an α-adrenergic blocking agent, increases blood flow to the fingers. Bosentan (Tracleer), an endothelin-receptor antagonist, and the vasodilator epoprostenol (Flolan) may improve blood flow to the lung.

NSAIDs and topical agents may give some relief from joint pain. Capsaicin cream may be useful, not only as a local analgesic but also as a vasodilator. Other therapies prescribed to treat specific systemic problems include (1) tetracycline for diarrhea caused by bacterial overgrowth, (2) histamine (H_2) receptor blockers or proton pump inhibitors (e.g., omeprazole) for reflux, and (3) antihypertensive agent (e.g., captopril, propranolol) for hypertension with renal involvement. Immunosuppressive drugs (e.g., cyclophosphamide) are used in severe cases.

❖ NURSING MANAGEMENT: SCLERODERMA

Nursing interventions often begin during hospitalization for diagnosis. Assess vital signs, weight, intake and output, respiratory and bowel function, and joint ROM regularly to plan care. Stress and cold ambient temperatures may aggravate Raynaud phenomenon. Avoid finger-stick blood testing because of compromised circulation and poor healing.

Teaching is important. Obvious changes in the face and hands often lead to poor self-image and loss of mobility and function. Teach the patient to regularly take part in therapeutic exercises at home to prevent skin retraction and promote vascularization. Mouth excursion (yawning with an open mouth) is a good exercise to help with temporomandibular joint function. Isometric exercises are best if the patient has arthropathy because no joint movement occurs. Encourage the use of moist

heat applications or paraffin baths to promote skin flexibility in the hands and feet. Teach the patient to use assistive devices as needed and organize activities to preserve strength and reduce disability.

Teach the patient to protect the hands and feet from cold exposure. Protect against burns or cuts that may heal slowly. Encourage the patient to avoid smoking because of its vasoconstricting effect. Report signs of infection promptly. Use alcohol-free lotions to improve skin dryness and cracking. They must be rubbed in for a long time to be absorbed through the thick skin.

Remind the patient to reduce dysphagia by eating small, frequent meals, chewing carefully and slowly, and drinking fluids. A consultation with a dietitian is helpful. Drugs for GERD and sitting upright for at least 2 hours after eating decrease the risk for heartburn. Using extra pillows or raising the head of the bed on blocks may reduce gastroesophageal reflux during the night.

Job alterations are often needed due to problems with climbing stairs, using a computer, writing, and being exposed to cold. The patient may be socially withdrawn as skin tightening changes the appearance of the face and hands. Dining out may become socially embarrassing because of the patient's small mouth, swallowing difficulty, and reflux. Some persons with scleroderma wear gloves to protect fingertip ulcers and provide extra warmth. Emphasize daily oral hygiene to avoid increased tooth and gum problems. The patient needs a dentist who is familiar with scleroderma and able to adapt care to a small mouth.

Psychologic support, biofeedback training, and relaxation can reduce stress and improve sleeping habits. Sexual problems from body changes, pain, muscular weakness, limited mobility, decreased self-esteem, erectile dysfunction, and decreased vaginal secretions may require sensitive counseling.

CHECK YOUR PRACTICE

A 34-year-old woman hospitalized for aspiration pneumonia has a 5-year history of scleroderma.

- How could scleroderma have contributed to the aspiration pneumonia?
- What strategies will you suggest to decrease the risk for pneumonia recurrence?
- What other self-care strategies will you reinforce with this patient?

AUTOIMMUNE MYOSITIS

Autoimmune myositis is a group of systemic disorders. **Polymyositis (PM)** is diffuse, idiopathic, inflammatory myopathy of striated muscle. It causes bilateral weakness, usually most severe in the proximal or limb girdle muscles. When muscle changes from PM are accompanied by distinctive skin changes, the disorder is called **dermatomyositis (DM)**.[26] These rare disorders can be similar in signs, symptoms, and treatment, but they are 2 distinct diseases. Patients with PM tend to have more severe disease than those with DM.

They typically affect children ages 5 to 15 years and adults ages 40 to 60 years. PM and DM occur twice as often in women.

Fig. 69.13 Dermatomyositis skin changes indicating Gottron papules. (From Firestein GS, Budd RC, Gabriel SE, McInnes IB: *Kelley's textbook of rheumatology*, ed 9, Philadelphia, 2012, Saunders.)

Etiology and Pathophysiology

We do not know the cause of PM and DM. We think there is an autoimmune origin with T cell–mediated destruction of unidentified muscle antigens. Environment factors are likely. These include viral and bacterial infection, certain drugs, supplements, vaccines, medical implants, and occupational exposure.

Clinical Manifestations and Complications

Muscular

The patient with PM and DM has weight loss and increasing fatigue, with gradually developing muscle weakness that causes difficulty in performing ADLs. Muscles affected most often are in the shoulders, legs, arms, and pelvis. The patient may have difficulty rising from a chair or bathtub, climbing stairs, combing hair, or reaching into a high cupboard. Repetitive movements are more likely to cause trouble than a single strength exercise. The patient may be unable to raise the head from a pillow as neck muscles weaken. Assessment shows an inability to move against resistance or even gravity. Weak pharyngeal muscles may cause dysphagia and dysphonia (nasal or hoarse voice).[26]

Skin

Rashes are typical with DM. They usually prompt earlier recognition of DM than PM, which has no rashes. Skin changes of DM include a classic red or purple symmetric rash *(heliotrope)* with edema around the eyelids. The typical skin rash is not often found with other disorders. A scaly, smooth, or raised rash may be seen on the knuckles and sides of the hands *(Gottron papules)* (Fig. 69.13).[26] Red, smooth, or scaly patches appear with the same symmetric distribution but sparing the interphalangeal spaces *(Gottron sign)*. The rash can be confused with psoriasis or seborrheic dermatitis. A red, scaling rash *(poikiloderma)* may develop as a late finding on the back, buttocks, and a V-shaped area of the anterior neck and chest.

Hyperemia and telangiectasia are often present at the nail beds. Calcium nodules *(calcinosis cutis)* can develop throughout the skin. They are common in long-standing DM.

Other Manifestations

Joint redness, pain, and inflammation often occur. They contribute to limited joint ROM in PM and DM. Contractures and muscle atrophy may occur with advanced disease. Weakened pharyngeal muscles can lead to poor cough effort, difficulty swallowing, and increased risk for aspiration pneumonia. Interstitial lung disease is a common complication. All patients should have routine chest x-rays and pulmonary function tests. Patients have an increased risk for cancer and should have appropriate screenings. PM and DM may be associated with other connective tissue disorders (e.g., scleroderma).

Diagnostic Studies

Biopsy is the standard for diagnosis. Muscle biopsy shows necrosis, degeneration, regeneration, and fibrosis with pathologic findings distinct for DM or PM. The biopsy should be taken from a muscle with edema found on MRI or weakness. It can also be taken from a contralateral pair of muscles found to be abnormal on EMG.[26] An EMG suggestive of PM shows bizarre high-frequency discharges and spontaneous fibrillation, with positive spikes at rest. Biopsy is not usually needed when skin findings are characteristic of DM. Laboratory tests are helpful, but not diagnostic of either disease. Increased muscle enzymes (e.g., creatine kinase [CK] myoglobin) reflect muscle damage but will decrease to normal or near normal with treatment. Increased ESR or CRP occurs with active disease.

◆ Interprofessional and Nursing Care

PM and DM are treated initially with high-dose oral corticosteroids. We taper the dose based on patient response. Most patients respond well to treatment. Long-term corticosteroid therapy may be needed because relapses are common when the drug is withdrawn. Serial CK values guide treatment effectiveness. When CK values return to normal, we gradually reduce corticosteroid doses. If CK increases, the dose is also increased.

Because the goal is to minimize corticosteroid exposure, a second drug is started at the same time or soon after starting treatment. Immunosuppressive drugs (methotrexate, azathioprine, tacrolimus) may be used in combination with steroids or as a second-line therapy if the patient does not respond to steroids. IV immunoglobulin (IVIG) may be given with corticosteroids or immunosuppressants, but it is not a first-line treatment.

DRUG ALERT

IV Immunoglobulin

- Give slowly to decrease risk for thromboembolic complications.
- Hydrate patient well to decrease risk for thrombosis and renal failure.
- Treat transient adverse effects, such as headache.

Synthetic ACTH injections may help with muscle strength and skin rash. PT can be helpful and is tailored to disease activity. Use massage and passive movement during active disease. Delay more aggressive exercises until disease activity is minimal based on low serum muscle enzymes.

Teach the patient about the disease, therapies, diagnostic tests, and the need for regular medical care. Help the patient understand that the benefits of therapy are often delayed. Patients treated long term with high-dose corticosteroids may become increasingly weak after the initial positive response. This is due to superimposed corticosteroid myopathy.[26] Encourage the use of assistive devices to decrease risk for falls. To prevent aspiration, encourage the patient to rest before meals, maintain an upright position when eating, and choose easily swallowed foods.

Help the patient to organize activities and use pacing techniques to conserve energy. Encourage daily ROM exercises to prevent contractures. When inflammation is decreased, start muscle-strengthening (repetitive) exercises. Home care and bed rest may be needed during acute PM, when the patient may not be able to complete ADLs because of profound muscle weakness.

MIXED CONNECTIVE TISSUE DISEASE

Patients having a combination of clinical features of several rheumatic diseases are described as having *mixed connective tissue disease.* The term describes a disorder with features primarily of SLE, scleroderma, and PM. However, there are no definitive diagnostic features of any one disease. This disease occurs most often in women in their 20s and 30s. People with one connective tissue disease may develop another related disease over the course of several years (known as *overlap syndrome*).

SJÖGREN SYNDROME

Sjögren syndrome is an autoimmune disease that targets the moisture-producing exocrine glands. This leads to *xerostomia* (dry mouth) and *keratoconjunctivitis sicca* (dry eyes).[27] The nose, throat, airways, and skin can become dry. It may affect other glands, including those in the stomach, pancreas, and intestines (extraglandular involvement). This increases the risk for non-Hodgkin lymphoma. The disease is usually diagnosed in people in their 40s and 50s. Most people with Sjögren syndrome are women.

People with primary Sjögren syndrome do not have another rheumatic disease. The secondary form of Sjögren syndrome occurs in combination with another rheumatic disease (e.g., RA, SLE, scleroderma).[27] Autoimmune thyroid disorders, including Graves disease and Hashimoto thyroiditis, are common with Sjögren syndrome.

Sjögren syndrome appears to be caused by genetic and environmental factors. A particular gene predisposes Whites to the disease. Other genes are linked to the disease in people of Japanese, Chinese, and African American ethnicity. The trigger may be a viral or bacterial infection that adversely stimulates the immune system.

In Sjögren syndrome, lymphocytes attack and damage the lacrimal and salivary glands. Decreased tearing causes dry eyes, which leads to a gritty sensation in the eyes, burning, blurred vision, and photosensitivity. Dry mouth causes buccal membrane fissures, changes in taste, dysphagia, and increased mouth infection or dental decay. Dry skin and rashes, joint and muscle pain, and thyroid problems may be present. Other exocrine

glands can be affected. For example, vaginal dryness may lead to painful intercourse *(dyspareunia)*. Symptoms may become more generalized and involve the lymph nodes, bone marrow, and visceral organs (pseudolymphoma).

Eye examination (Schirmer test for tear production), measures of salivary gland function, and lower lip biopsy of minor salivary glands aid in diagnosis. Treatment is symptomatic. Instilling preservative-free artificial tears or antiinflammatory eye drops (e.g., cyclosporine [Restasis]) provides adequate hydration and lubrication. Some patients have surgical punctal occlusion.

Encourage increased fluids with meals. Dental hygiene is important. Pilocarpine (Salagen) and cevimeline (Evoxac) can ease the dry mouth and decrease risk of dental caries. Increased humidity at home may reduce respiratory infections. Vaginal lubrication with a water-soluble product, such as K-Y Jelly, may increase comfort during intercourse.

! SAFETY ALERT

Sjögren Syndrome

To help with chewing and swallowing:

- Moisten food with mayonnaise, sauces, gravy, or yogurt.
- Thin foods with skim milk or broth.
- Use a food processor or blender to finely chop or liquefy foods.
- Try soft, creamy foods (e.g., mashed potatoes, macaroni and cheese).
- Drink high-calorie cold liquids (e.g., breakfast drinks).
- Avoid salty, acidic, or spicy foods.

MYOFASCIAL PAIN SYNDROME

Myofascial pain syndrome is a chronic form of muscle pain and tenderness, typically confined to one area in the chest, neck, shoulders, hips, or lower back. Potential but infrequent symptoms include muscle stiffness, fatigue, poor sleep, headaches, and postural abnormalities (e.g., hunching, shoulder rounding, forward head posture). Regions of pain are often within the connective tissue *(fascia)* that covers skeletal muscles. Trigger or tender points are thought to activate a characteristic pattern of pain that worsens with activity or stress.[28]

Myofascial pain syndrome occurs more often in middle-aged adults and in women. Patients report deep, aching pain with a sensation of burning, stinging, and stiffness. It should not be confused with FMS, which is marked by pain and tenderness throughout the body.

Diagnosis is largely by eliminating other conditions that may cause the pain through imaging and tests. The HCP applies gentle pressure to identify tight muscle bands that trigger pain or muscle twitches. We may see posture abnormalities.

Most treatments focus on trigger points. Options include cold laser (low-level light therapy), wet or dry needling, electrical stimulation with electrode application, and transcutaneous electronic nerve stimulation (low-voltage electric signals sent to painful area). Drug therapy includes NSAIDs, lidocaine patch, muscle relaxants, steroids, and the antidepressant duloxetine (Cymbalta).[28] PT, behavior modification, heat, ultrasound, massage, stretching, and acupuncture are helpful.

TABLE 69.21 Common Features of FMS and SEID

Occurrence	Previously healthy, young and middle-aged women
Etiology (Theories)	Infectious trigger, dysfunction in HPA axis, CNS problem
Clinical Manifestations	Generalized musculoskeletal pain, malaise and fatigue, cognitive problems, headaches, sleep problems, depression, anxiety, fever
Disease Course	Variable intensity of symptoms, fluctuates over time
Diagnosis	No definitive laboratory tests or joint and muscle assessments Mainly a diagnosis of exclusion
Management	Symptomatic treatment may include antidepressant drugs, such as amitriptyline and fluoxetine (Prozac). Nondrug measures include heat, massage, regular stretching, biofeedback, stress management, and relaxation training

CNS, Central nervous system; *HPA,* hypothalamic-pituitary-adrenal.

FIBROMYALGIA

Fibromyalgia (FMS) is a chronic central pain syndrome marked by widespread, nonarticular musculoskeletal pain and fatigue with multiple tender points. It is a common musculoskeletal disorder and a major cause of disability. FMS affects about 4 million Americans. Women are twice as likely to get FMS.[29] It is the most common cause of musculoskeletal pain in women ages 20 to 55. Symptoms usually appear between ages 30 and 55 years.[30] FMS and systemic exertion intolerance disease (SEID) share many features (Table 69.21).

Etiology and Pathophysiology

FMS involves abnormal central processing of nociceptive pain input in the CNS. PET scans of the brains of people with FMS have shown widespread neuroinflammation. Spinal fluid can contain proteins linked to neuroinflammation. Pain inhibitory pathways do not work effectively. Genetic factors contribute to the development of FMS as a familial tendency exists. People with other autoimmune diseases such as SLE or RA are at risk. Infection or trauma may be a trigger in susceptible people.

Clinical Manifestations and Complications

The patient reports widespread burning pain that fluctuates through the course of a day. The patient often cannot determine if pain occurs in the muscles, joints, or soft tissues. Head or facial pain often results from stiff or painful neck and shoulder muscles. The pain can accompany temporomandibular joint dysfunction, which affects about one-third of patients with FMS.

Assessment usually shows point tenderness at 11 or more of 18 identified tender points (9 pairs) (Fig. 69.14). Patients are sensitive to painful stimuli throughout the body, not just at the identified tender sites. They may have pain in response to

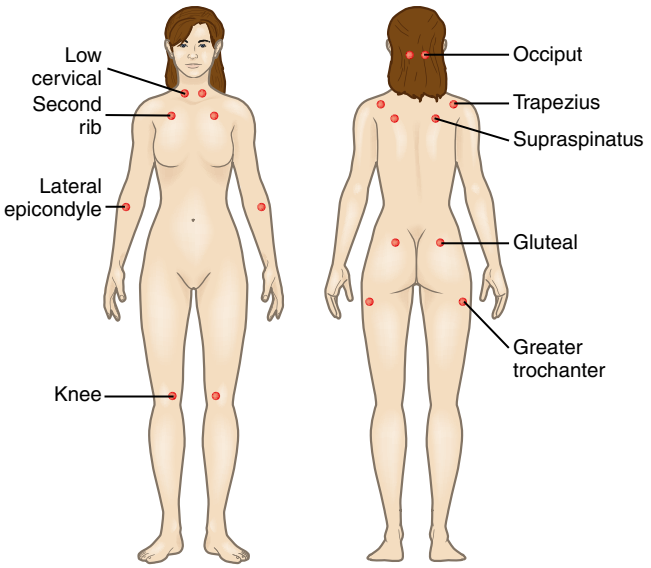

Fig. 69.14 Tender points in fibromyalgia.

a stimulus that does not typically cause pain *(allodynia)*. Point tenderness can vary from day to day. Sometimes, the patient may respond to fewer than 11 tender points. At other times, palpation of all sites may cause pain. Some are very sensitive to pain that would not bother most people.

Cognitive effects range from difficulty concentrating to memory lapses ("fibro fog") and a feeling of being overwhelmed when dealing with multiple tasks. They may be less able to manage stress. Many patients have migraine headaches. Depression and anxiety often occur. Stiffness, nonrefreshing sleep, fatigue, and numbness or tingling in the hands or feet often accompany FMS. Restless legs syndrome is typical. Some describe an irresistible urge to move the legs when at rest or lying down.

Irritable bowel syndrome with constipation and/or diarrhea, abdominal pain, and bloating is common. Patients may have difficulty swallowing, perhaps because of problems in esophageal smooth muscle function. Increased frequency of urination and urinary urgency, in the absence of a bladder infection, may occur. Women may have more difficult menstruation, with disease symptoms worse during this time.

Diagnostic Studies

A definitive diagnosis of FMS is based on 2 elements. First, the Widespread Pain Index (WPI) assesses if (1) pain is experienced in 11 of the 18 tender points on palpation over the past week (Fig. 69.14) and (2) a history of widespread pain is noted for at least 3 months. Widespread pain is defined as pain that occurs on both sides of the body and above and below the waist. Score on the Symptom Severity Index (SSI) is also calculated. To be diagnosed with FMS, the patient must have a WPI score of 7 or more and SSI score of 5 or more, or a WPI score between 3 and 6 and SSI score of 9 or more.[31] Fatigue, cognitive symptoms, and extensive somatic symptoms are considered in establishing a diagnosis.

◆ Interprofessional and Nursing Care

Treatment is symptomatic. Because of the chronic nature of FMS, the patient needs consistent support from the health care team. Encourage the patient to be an active participant in treatment.

Drug therapy for the chronic widespread pain includes pregabalin (Lyrica), duloxetine (Cymbalta), and milnacipran (Savella). Low-dose tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), or benzodiazepines (e.g., diazepam) may be prescribed. SSRI antidepressants (e.g., sertraline, paroxetine) tend to be reserved for patients who also have depression.[32] SSRIs may have to be prescribed at higher doses than when used to treat depression.

Rest can help the pain, aching, and tenderness. In some patients, pain can be managed with OTC analgesics, such as acetaminophen, ibuprofen, or naproxen (Aleve). Nonopioids, such as tramadol (Ultram), may be used. Long-acting opioids are not used unless other therapies are not successful. Short-term use of zolpidem (Ambien) or trazodone can help patients with severe sleep problems. Antidepressants and muscle relaxants have sedative effects that can improve sleep.

Regular, gentle exercise and stretching can help maintain muscle tone and decrease pain. Yoga and Tai Chi are often helpful. Low-impact aerobic exercise, such as walking, can help prevent muscle atrophy. Massage is often combined with ultrasound or use of alternating heat and cold packs to soothe tense, sore muscles and increase blood circulation.

Patients may consider limiting intake of sugar, caffeine, and alcohol because they may be muscle irritants. Vitamin and mineral supplements may help combat stress, correct deficiencies, and support the immune system. Encourage the patient to follow a healthy diet (Box 69.4). Review ways to lose weight with the patient who is obese (see Chapter 45).

Pain and the related symptoms of FMS can cause significant stress. Patients may not cope well with stress. Mental health support is critical. Psychologic counseling (individual, group) and a support group may be helpful. Relaxation strategies include biofeedback, imagery, meditation, and cognitive-behavioral therapy. Patients need initial training for these interventions, but they can continue to practice in their own homes. Stress management is discussed in Chapter 7.

SYSTEMIC EXERTION INTOLERANCE DISEASE

Systemic exertion intolerance disease (SEID), also called *chronic fatigue syndrome* or *myalgic encephalomyelitis,* is a serious, complex, multisystem disease in which exertion of any sort (physical, emotional, cognitive) is impaired and accompanied by profound fatigue. People with SEID are not able to do their usual activities and may even be confined to bed.[33] SEID is a poorly understood condition that can have a devastating impact on the lives of patients and their families.

SEID affects between 800,000 and 2.5 million people in the United States. The condition is 3 times more common in women. The illness is more common in minorities and socioeconomically disadvantaged groups. The true prevalence of SEID is unknown because many people with the disease have not been diagnosed.

BOX 69.4 EVIDENCE-BASED PRACTICE

Nutrition and FMS

You are discharging C.K., a 42-year-old woman who was treated successfully for COVID-19. You note that C.K. was diagnosed with FMS 10 years ago. She has a body mass index of 32 and a history of hypertension. As you discuss C.K.'s home activity orders, she tells you, "I felt terrible even before the COVID. My pain is sometimes so bad that I don't want to get out of bed. It's depressing that I can't lose weight."

Making Clinical Decisions

Synthesis of Best Available Evidence

FMS is a chronic musculoskeletal pain condition characterized by a wide range of symptoms. Osteoporosis has been linked to FMS. Although we do not know exactly how the 2 diseases are linked, research suggests FMS is mediated by common factors. For example, obesity is related to greater pain and disease severity among persons with FMS. Obesity is a risk factor for osteoporosis.

Clinician Expertise

You ask C.K. to describe her usual eating in a 24-hour period. She tells you, "I used to enjoy cooking, but now I can't stand for long periods. My husband hates cooking, so his idea of preparing dinner is bringing home pizza or hamburgers and fries. If I eat breakfast, it is a bowl of cereal. Lunch is often a sandwich and chips." You ask the patient what kinds of food she likes to eat. C.K. says, "I grew up on a farm and used to love fresh vegetables. I also really like fish…but I'm sure I shouldn't be eating fish sticks or fried fish." You ask C.K. if she would be interested in getting information from a dietitian about the Mediterranean diet, a meal plan that includes daily consumption of vegetables, fruits, and grains with weekly intake of fish, poultry, beans, and eggs. You tell C.K. that the Mediterranean diet contributes to improved bone health.

Patient Preferences and Values

C. K. tells you, "Having COVID really scared me. I know I need to eat better and get more active to lose weight. I just need to start with some easy recipes for the right foods." She asks you to schedule her outpatient appointment with the dietitian.

Implications for Nursing Practice

1. In conjunction with the Mediterranean diet, what types of activity should C.K. pursue to lose weight and improve bone health?
2. What might be the benefits of linking C.K. to an FMS support group as she begins the Mediterranean diet?

Reference for Evidence

Correa-Rodriguez M, El Mansouri-Yachou J, Tapia-Haro RM, et al.: Mediterranean diet, body composition, and activity associated with bone health in women with fibromyalgia syndrome, *Nurs Res* 68:358, 2019.

Etiology and Pathophysiology

We do not know the cause or pathology of SEID. Many theories exist about the cause of SEID. Several microorganisms have been researched as causative agents, including herpes viruses (e.g., Epstein-Barr virus [EBV], cytomegalovirus [CMV]), retroviruses, enteroviruses, *Candida albicans,* and mycoplasma. Mental or physical stress may be the cause of SEID. For example, the condition may be triggered by how a patient's immune system responds to stress or illness.

Clinical Manifestations

Severe fatigue is the most common symptom and the problem that causes the patient to seek health care. SEID is often hard to discern from FMS because many clinical features are similar (Table 69.21). In about half the cases, SEID develops slowly, or the patient may have periodic episodes that gradually become chronic. SEID can arise suddenly in a previously active, healthy person. Associated symptoms may vary in intensity over time.

TABLE 69.22 Diagnostic Criteria

SEID

Diagnosis of SEID requires that the patient have the following 3 symptoms:

1. Impaired ability to engage in pre-illness occupational, social, educational, or personal activities lasting at least 6 months and accompanied by profound fatigue
2. Malaise after exertion: total exhaustion after even minor physical or mental exertion that the patient sometimes describes as a "crash"
3. Unrefreshing sleep

At least 1 of the following manifestations is required:

1. Cognitive impairment ("brain fog," confusion)
2. Orthostatic intolerance (lightheadedness, dizziness, imbalance, fainting)

Diagnostic Studies

Physical assessment and diagnostic studies can be used to rule out other possible causes of the patient's symptoms. No laboratory test can diagnose SEID or measure its severity. SEID is a diagnosis of exclusion, based on symptoms (Table 69.22). The patient may become angry and frustrated with HCPs who cannot diagnose a problem.

Interprofessional and Nursing Care

No definitive treatment exists for SEID. Supportive management is essential. Tell the patient what we know about the disease.

NSAIDs can be used to treat headaches, muscle and joint aches, and fever (see Table 12.5). Because many patients with SEID have allergies and sinusitis, antihistamines and decongestants can be used to treat allergic symptoms. Tricyclic antidepressants (e.g., doxepin, amitriptyline) and SSRIs (e.g., fluoxetine, paroxetine) can improve mood and sleep. Clonazepam is an option for sleep problems and panic disorders. Low-dose hydrocortisone to decrease fatigue and disability is being studied.

Teach the patient to avoid total rest because it can create a self-image of the patient as an invalid. On the other hand, strenuous exertion can worsen the exhaustion. Urge the patient to plan a carefully graduated exercise program. Encourage a well-balanced diet, including fiber and fresh dark-colored fruits and vegetables for antioxidant action. Behavior therapy may be used to promote a positive outlook and improve overall disability and fatigue.

The disorder may have a major impact on work and family responsibilities. Some people may need help with ADLs. One major problem facing many patients is loss of livelihood and economic security. When the illness strikes, they cannot work or must decrease the amount of work. Loss of a job often leads to loss of medical insurance. Obtaining disability benefits can be frustrating because of the difficulty of establishing a definitive diagnosis of SEID. Patients with SEID may have severe psychosocial losses, including social pressure and isolation from being labelled as lazy or crazy.

SEID does not appear to progress. Although most patients recover or at least gradually improve, some do not show substantial improvement. Recovery is more common in persons with a sudden onset of SEID.

Case Study

Ankylosing Spondylitis

(© SensorSpot/ iStock.com)

Patient Profile

R.B., a 34-year-old man, comes to the rheumatology clinic with low back pain. He states he has had early morning stiffness that started in the lower back about 6 months ago. He says it is interfering with his work as he "can't move like he used to."

Subjective Data

- Taking acetaminophen, with minimal relief
- Father diagnosed with psoriatic arthritis 15 years ago
- Expresses concern about continued employment due to increasing pain

Objective Data

Physical Assessment

- Severely limited spinal flexion
- Moderate pain over sacroiliac joints
- Mild sternal tenderness

Diagnostic Studies

- Positive ESR, HLA-B27
- Left sacroiliac sclerosis on MRI

Interprofessional Care

- Diagnosed with ankylosing spondylitis
- Started on etanercept subcutaneously once per week, meloxicam once daily

Discussion Questions

1. ***Recognize:*** How will you explain the pathophysiology of AS to R.B.?
2. ***Analyze:*** R.B. asks you if genetic factors are related to AS. How will you respond?
3. ***Plan:*** What referrals may be needed for R.B.?
4. ***Prioritize:*** Based on the assessment data presented, what are the priority clinical problems?
5. ***Act:*** What are some home and work modifications you can suggest to R.B. to facilitate self-care?
6. ***Act:*** Why is an exercise program important in the treatment plan for R.B.?
7. ***Evaluate:*** What outcomes would indicate interprofessional care was effective?
8. Develop a conceptual care map for R.B.

Answers and a corresponding conceptual care map available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. In assessing the joints of a patient with osteoarthritis, the nurse understands that Heberden nodes
   - **a.** are often red, swollen, and tender.
   - **b.** indicate osteophyte formation at the DIP joints.
   - **c.** are the result of pannus formation at the PIP joints.
   - **d.** occur from deterioration of cartilage caused by proteolytic enzymes.
2. Assessment findings that the nurse would expect in a patient with rheumatoid arthritis who has articular involvement include *(select all that apply)*
   - **a.** bamboo-shaped fingers
   - **b.** metatarsal head dislocation in feet
   - **c.** noninflammatory pain in large joints
   - **d.** asymmetric involvement of small joints
   - **e.** morning stiffness lasting 60 minutes or more
3. Which drug would the nurse prepare to administer to the patient with acute gout?
   - **a.** Colchicine
   - **b.** Allopurinol
   - **c.** Sulfasalazine
   - **d.** Cyclosporine
4. The nurse should teach the patient with ankylosing spondylitis the importance of
   - **a.** avoiding extremes in environmental temperatures.
   - **b.** regularly exercising and maintaining proper posture.
   - **c.** maintaining the patient's usual physical activity during flares.
   - **d.** applying hot and cool compresses for relief of local symptoms.
5. In teaching a patient with systemic lupus erythematosus about the disorder, the nurse knows the pathophysiology includes
   - **a.** circulating immune complexes formed from IgG autoantibodies reacting with IgG.
   - **b.** an autoimmune T-cell reaction that results in destruction of the deep dermal skin layer.
   - **c.** immunologic dysfunction leading to chronic inflammation in the cartilage and muscles.
   - **d.** the production of a variety of autoantibodies directed against components of the cell nucleus.
6. Which drug would the nurse plan to administer to the patient with Sjögren syndrome with the goal of improving symptoms of dry eyes?
   - **a.** Etanercept (Enbrel)
   - **b.** Pilocarpine (Salagen)
   - **c.** Cyclosporine (Restasis)
   - **d.** Cyclobenzaprine (Flexeril)
7. Teach the patient with fibromyalgia the importance of limiting intake of which foods? *(select all that apply)*
   - **a.** Sugar
   - **b.** Gluten
   - **c.** Alcohol
   - **d.** Caffeine
   - **e.** Red meat

Case Study

Applying Clinical Judgment With Multiple Patients

You are working on the medical-surgical unit and have been assigned to care for the following 4 patients. You have an AP who is helping another nurse and you.

(© iStockphoto/ Thinkstock.)	J.K. is a 57-year-old woman who had debulking surgery for a temporal-parietal glioblastoma. 4 days ago, she had a hemorrhagic stroke into the site of the tumor bed extending into the thalamus. Has left homonymous hemianopsia. Left arm weakness (3/5) greater than leg weakness (4/5). Vital signs: 150/90, 68, RR 20.
(© iStockphoto/ Thinkstock.)	M.Y., a 78-year-man, had an ORIF 2 days ago for a fractured left hip. He has a 3-year history of Alzheimer disease and is confused to place and time. He has been pleasant and cooperative. He has a personal alarm and bed alarm on for safety. His hip dressing is dry and intact, and the drainage in the Hemovac drain is minimal.
(© iStockphoto/ Thinkstock.)	S.W. is an 18-year-old woman with a C5 cervical spinal cord injury. After spending 1 week in an inpatient rehabilitation facility, she was admitted this morning with severe headaches. She is reporting periodic blurred vision and nausea. Vital signs: 164/94, 84, RR 18.
(© aronaze/ iStock.com.)	M.C. is a 64-year-old man who had a right proximal femur fracture at the greater trochanter with loss of fixation in the femoral part of a THA he had previously. He had surgery 3 days ago, and discharge is planned today.

1. Highlight all the findings above that require your follow-up.
2. After receiving report, which patient should you see first? Why?
3. Which tasks could you delegate to the AP? *(Select all that apply.)*
   a. Explain discharge instructions to M.C.
   b. Change the dressing on M.Y.'s left hip.
   c. Obtain vital signs on M.C. before discharge.
   d. Assist S.W. with hygienic care and repositioning.
   e. Assess J.K.'s ability to swallow before feeding her breakfast.
4. When you enter the room to assess S.W., you find her diaphoretic with a flushed face and pale extremities. Her BP is 200/102 mm Hg.

Use an X for the nursing actions listed below that are Indicated (appropriate or necessary), Contraindicated (could be harmful), or Nonessential (makes no difference or not necessary) at this time.

Nursing Action	Indicated	Contraindicated	Nonessential
Assess for the presence of any noxious stimuli.			
Direct the AP to stay with S.W. while you contact the HCP.			
Obtain a STAT bladder scan.			
Administer as-needed oral hypertensive medication.			
Place the head of the bed flat.			
Review recent laboratory results.			

Case Study Progression

S.W.'s bladder scan showed 700 mL of urine. Her symptoms subside after you catheterize her. You take this time to teach S.W. about autonomic dysreflexia. You discuss bladder training strategies and how to avoid bladder distention. S.W. is grateful for the information and your caring attitude. As you are finishing, the AP tells you that M.Y. has pulled out his Hemovac drain.

4. What should be your *initial* intervention for M.Y.?
   a. Reinsert the Hemovac drain.
   b. Assess the incision site for a hematoma.
   c. Notify M.Y.'s HCP that the drain was removed.
   d. Apply pressure to the site where the drain was placed.
5. You receive M.Y.'s morning laboratory results and compare them with the day prior.

Laboratory Results

	Postop Day 1	Postop Day 2
RBC	$4.8 \times 10^6/\mu L$	$4.9 \times 10^6/\mu L$
WBC	5000	11,800
Platelets	180,000 μ/L	170,000 μ/L
Hemoglobin	Hgb 10.9 g/dL	Hgb 10.4 g/dL
Hematocrit	Hct 41.2%	Hct 38.2%
Glucose	132 mg/dL	142 mg/dL
INR	1.3	1.4

Choose the most *likely* option for the information missing from statement below by selecting from the lists of options provided.

Based on the laboratory results, you determine M.Y. may be experiencing the priority problem of _____**1**_____. To manage this problem, you expect that the HCP will order _____**2**_____.

Options for 1	Options for 2
Anemia with hypovolemia	Antibiotic therapy
Hyperglycemia	Blood transfusion
Infection	Insulin

6. As you are preparing J.K.'s medications, the EHR system alerts you that patient teaching has yet to be documented for some of her medications. For each medication, select the most likely option for Drug Classification and patient teaching.

Medication	Drug Classification	Patient Teaching
furosemide	Loop diuretic	Take this medication at bedtime
	Potassium-sparing diuretic	Limit oral fluid intake to 1000 mL/day
	Thiazide diuretic	Include foods high in potassium in the diet

Case Study—cont'd

Medication	Drug Classification	Patient Teaching
nimodipine	Calcium-channel blocker	Report a night cough or slowed pulse to health care provider
	ACE inhibitor	This drug may lower blood glucose levels
	Angiotensin receptor blocker	Take on an empty stomach
phenytoin	Serotonin receptor agonist	Maintain good oral hygiene.
	Antiseizure agent	Report the new onset of signs of depression.
	Antineoplastic	Avoid persons who have an infection.

7. Which intervention would be *most* appropriate in caring for J.K.?
   a. Place her left arm in a sling for support.
   b. Arrange the food tray so that all foods are on the right side.
   c. Position her left leg so that the ankle is lower than the knee.
   d. Call the provider to get an order of warfarin to prevent VTE.
8. As you enter M.C.'s room to discuss his discharge plans, you find him all packed up and ready to go. He tells you the AP already told him what he needed to do. What is your *best* initial action?
   a. Ask M.C. if he has any further questions.
   b. Call the AP to M.C.'s room to find out what she told him.
   c. Review discharge instructions with M.C. to ascertain correct understanding.
   d. Give M.C. a telephone number to call in case he has any concerns when he gets home.

Answers and rationales available at http://evolve.elsevier.com/Lewis/medsurg.

A APPENDIX

Basic Life Support for Health Care Providers

Mariann M. Harding

Basic life support (BLS) for HCPs consists of a series of actions and skills performed by the rescuer(s) based on assessment findings. Cardiac arrest is characterized by the absence of a pulse and breathing in an unconscious victim. The current approach for *cardiopulmonary resuscitation* (CPR) is the chest *compressions-airway-breathing* (CAB) sequence.

CARDIOPULMONARY RESUSCITATION

The first action the rescuer performs upon finding an adult victim is assessing for responsiveness. This is done by tapping or shaking the victim's shoulder and asking, "Are you all right?" If the victim does not respond, simultaneously scan the victim's chest for signs of absent or abnormal breathing and perform a pulse check by palpating the carotid pulse for at least 5 but no more than 10 seconds. Remember that gasping and/or irregular or agonal respirations are not considered breathing.

To palpate the carotid pulse, maintain a head-tilt position with 1 hand on the victim's forehead and locate the victim's trachea using 2 or 3 fingers of your other hand. Slide these fingers into the groove between the trachea and neck muscles where the carotid pulse can be felt. The technique is more easily performed on the side nearest you.

If a pulse is felt, give 1 rescue breath every 6 seconds (10 to 12 breaths/min) and recheck the pulse every 2 minutes (Fig. A.1). If no pulse is felt, start CAB.

If the rescuer is alone, the rescuer shouts for help. If someone responds, the rescuer asks them to activate the *emergency response system* (ERS) (if outside of the hospital) or call a code (in the hospital) and get an *automatic external defibrillator* (AED) (if available) or crash cart (in the hospital). If no one responds and the rescuer does not have a mobile phone, the rescuer should leave to activate the ERS, get an AED (if available), and return to the victim before beginning CAB and defibrillation if necessary.

Chest Compressions

The proper technique for providing chest compressions is shown in Fig. A.2. Chest compression technique consists of fast and deep applications of pressure on the lower half of the sternum. The victim must be in the supine position when compressions are performed. The victim must be lying on a flat, hard surface, such as a CPR board (specially designed for use in CPR), a headboard from a unit bed, or, if necessary, the floor. Position yourself close to the side of the victim's chest. More frequently, mechanical chest compression devices are being used to provide chest compressions both prehospital and in the emergency department.

Chest compressions are combined with rescue breathing for an effective resuscitation effort of the adult victim of cardiac arrest. The compression-to-ventilation ratio for 1- or 2-rescuer CPR is 30 compressions to 2 breaths (Table A.1). However, if the patient has an advanced airway (e.g., endotracheal tube, laryngeal mask airway), do not pause between compressions for breaths and deliver 1 breath every 6 seconds (10 breaths/min).

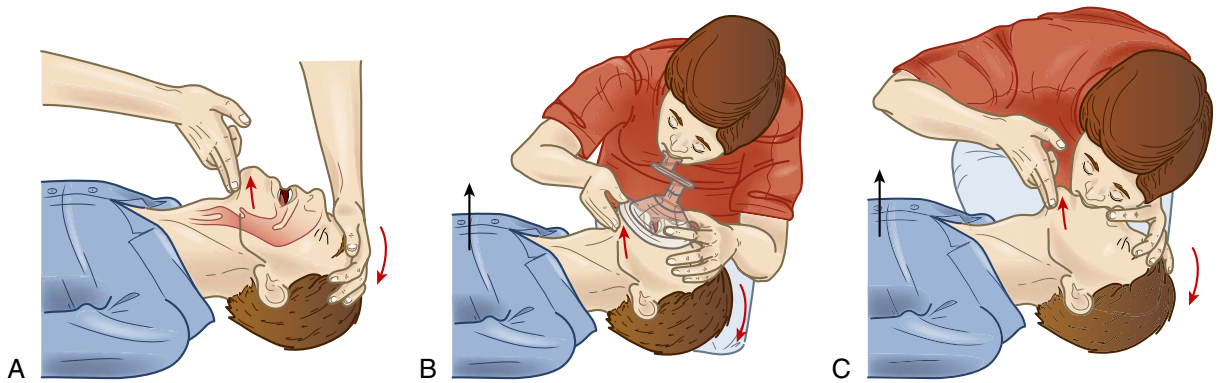

Fig. A.1 The head tilt–chin lift maneuver is used to open the victim's airway to give rescue breaths. (A) Rescuer places 1 hand on the victim's forehead and applies firm, backward pressure with the palm to tilt the head back. The chin is lifted and brought forward with the fingers of the other hand. (B) Mouth-to-barrier device: Rescuer places the device tightly over the victim's mouth and nose and delivers a regular breath. (C) Mouth-to-mouth technique: Rescuer pinches the victim's nostrils, tightly seals mouth over victim's mouth, and delivers a regular breath. NOTE: Rescuer should observe for a rise in the victim's chest *(black arrows)*.

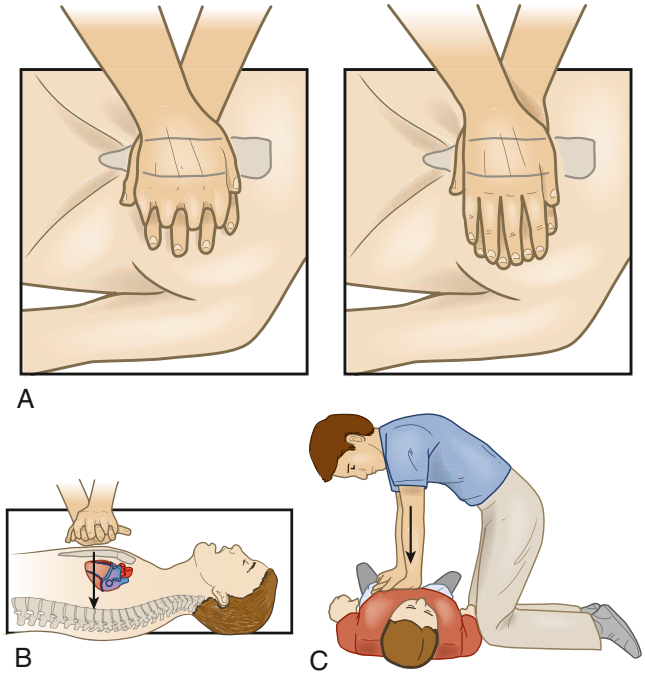

Fig. A.2 CPR. (A) Position of the hands on the lower half of the sternum during chest compressions. (B) When pressure is applied, the sternum is displaced posteriorly with the heel of the hand. (C) Arms are kept straight, and the rescuer pushes deep (at least 2 in [5 cm]) and fast (a rate of 100 to 120 compressions per minute).

If a mechanical chest compression device is not used, it is preferable to have 2 persons performing CPR. One rescuer, positioned at the victim's side, performs chest compressions while the second rescuer, positioned at the victim's head, maintains an open airway and performs ventilations. To maintain the quality and rate of compressions, rescuers should change roles every 2 minutes. Interruptions in CPR should be limited.

Defibrillation

When the AED or advanced cardiovascular life support (ACLS) team arrives, assess the victim's rhythm. If the victim has a shockable rhythm (e.g., ventricular tachycardia, ventricular fibrillation), deliver 1 shock and immediately resume CPR for about 2 minutes before checking the rhythm again. If the rhythm is not a shockable rhythm, immediately resume CPR and recheck the rhythm after 2 minutes. CPR should continue between rhythm checks and shocks and until the ACLS team arrives or the victim shows signs of movement.

The American Heart Association includes training in the use of AEDs with BLS instruction of HCPs and laypersons. Survival from cardiac arrest is the highest when immediate CPR is provided and defibrillation occurs within 3 to 5 minutes. AEDs are found in many out-of-hospital, public settings (Fig. A.3).

Airway and Breathing

If a victim has a pulse but is gasping (e.g., agonal breathing) or not breathing, establish an open airway and begin rescue breathing. Open an adult's airway by hyperextending the head (Fig. A.1). Use the *head tilt–chin lift maneuver.* This involves tilting the head back with 1 hand and lifting the chin forward with the fingers of the other hand. Use the *jaw-thrust maneuver* if you suspect a cervical spine injury. Try to provide ventilation to the victim using a mouth-to-barrier (recommended) device (e.g., face mask or bag-valve mask) or mouth-to-mouth resuscitation (Fig. A.1B and C).

For mouth-to-mouth resuscitation give ventilations with the victim's nostrils pinched. Take a regular (not deep) breath and tightly seal your lips around the victim's mouth. Give 1 breath and watch for a rise in the victim's chest. Continue rescue breaths at a rate of 10 to 12 per minute. When the victim has a tracheostomy, give ventilations through the stoma.

If the victim cannot be ventilated, proceed with CPR. When providing the next rescue breaths, look for any objects in the victim's mouth. If any objects are visible, remove them (Table A.2).

TABLE A.1 Adult 1- and 2-Rescuer Basic Life Support With AED

Assess

Determine unresponsiveness: tap or shake victim's shoulder; shout, "Are you all right?"

Check for no breathing or abnormal breathing (e.g., gasping) while simultaneously performing a pulse check (5–10 sec).

Activate Emergency Response System (ERS)

Activate ERS (e.g., call 911) and get the AED (if available) (outside of hospital).

Call a code and ask for the AED or crash cart (in hospital).

Begin High-Quality CPR

If victim has a pulse but is not breathing or not breathing adequately, begin rescue breathing at a rate of 1 breath every 3–5 sec, or about 12–20/min (Fig. A.1). Recheck the pulse every 2 min.[a]

If there is no pulse, expose the victim's chest and immediately begin chest compressions (Fig. A.2).

Deliver compressions at a rate of 100–120/min.

Compress the chest at least 2 in (5 cm) but not greater than 2.4 in (6 cm).

Allow for complete chest recoil after each compression.

Deliver a compression-ventilation ratio of 30 compressions to 2 breaths.[b]

Minimize interruptions in compressions by delivering the 2 breaths in <10 sec.

Deliver Effective Breaths

Open airway adequately (Fig. A.1A).

Deliver breath to produce a visible chest rise (Fig. A.1B and C).

Avoid excessive ventilation.

Integrate Prompt Use of the AED

Use AED as soon as possible.

If rhythm is shockable, deliver 1 shock and then resume chest compressions immediately after delivery of shock.

If the rhythm is not shockable, resume CPR and recheck rhythm every 5 cycles.

Continue CPR

Continue CPR between rhythm checks and shocks, and until ACLS providers arrive or the victim shows signs of movement.

[a]If possible opioid overdose, give naloxone if available and per protocol.

[b]For patients with ongoing CPR and an advanced airway in place, a ventilation rate of 1 breath every 6 seconds (10 breaths/min) with no interruption in compressions is recommended.

Source: American Heart Association: *Basic life support provider manual,* Dallas, 2020, The Association.

TABLE A.2 Management of the Adult Choking Victim

Conscious Adult Choking Victim

Assess victim for severe airway obstruction.

Look for any of the following signs:

- Poor or no air exchange
- Clutching the neck with the hands, making the universal choking sign
- Weak, ineffective cough or no cough at all
- High-pitched noise while inhaling or no noise at all
- Increased respiratory difficulty
- Possible cyanosis

Ask the victim if he or she is choking. If the victim nods yes and cannot talk or has any of the symptoms noted above, severe airway obstruction is present and you must take immediate action.

Abdominal Thrusts (Heimlich Maneuver) With Standing or Sitting Victim (Fig. A.4)

1. Stand or kneel behind victim and wrap arms around the victim's waist.
2. Make fist with 1 hand.
3. Place thumb side of fist against victim's abdomen. Position fist midline, slightly above navel and well below breastbone.
4. Grasp fist with other hand and press fist into victim's abdomen with a quick, forceful upward thrust.
5. Give each new thrust with a separate, distinct movement to relieve the obstruction. *Caution:* If victim is pregnant or obese, give chest thrusts instead of abdominal thrusts. Position hands (as described) over lower portion of the breastbone and apply quick backward thrusts.
6. Repeat thrusts until object is expelled or victim becomes unresponsive.

Unconscious Adult Choking Victim

If you see a choking victim collapse and become unresponsive:

1. Activate the emergency response system.
2. Lower the victim to the ground and begin CPR, starting with compressions (do not check for a pulse).
3. Open the victim's mouth wide each time you prepare to give breaths. Look for the object. If you see the object and can easily remove it, do so with your fingers. If you do not see the object, continue with CPR using the chest compression–airway–breathing sequence (Table A.1).
4. If efforts to ventilate are unsuccessful, continue with CPR.

Source: American Heart Association: *Basic life support provider manual,* Dallas, 2020, The Association.

Fig. A.3 AED located in an airport.

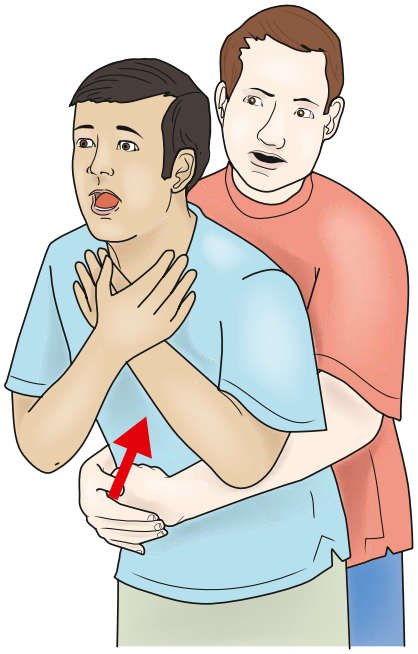

Fig. A.4 Abdominal thrusts (Heimlich maneuver) administered to a conscious (standing) choking victim.

HANDS-ONLY CPR

Hands-only CPR can be used to help adult victims who suddenly collapse from cardiac arrest outside of a health care setting. If an untrained person witnesses the event, the person should provide compression-only CPR. If you are trained and witness the event (as a bystander), you should provide conventional CPR (described previously). If you are unable to do so, provide chest compressions only (push fast and deep in the center of the chest). Both methods are effective when done in the first few minutes of an out-of-hospital cardiac arrest.

APPENDIX B

Clinical Problems With Definitions

1. Acid-Base Imbalance: Imbalance in the state of equilibrium between the acidity and alkalinity of body fluids.
2. Activity Intolerance: Inadequate energy to complete daily activities or desired activities.
3. Allergy: Hypersensitivity induced by exposure to an allergen, resulting in harmful immune responses on subsequent exposures.
4. Altered Blood Glucose Level: Impaired ability to maintain optimal blood glucose levels.
5. Altered Blood Pressure: A force propelling blood through the body at a level inadequate for perfusion.
6. Altered Temperature: Inability to maintain core body temperature from 36.2°C to 37.6°C (97.0°F to 100°F).
7. Anxiety: Feelings of threat, fear, apprehension, danger, or distress.
8. Body Weight Problem: Being either overweight or underweight.
9. Caregiver Role Strain: Distress in performing responsibilities of providing health-related care for a family member or significant other.
10. Continuity of Care Problem: Inadequate coordination across aspects of health care, including a lack of consistency in being able to see the same provider, poor communication and transfer of information across providers and settings, and a lack of follow-up/ongoing monitoring.
11. Cultural Belief Conflict: Differences in values and beliefs that place a person at odds with health care providers or health recommendations.
12. Decisional Conflict: A delay in making a health or treatment choice with accompanying distress and/or uncertainty about the choice.
13. Deficient Knowledge: Lacking information on a specific topic.
14. Depressed Mood: Depressed mood lasting 2 weeks or longer and accompanied by lack of pleasure or interest in most other activities.
15. Difficulty Coping: Inadequate personal ability to manage problems, stress, or responsibilities.
16. Dying Process: Progress toward the end of life.
17. Electrolyte Imbalance: Higher or lower than normal concentrations of an electrolyte.
18. Emotional Problem: An emotional state that interferes with or results in functional impairment.
19. Fatigue: Lack of physical and/or mental energy that interferes with usual and desired activities.
20. Fluid Imbalance: Any change in or modification of body fluid balance.
21. Grief: A pattern of physical and emotional responses to bereavement, separation, or loss.
22. Health Care–Associated Complication: A detrimental patient condition that occurs during the process of providing health care.
23. Health Maintenance Alteration: Impaired ability to manage health and/or access help to maintain health.
24. Impaired Bowel Elimination: Difficulty with formation and evacuation of stool.
25. Impaired Cardiac Function: Inadequate blood pumped from the heart to meet the body's needs.
26. Impaired Cognition: An observable or measurable disturbance in one or more of the thinking processes resulting from an abnormality within the brain or a factor interfering with normal brain function.
27. Impaired Communication: Impediment or blockage to exchanging thoughts, messages, or information.
28. Impaired Endocrine Function: A problem involving the mechanisms that regulate the secretion and action of hormones of the endocrine system.
29. Impaired Family Function: Inability of the family to meet family members' needs.
30. Impaired Fertility: Impaired capacity to reproduce or conceive.
31. Impaired Gastrointestinal Function: Impaired ability of the gastrointestinal system to the ability to ingest, absorb, and/or digest food.
32. Impaired Growth and Development: A delay or decline in growth or one or more areas of development.
33. Impaired Immunity: Impaired ability of the body to resist disease.
34. Impaired Psychologic Status: A state in which there is a loss of contact with reality.
35. Impaired Respiratory Function: Inability to ventilate, clear the airway, and/or diffuse oxygen and carbon dioxide.
36. Impaired Role Performance: Impaired ability to perform normal daily activities required to fulfill usual roles in the family, workplace, and community.
37. Impaired Sexual Function: Presence of a problem with sexual function that prevents the person from experiencing satisfaction from sexual activity.
38. Impaired Sleep: Not obtaining adequate sleep.
39. Impaired Socialization: Insufficient or excessive quantity or ineffective quality of human interaction.

40. Impaired Tissue Integrity: Damage, inflammation, or lesion to the skin or underlying structures.
41. Impaired Urinary Elimination: Difficulty with the collection and discharge of urine.
42. Inadequate Community Resources: Deficiency in environmental support for health.
43. Inadequate Tissue Perfusion: Inadequate blood circulation to a particular area of the body.
44. Increased Intracranial Pressure: A potentially life-threatening situation that results from an increase in brain tissue, blood, and/or cerebrospinal fluid within the skull.
45. Infant Feeding Problem: Any difficulty with the effective feeding of an infant.
46. Infection: Disease caused by the invasion of the body by pathogenic microorganisms.
47. Inflammation: Immunologic response to tissue injury, infection, or allergy.
48. Literacy Problem: Limited ability to obtain and understand basic health information needed to make appropriate health decisions.
49. Musculoskeletal Problem: Impaired ability to move one or more extremities.
50. Negative Self-Image: Negative self-evaluation of oneself.
51. Neurologic Problem: Impaired cognition, motor, sensory, and/or regulatory functions of the central or peripheral nervous system.
52. Nonadherence: An intentional choice to omit or an unintentional overlooking of health-promoting actions.
53. Nutritionally Compromised: Condition of poor nutrition due to intake of unbalanced or insufficient quality of nutrients.
54. Pain: An unpleasant sensory and emotional experience associated with actual or potential tissue damage.
55. Parenting Problem: Inability or change of the parent to provide care that promotes optimal growth and development of the child.
56. Personal Care Problem: Impaired ability to adequately perform personal care.
57. Risk for Disease: A characteristic, condition, or behavior that increases the likelihood of developing a disease or being injured.
58. Risk for Environmental Injury: Risk for adverse health outcomes associated with exposure to environmental contaminants.
59. Risk for Impaired Skin Integrity: At risk for loss of intact skin/tissue barrier.
60. Risk for Infection: Increased risk for a disease caused by the invasion of the body by pathogenic microorganisms.
61. Risk for Injury: State in which a person is at an increased risk for harm.
62. Risk for Perinatal Problems: Increased risk for complications during the perinatal period.
63. Sensory Deficit: Impaired ability to hear, see, taste, smell, or correctly perceive touch.
64. Socioeconomic Difficulty: Challenges to health based on income, educational attainment, financial security, and subjective perceptions of social status and social class.
65. Spiritual Problem: Distress associated with conflicts regarding meaning and purpose in life.
66. Substance Use: Dependence on a substance that leads to detrimental effects to the person's physical or mental health, or the welfare of others.
67. Victim of Violence: Having been harmed or under threat of harm by another person.
68. Violent Behavior: Force, physical or emotional, exerted to cause injury to others or destruction of property.

APPENDIX C

Laboratory Reference Intervals

The tables in this appendix list some of the most common tests, their reference intervals (formally referred to as *normal values*), and possible causes of abnormal results. Laboratory results may vary depending on different techniques or different laboratories. Abbreviations appearing in the tables are defined as follows:

mEq = milliequivalent
mm Hg = millimeter of mercury
mm = millimeter
mOsm = milliosmole
L = liter
dL = deciliter (10^{-1} liter)
mL = milliliter (10^{-3} liter)
µL = microliter (10^{-6} liter, 10^{-3} milliliter)
fL = femtoliter (10^{-15} liter, 10^{-12} milliliter)
g = gram
mg = milligram (10^{-3} gram)
mcg = microgram (10^{-6} gram)
ng = nanogram (10^{-9} gram)

TABLE C.1 Serum, Plasma, and Whole Blood Chemistries

	REFERENCE INTERVALS		POSSIBLE CAUSE	
Test	Conventional Units	SI Units	High	Low
Aldolase	22–59 mU/L	22–59 mU/L	Skeletal muscle disease	Muscle-wasting disease
α_1-Antitrypsin	85–213 mg/dL	0.85–2.13 g/L	Acute and chronic inflammation, arthritis	Early-onset emphysema, malnutrition, nephrotic syndrome
α_1-Fetoprotein	<40 ng/mL	<40 mcg/L	Cancer of testes, ovaries, and liver	
Ammonia	10–80 mcg/dL	6–47 µmol/L	Severe liver disease	
Amylase	60–120 Somogyi U/dL	30–220 U/L	Pancreatitis, salivary gland disease, perforated ulcers	Acute alcoholism, cirrhosis, extensive destruction of pancreas
Bicarbonate	21–28 mEq/L	21–28 mmol/L	Compensated respiratory acidosis, metabolic alkalosis	Compensated respiratory alkalosis, metabolic acidosis
b-Type natriuretic peptide (BNP)	<100 pg/mL	<100 pmol/L	Heart failure	
Bilirubin			Biliary obstruction, hemolytic anemia, impaired liver function, pernicious anemia	
• Total	0.3–1.0 mg/dL	5.1–17 µmol/L		
• Indirect	0.2–0.8 mg/dL	3.4–12.0 µmol/L		
• Direct	0.1–0.3 mg/dL	1.7–5.1 µmol/L		

Continued

TABLE C.1 Serum, Plasma, and Whole Blood Chemistries—cont'd

Test	REFERENCE INTERVALS: Conventional Units	REFERENCE INTERVALS: SI Units	POSSIBLE CAUSE: High	POSSIBLE CAUSE: Low
Blood gases[a]				
• Arterial pH	7.35–7.45	7.35–7.45	Alkalosis	Acidosis
• Venous pH	7.31–7.41	7.31–7.41		
• $PaCO_2$	35–45 mm Hg	4.66–5.98 kPa	Compensated metabolic alkalosis	Compensated metabolic acidosis
• $PvCO_2$	40–50 mm Hg	5.06–7.32 kPa	Respiratory acidosis	Respiratory alkalosis
• PaO_2	80–100 mm Hg	10.6–13.33 kPa	Receiving high concentration of O_2	Chronic lung disease, decreased cardiac output
• PvO_2	40–50 mm Hg	5.04–5.57 kPa		
Calcium (total)	9.0–10.5 mg/dL	2.25–2.62 mmol/L	Hyperthyroidism, hyperparathyroidism, vitamin D intoxication, multiple myeloma	Pancreatitis, hypoparathyroidism, malabsorption syndrome, renal failure, vitamin D deficiency
Calcium (ionized)	4.5–5.6 mg/dL	1.05–1.3 mmol/L	Acidosis	Alkalosis
Chloride	98–106 mEq/L	98–106 mmol/L	Metabolic acidosis, respiratory alkalosis, corticosteroid therapy, uremia	Addison disease, vomiting, metabolic alkalosis, respiratory acidosis
Cholesterol	<200 mg/dL	<5.2 mmol/L	Biliary obstruction, hypothyroidism, idiopathic hypercholesterolemia, renal disease, uncontrolled diabetes	Extensive liver disease, hyperthyroidism, malnutrition, malabsorption
• High-density lipoproteins (HDLs)	*Male:* >45 mg/dL *Female:* >55 mg/dL	*Male:* >0.75 mmol/L *Female:* >0.91 mmol/L	Excessive exercise	Metabolic syndrome, liver disease
• Low-density lipoproteins (LDLs)	*Recommended:* <130 mg/dL		Chronic liver disease, familial hypercholesterolemia, nephrotic syndrome	Hyperthyroidism
• Very low-density lipoproteins (VLDLs)	7–32 mg/dL		Familial hypercholesterolemia, nephrotic syndrome	Hyperthyroidism
Cortisol	8 AM: 5–23 mcg/dL 4 PM: 3–13 mcg/dL	8 AM: 138–635 nmol/L 4 PM: 83–359 nmol/L	Cushing syndrome, hyperthyroidism	Adrenal insufficiency, panhypopituitary states
Creatine kinase (CK)	20–200 U/L	20–200 U/L	Musculoskeletal injury or disease, myocardial infarction, severe myocarditis, exercise, numerous IM injections	
• CK-MB	<4%–6% of total CK	<0.4–0.6	Myocardial infarction	
Creatinine	*Male*: 0.6–1.2 mg/dL *Female:* 0.5–1.1 mg/dL	*Male*: 53–106 µmol/L *Female:* 44–97 µmol/L	Severe renal disease	Decreased muscle mass, dehabilitation
Ferritin	*Male*: 12–300 ng/mL *Female*: 10–150 ng/mL	*Male:* 12–300 mcg/L *Female*: 10–150 mcg/L	Anemia of chronic disease, sideroblastic anemia	Iron-deficiency anemia
Folic acid (folate)	5–25 ng/mL	11–57 nmol/L	Hypothyroidism, pernicious anemia	Alcoholism, hemolytic anemia, inadequate diet, malabsorption syndrome, megaloblastic anemia

TABLE C.1 Serum, Plasma, and Whole Blood Chemistries—cont'd

Test	REFERENCE INTERVALS: Conventional Units	REFERENCE INTERVALS: SI Units	POSSIBLE CAUSE: High	POSSIBLE CAUSE: Low
γ-Glutamyl transferase (GGT)	*Male and Female >45*: 8–38 U/L *Female <45*: 5–27 U/L	*Male and Female >45*: 8–38 U/L *Female <45:* 5–27 U/L	Liver disease, infectious myocardial infarction, pancreatitis, hyperthyroidism	Hypothyroidism
Glucose (fasting)	74–106 mg/dL	4.1–5.9 mmol/L	Acute stress, Cushing disease, diabetes, hyperthyroidism, pancreatic insufficiency	Addison disease, liver disease, hypothyroidism, insulin overdosage, pancreatic tumor, pituitary hypofunction
Haptoglobin	50–220 mg/dL	0.5–2.2 g/L	Infectious and inflammatory processes, cancer	Hemolytic anemia, malnutrition, chronic liver disease
Insulin (fasting)	6–26 μU/mL	43–186 pmol/L	Acromegaly, adenoma of pancreatic islet cells, Cushing syndrome	Diabetes, hypopituitarism
Iron, total	*Male:* 80–180 mcg/dL *Female:* 60–160 mcg/dL	*Male:* 14–32 μmol/L *Female:* 11–29 μmol/L	Excess RBC destruction, hepatitis, massive blood transfusion	Anemia of chronic disease, iron-deficiency anemia, cancer
(Total) iron-binding capacity	250–460 mcg/dL	45–82 μmol/L	Iron-deficient state, polycythemia	Cirrhosis, chronic infections, pernicious anemia
Lactic acid (L-Lactate), venous	5–20 mg/dL	0.6–2.2 mmol/L	Acidosis, liver disease, sepsis, shock	
Lactic dehydrogenase (LDH)	100–190 U/L	100–190 U/L	Heart failure, hemolytic disorders, hepatitis, metastatic liver cancer, myocardial infarction, pernicious anemia, pulmonary embolus, skeletal muscle damage	
Lactic dehydrogenase isoenzymes				
• LDH1	17%–27%	0.17–0.27	Myocardial infarction, pernicious anemia	
• LDH2	27%–37%	0.27–0.37	Pulmonary embolus, sickle cell crisis	
• LDH3	18%–25%	0.18–0.25	Lymphoma, pulmonary embolus	
• LDH4	3%–8%	0.03–0.08	Systemic lupus erythematosus, pulmonary infarction	
• LDH5	0%–5%	0.00–0.05	Heart failure, hepatitis, pulmonary embolus and infarction, skeletal muscle damage	
Lipase	0–160 U/L	0–160 U/L	Pancreatitis, liver disorders, perforated peptic ulcer	
Magnesium	1.3–2.1 mEq/L	0.65–1.05 mmol/L	Addison disease, hypothyroidism, renal failure	Alcoholism, severe malabsorption
Osmolality	285–295 mOsm/kg	285–295 mmol/kg	Chronic renal disease, diabetes, diabetes insipidus	Addison disease, diuretic therapy, SIADH, hypervolemia
O_2 saturation (arterial) (SaO_2)	>95%	>0.95	Polycythemia	Anemia, cardiac decompensation, respiratory disorders

Continued

TABLE C.1 Serum, Plasma, and Whole Blood Chemistries—cont'd

Test	REFERENCE INTERVALS: Conventional Units	REFERENCE INTERVALS: SI Units	POSSIBLE CAUSE: High	POSSIBLE CAUSE: Low
Phosphatase, alkaline	30–120 U/L	0.5–2.0 μkat/L	Biliary system obstruction, bone diseases, marked hyperparathyroidism, rickets	Excess vitamin D ingestion, hypothyroidism
Phosphorus (phosphate)	3.0–4.5 mg/dL	0.97–1.45 mmol/L	Bone cancer, hypoparathyroidism, renal disease, vitamin D intoxication, hypocalcemia	Diabetes, hyperparathyroidism, vitamin D deficiency
Potassium	3.5–5.0 mEq/L	3.5–5.0 mmol/L	Addison disease, diabetic ketosis, massive tissue destruction, renal failure, infection, dehydration	Cushing syndrome, diarrhea (severe), diuretic therapy, gastrointestinal fistula, starvation, vomiting
Progesterone (female)				
• Follicular phase	<50 ng/dL	0.5–2.2 nmol/L	Adrenal hyperplasia, choriocarcinoma of ovary, pregnancy, ovarian cysts	Threatened abortion, hypogonadism, amenorrhea, ovarian tumor
• Luteal phase	300–2500 ng/dL	6.4–79.5 nmol/L		
• Postmenopause	<40 ng/dL	1.28 nmol/L		
Prostate-specific antigen (PSA)	<2.5 ng/mL	<2.5 mcg/L	Prostate cancer, prostatitis, benign prostatic hypertrophy	
Proteins			Burns, cirrhosis (globulin fraction), dehydration	Liver disease, malabsorption
• Total	6.4–8.3 g/dL	64–83 g/L		
• Albumin	3.5–5.0 g/dL	35–50 g/L		
• Globulin	2.3–3.4 g/dL	23–34 g/L		
• Albumin/globulin ratio	1.5:1–2.5:1	1.5:1–2.5:1	Multiple myeloma (globulin fraction), shock, vomiting	Malnutrition, nephrotic syndrome, proteinuria, renal disease, severe burns
Sodium	136–145 mEq/L	136–145 mmol/L	Dehydration, impaired renal function, primary aldosteronism, corticosteroid therapy	Addison disease, diabetic ketoacidosis, diuretic therapy, excessive loss from GI tract, excessive perspiration, water intoxication
Testosterone (total)	*Male:* 280–1080 ng/dL	*Male:* 280–1080 ng/dL	Hyperthyroidism	Hypofunction of testes, hypogonadism
	Female: <70 ng/dL	*Female:* <70 ng/dL	Polycystic ovary, virilizing tumors	
T_4 (thyroxine), total	*Male*: 4–12 mcg/dL *Female*: 5–12 mcg/dL	*Male*: 59–135 nmol/L *Female*: 71–142 nmol/L	Hyperthyroidism, thyroiditis, hepatitis, Graves disease, thyroid cancer	Cretinism, hypothyroidism, myxedema, Cushing syndrome, renal failure
T_4 (thyroxine), free	0.8–2.8 ng/dL	10–36 pmol/L		
T_3 uptake	24%–34%	24%–34%	Hyperthyroidism	Hypothyroidism
T_3 (triiodothyronine), total	*Age 20–50:* 70–205 ng/dL *Age >50:* 40–180 ng/dL	1.2–3.4 nmol/L 0.60–2.8 nmol/L	Hyperthyroidism	Hypothyroidism
Thyroid-stimulating hormone (TSH)	2.0–10 μU/mL	2.0–10 mU/L	Myxedema, primary hypothyroidism	Secondary hypothyroidism, hyperthyroidism
Transaminases				
• Aspartate aminotransferase (AST)	0–35 U/L	0–0.58 μkat/L	Liver disease, myocardial infarction, pulmonary infarction, hepatitis	Acute renal disease, diabetic ketoacidosis

TABLE C.1 Serum, Plasma, and Whole Blood Chemistries—cont'd

Test	REFERENCE INTERVALS: Conventional Units	REFERENCE INTERVALS: SI Units	POSSIBLE CAUSE: High	POSSIBLE CAUSE: Low
• Alanine aminotransferase (ALT)	4–36 U/L	4–36 U/L	Liver disease, shock	
Transferrin	*Male*: 215–365 mg/dL *Female*: 250–380 mg/dL	*Male*: 2.15–3.65 g/L *Female*: 2.5–3.8 g/L	Iron-deficiency anemia, polycythemia vera	Cirrhosis, pernicious anemia, sickle cell disease
Transferrin saturation (%)	*Male*: 20%–50% *Female*: 15%–50%	*Male*: 20%–50% *Female*: 15%–50%	Hemolytic anemia, iron overdose	Malnutrition
Triglycerides	*Male*: 40–160 mg/dL *Female*: 35–135 mg/dL	*Male*: 0.45–1.81 g/L *Female*: 0.40–1.52 g/L	Diabetes, hyperlipidemia, hypothyroidism, liver disease	Malnutrition
Troponins (cardiac)			Myocardial infarction, myocardial injury	
• Troponin T (cTnT)	<0.1 ng/mL	<0.1 mcg/L		
• Troponin I (cTnI)	<0.03 ng/mL	<0.03 mcg/L		
Urea nitrogen (BUN)	10–20 mg/dL	3.6–7.1 mmol/L	Increase in protein catabolism (fever, sepsis, stress), renal disease, heart failure, myocardial infarction	Malnutrition, severe liver damage
Uric acid	*Male:* 4.0–8.5 mg/dL *Female:* 2.7–7.3 mg/dL	*Male:* 0.24–0.51 mmol/L *Female:* 0.16–0.43 mmol/L	Gout, gross tissue destruction, high-protein weight reduction diet, leukemia, renal failure	Administration of uricosuric drugs
Vitamin B_{12} (cobalamin)	160–950 pg/mL	118–701 pmol/L	Chronic myeloid leukemia	Strict vegetarianism, malabsorption syndrome, pernicious anemia, total or partial gastrectomy
Vitamin C (ascorbic acid)	0.4–2.0 mg/dL	23–114 µmol/L	Excessive ingestion of vitamin C	Connective tissue disorders, liver disease, renal disease, rheumatic fever, vitamin C deficiency
Vitamin D	25–80 ng/dL	25–80 ng/dL	Excess dietary supplement	Liver disease, malabsorption syndromes, osteoporosis, renal disease

$PaCO_2$, Partial pressure of CO_2 in arterial blood; *PaO_2,* partial pressure of oxygen in arterial blood; *$PvCO_2$,* partial pressure of CO_2 in venous blood; *PvO_2,* partial pressure of oxygen in venous blood; *RBC,* red blood cell; *SaO_2,* arterial oxygen saturation.

[a]Because arterial blood gases are influenced by altitude, the value for PaO_2 decreases as altitude increases. The lower value is normal for an altitude of 1 mile.

TABLE C.2 Hematology

Test	REFERENCE INTERVALS: Conventional Units	REFERENCE INTERVALS: SI Units	POSSIBLE CAUSE: High	POSSIBLE CAUSE: Low
Activated partial thromboplastin time (aPTT)	30–40 sec[a]	30–40 sec[a]	Factors I, II, V, VIII, IX, X, XI, XII deficiency; hemophilia, heparin therapy, liver disease	Early DIC, extensive cancer
Bleeding time	1–9 min	60–540 sec	Aspirin ingestion, ineffective platelet function, thrombocytopenia, vascular disease, von Willebrand disease	

Continued

TABLE C.2 Hematology—cont'd

Test	REFERENCE INTERVALS: Conventional Units	REFERENCE INTERVALS: SI Units	POSSIBLE CAUSE: High	POSSIBLE CAUSE: Low
D-Dimer	<250 ng/mL	<250 mcg/L	DIC, myocardial infarction, VTE, unstable angina, cancer	
Erythrocyte sedimentation rate (ESR)	<20 mm/hr (some gender variation)	<20 mm/hr (some gender variation)	*Moderate increase:* hepatitis, myocardial infarction; rheumatoid arthritis *Marked increase:* acute and severe bacterial infections, cancer, pelvic inflammatory disease	Malaria, severe liver disease, sickle cell anemia
Fibrinogen	200–400 mg/dL	2–4 g/L	Burns (after first 36 hr), inflammatory disease, stroke, myocardial infarction	Burns (during first 36 hr), DIC, severe liver disease, malnutrition
Fibrin split (degradation) products	<10 mcg/mL	<10 mg/L	Acute DIC, massive hemorrhage, primary fibrinolysis	
Hematocrit[b] (altitude dependent)	*Male:* 42%–52% *Female:* 37%–47%	*Male:* 0.42–0.52 *Female:* 0.37–0.47	Dehydration, high altitudes, polycythemia, COPD	Anemia, hemorrhage, overhydration, cirrhosis, kidney disease
Hemoglobin[b] (altitude dependent)	*Male:* 14–18 g/dL *Female:* 12–16 g/dL	*Male:* 140–180 g/L *Female:* 120–160 g/L	COPD, high altitudes, polycythemia, dehydration, burns	Anemia, hemorrhage, kidney disease, cancer
Hemoglobin, glycosylated (A1C)	4.0%–5.9%	4.0%–5.9%	Diabetes, pre-diabetes	Sickle cell anemia, chronic renal failure, pregnancy
Platelets (thrombocytes)	150–400 × 10^3/μL	150–400 × 10^9/L	Acute infections, chronic granulocytic leukemia, chronic pancreatitis, cirrhosis, collagen disorders, polycythemia, postsplenectomy	Leukemia, DIC, thrombocytopenic purpura
Prothrombin time (protime, PT)	11–12.5 sec[a]	11–12.5 sec[a]	Deficiency of factors I, II, V, VII, and X; liver disease; vitamin K deficiency; warfarin therapy	
Red blood cell count[b] (altitude dependent)	*Male:* 4.7–6.1 × 10^6/μL *Female:* 4.2–5.4 × 10^6/μL	*Male:* 4.7–6.1 × 10^{12}/L *Female:* 4.2–5.4 × 10^{12}/L	Dehydration, high altitudes, polycythemia vera, severe COPD	Anemia, leukemia, hemorrhage, cancer, chronic illness, kidney disease
Red blood cell indices				
• Mean corpuscular volume (MCV)	80–95 fL	80–95 fL	Alcoholism, liver disease, macrocytic anemia	Microcytic anemia, thalassemia
• Mean corpuscular hemoglobin (MCH)	27–31 pg	27–31 pg	Macrocytic anemia	Microcytic anemia
• Mean corpuscular hemoglobin concentration (MCHC)	32%–36%	32–36 g/dL	Spherocytosis	Iron deficiency anemia, thalassemia
Platelets (thrombocytes)	150–400 × 10^3/μL	150–400 × 10^9/L	Acute infections, chronic granulocytic leukemia, chronic pancreatitis, cirrhosis, collagen disorders, polycythemia, postsplenectomy	Leukemia, DIC, thrombocytopenic purpura

TABLE C.2 Hematology—cont'd

Test	REFERENCE INTERVALS		POSSIBLE CAUSE	
	Conventional Units	SI Units	High	Low
Reticulocyte count	0.5%–2.0% of RBC	0.5%–2.0% of RBC	Hemolytic anemia, polycythemia vera	Hypoproliferative anemia, macrocytic anemia, microcytic anemia
White blood cell (WBC) count[b]	5000–10,000/mm^3	5.0–10.0 × 10^9/L	Inflammatory and infectious processes, leukemia	Aplastic anemia, side effects of chemotherapy and radiation
WBC differential				
• Segmented neutrophils	55%–70%	0.55–0.70	Bacterial infections, collagen diseases, Hodgkin lymphoma	Aplastic anemia, viral infections
• Band neutrophils	0%–8%	0–0.08	Acute infections	
• Lymphocytes	20%–40%	0.20–0.40	Chronic infections, lymphocytic leukemia, mononucleosis, viral infections	Corticosteroid therapy, whole body irradiation
• Monocytes	2%–8%	0.02–0.08	Chronic inflammatory disorders, malaria, monocytic leukemia, acute infections, Hodgkin lymphoma	
• Eosinophils	1%–5%	0.01–0.05	Allergic reactions, eosinophilic and chronic granulocytic leukemia, parasitic disorders, Hodgkin lymphoma	Corticosteroid therapy
• Basophils	0.5%–1%	0.005–0.01	Hypothyroidism, ulcerative colitis, myeloproliferative diseases	Hyperthyroidism, stress

[a]Values depend on reagent and instrumentation used.
[b]Components of complete blood count (CBC).

TABLE C.3 Serology-Immunology

Test	REFERENCE INTERVALS		POSSIBLE CAUSE	
	Conventional Units	SI Units	High/Positive	Low
Antinuclear antibody (ANA)	Negative at 1:40 dilution	Negative at 1:40 dilution	Chronic hepatitis, rheumatoid arthritis, scleroderma, systemic lupus erythematosus (SLE)	
Anti-DNA antibody	<5 IU/mL	<5 IU/mL	SLE	
Anti-Sm (Smith)	Negative	Negative	SLE	
C-reactive protein (CRP)	<1.0 mg/dL	<10.0 mg/L	Acute infections, any inflammatory condition, widespread cancer	
Carcinoembryonic antigen (CEA)	*Nonsmoker:* <3 ng/mL *Smoker:* <5 ng/mL	*Nonsmoker:* <3 mcg/L *Smoker:* <5 mcg/L	Cancer of colon, liver, pancreas; cigarette smoking; inflammatory bowel disease	
Complement, total hemolytic (CH_{50})	30–75 U/mL	30–75 U/mL	Cancer, ulcerative colitis	Bacterial endocarditis, glomerulonephritis, rheumatoid arthritis, systemic lupus erythematosus

Continued

TABLE C.3 Serology-Immunology—cont'd

Test	REFERENCE INTERVALS Conventional Units	SI Units	POSSIBLE CAUSE High/Positive	Low
Direct Coombs or direct antihuman globulin test (DAT)	Negative	Negative	Acquired hemolytic anemia, drug reactions, transfusion reactions	
Fluorescent treponemal antibody absorption (FTA-Abs)	Negative or nonreactive	Negative or nonreactive	Syphilis	
Hepatitis A antibody	Negative	Negative	Hepatitis A	
Hepatitis B surface antigen (HB_sAg)	Negative	Negative	Hepatitis B	
Hepatitis C antibody	Negative	Negative	Hepatitis C	
Monospot or monotest	Negative	Negative	Infectious mononucleosis	
Rheumatoid factor (RF)	Negative or titer <1:17	Negative or titer <1:17	Rheumatoid arthritis, Sjögren's syndrome, SLE	
RPR	Negative or nonreactive	Negative or nonreactive	Leprosy, malaria, rheumatoid arthritis, SLE, syphilis,	
VDRL	Negative or nonreactive	Negative or nonreactive	Syphilis	

RPR, Rapid plasma reagin test; *VDRL,* Venereal Disease Research Laboratory test.

TABLE C.4 Urine Chemistry

Test	REFERENCE INTERVALS Specimen	Units	SI Units	POSSIBLE CAUSE High	Low
Acetone	Random	Negative	Negative	Diabetes, high-fat and low-carbohydrate diets, starvation	
Aldosterone	24 hr	2–26 mcg/day	6–72 nmol/day	*Primary aldosteronism:* adrenocortical tumors *Secondary aldosteronism:* cirrhosis, heart failure, hyperkalemia, hyponatremia	ACTH deficiency, Addison disease, corticosteroid therapy, hypokalemia
Amylase	24 hr	<5000 Somogyi U/day	6.5–48.1 U/hr	Pancreatitis	
Bence Jones protein	Random	<0.68 mg/dL	<0.68 mg/dL	Multiple myeloma	
Bilirubin	Random	Negative	Negative	Liver disorders	
Catecholamines	24 hr			Heart failure, pheochromocytoma, progressive muscular dystrophy	
• Epinephrine		<20 mcg/day	<109 nmol/day		
• Norepinephrine		<100 mcg/day	<590 nmol/day		
Cortisol	24 hr	<100 mcg/day	<276 nmol/day	Adrenal cancer, Cushing syndrome, hyperthyroidism, obesity, stress	Addison disease, hypothyroidism, liver disease
Creatinine clearance	24 hr	*Male*: 107–139 mL/min *Female:* 87–107 mL/min	*Male*: 1.78–2.32 mL/sec *Female:* 1.45–1.78 mL/sec	Exercise, pregnancy	Cirrhosis, heart failure, renal disease

TABLE C.4 Urine Chemistry—cont'd

Test	REFERENCE INTERVALS			POSSIBLE CAUSE	
	Specimen	Units	SI Units	High	Low
Estrogens	24 hr				
• Female				Gonadal or adrenal tumor	Endocrine disturbance, ovarian dysfunction, menopause
• Nonpregnant		4–60 mcg/day	4–60 mcg/day		
• Postmenopause		<20 mcg/day	<20 mcg/day		
• Male		4–25 mcg/day	4–25 mcg/day		
Glucose	Random	Negative	Negative	Diabetes, pituitary disorders	
Hemoglobin	Random	Negative	Negative	Extensive burns, glomerulonephritis, hemolytic anemia, hemolytic transfusion reaction	
5-Hydroxyindole acetic acid (5-HIAA)	24 hr	2–8 mg/day	10–40 µmol/day	Malignant carcinoid syndrome	
Ketones	Random	Negative	Negative	Diabetes, starvation, dehydration	
Metanephrine	24 hr	<1.3 mg/day	<7 µmol/day	Pheochromocytoma	
Myoglobin	Random	Negative	Negative	Crushing injuries, electric injuries, extreme physical exertion	
Osmolality	Random	50–1200 mOsm/kg	50–1200 mmol/kg	Heart failure, liver disease, shock, SIADH	Aldosteronism, diabetes insipidus, hypokalemia, pyelonephritis
pH	Random	4.6–8.0	4.6–8.0	Urinary tract infection, urine allowed to stand at room temperature	Respiratory or metabolic acidosis
Protein	Random	0–8 mg/dL	0–8 mg/dL	Acute and chronic renal disease, heart failure	
Protein (quantitative)	24 hr	50–80 mg/day	50–80 mg/day	Heart failure, urinary tract inflammation, nephritis, nephrosis, strenuous exercise	
Sodium	24 hr	40–220 mEq/day	40–220 mmol/day	Acute tubular necrosis	Hyponatremia
Specific gravity	Random	1.005–1.030	1.005–1.030	Albuminuria, dehydration, glycosuria, fever	Diabetes insipidus, hypothermia, diuresis
Uric acid	24 hr	250–750 mg/day	1.48–4.43 mmol/day	Gout, leukemia	Nephritis
Urobilinogen	Random	Negative	Negative	Hemolytic disease, liver parenchymal cell damage, liver disease	Complete bile duct obstruction
Vanillylmandelic acid	24 hr	<6.8 mg/day	<35 µmol/day	Pheochromocytoma	

ACTH, Adrenocorticotropic hormone.

TABLE C.5 Fecal Analysis

Test	REFERENCE INTERVALS		Possible Cause
	Conventional Units	SI Units	
Fecal fat	2–6 g/24 h	7–21 mmol/day	Common bile duct obstruction, malabsorption syndrome, pancreatic disease
Mucus	Negative	Negative	Mucous colitis, spastic constipation
Pus	Negative	Negative	Chronic bacillary dysentery, chronic ulcerative colitis, localized abscesses
Blood[a]	Negative	Negative	Anal fissures, gastrointestinal cancer, hemorrhoids, inflammatory bowel disease, peptic ulcer disease
Color			
• Brown			Various color depending on diet
• Clay			Biliary obstruction, presence of barium sulfate
• Tarry			More than 100 mL of blood in gastrointestinal tract
• Red			Blood in large intestine
• Black			Blood in upper gastrointestinal tract, iron medication

[a]Ingesting meat may produce false-positive results. Patient may be placed on a meat-free diet for 3 days before the test.

TABLE C.6 Cerebrospinal Fluid Analysis

Test	REFERENCE INTERVALS		POSSIBLE CAUSE	
	Conventional Units	SI Units	High	Low
Pressure	<20 mm H_2O	<20 mm H_2O	Hemorrhage, intracranial tumor, meningitis	Head injury, spinal tumor, subdural hematoma
Blood cell count (age dependent)	Negative	Negative	Intracranial hemorrhage CNS infection or inflammation	
• WBC	0–5 cells/μL	0–5 × 10^6 cells/L		
• RBC	Negative	Negative		
Chloride	700–750 mg/dL	118–132 mmol/L	Uremia	CNS bacterial infection
Glucose	50–75 mg/dL	2.2–3.9 mmol/L	CNS viral infection, diabetes	Bacterial infection, CNS tuberculosis
Protein				
• Lumbar	15–45 mg/dL	0.15–0.45 g/L	Guillain-Barré syndrome, poliomyelitis, trauma	
• Cisternal	15–25 mg/dL	0.15–0.25 g/L	CNS syphilis	
• Ventricular	5–15 mg/dL	0.05–0.15 g/L	Acute meningitis, brain tumor, chronic CNS infection, multiple sclerosis

evaluation of, 420
health promotion of, 419
nonoptical methods for vision enhancement, 420
nonsurgical corrections, 418
nursing assessment of, 419
nursing implementation of, 419–420
nursing management of, **419–420**
in older adults, 420
optical devices for vision enhancement, 420
planning, 419
severe, 419
surgical therapy for, 418–419
Visual pathways**, 410**, 411f
Visual problems, 414b, **417–419**, 418t
assessment and management of, **407–435**
Visual system**, 407–410**, 417b
abnormalities, 416b
assessment of, **410–417**, 412b, 416b–417b
activity-exercise pattern, 412–413
cognitive-perceptual pattern, 413
coping-stress tolerance pattern, 414
elimination pattern, 412
functional health patterns, 411–414
functional status, 414–415
health perception-health management pattern, 411–412
initial observation, 414
medications, 411
normal, 414t
nutritional-metabolic pattern, 412
physical examination, 414–417
role-relationship pattern, 413
self-perception-self-concept pattern, 413
sexuality-reproductive pattern, 413
sleep-rest pattern, 413
surgery or other treatments, 411
techniques for, 415b, 417
value-belief pattern, 414
case study on, 411b, 414b, 417b
diagnostic studies of, **417**, 418t

Visual system **(Continued)**
health history, 413b
in older adults, 412b
structures and functions of, **407–410**
external ocular, 409
internal, 410
middle ocular, 410
periocular, 408–409
Vital capacity (VC), 536t
Vital signs
assessment of, 775
in increased intracranial pressure, 1487, 1487b
for inflammation, 183
Vitamin A, recommended daily intake, 1013t
Vitamin A deficiency, 1013t
Vitamin B_2, food sources, 719b
Vitamin B_5, 719b
Vitamin B_6, 1013t
food sources, 719b
Vitamin B_6 deficiency, 1013t
Vitamin B_{12}
food sources, 719b
recommended daily intake, 1013t
Vitamin B_{12} deficiency, 722
clinical manifestations of, 1013t
Vitamin C (ascorbic acid), 719b
recommended daily intake, 1013t
Vitamin C deficiency
clinical manifestations of, 1013t
wound healing and, 188t
Vitamin D, 1013t
Vitamin D deficiency, 1013t
Vitamin D supplements, 1691
Vitamin E, 719b, 1013t
Vitamin E deficiency, 1013t
Vitamin K
liver function test, 1006t
recommended daily intake, 1013t
Vitamin K antagonists, 834b–835b, 950t, 951
Vitamin K deficiency, 1013t
Vitamins, 1010
fat-soluble, 1010
for inflammation, 184b
in parenteral nutrition, 1025
recommended daily intakes, 1013t
water-soluble, 1010
Vitiligo, 465, 466b, 467f, 489, 1276–1278
Vitrectomy, 428
Vitreous humor, 410, 412b
VLDLs. *See* Very-low-density lipoproteins
Vocal cord stripping, 589t
Voiding, 1181
Voiding cystourethrogram, 1190t–1192t
Voiding dysfunction, drug therapy for**,** 1222b
Voiding pressure flow study, 1190t–1192t
Volatile liquids, 360b
Voltaren gel. *See* Diclofenac sodium
Volume ventilation, 553
modes of, 555–557
Volutrauma, 565, 686
Volvulus, 1112f
Vomiting
cyclic vomiting syndrome, 1053
definition of, 1050–1051
at end of life, 157b–158b
in increased intracranial pressure, 1488
nausea and vomiting, **1050–1052**
nursing management of, 1023b
projectile, 1052
Von Willebrand disease, 735–737
Von Willebrand factor, 737b
Vorapaxar (Zontivity), 834b–835b
VT. *See* Ventricular tachycardia
VTE. *See* Venous thromboembolism
Vulva, 1355
Vulvar cancer, 1430
Vulvar discharge, 1365b
Vulvar growths, 1365b
Vulvar redness, 1365b
Vulvovaginal candidiasis, 1422, 1422t

W

Waist circumference, 1036
Waist-to-hip ratio (WHR), 1036
Wake behavior, 106
Warfarin (Coumadin), 950t
mechanism of action, 834b–835b
pharmacogenetics of, 208t, 209f
for VTE, 951
Warm extremities, 776b–777b
Warming
active measures, 377
passive measures, 377
Warts, 477, 479f, 486t
genital, **1402–1404**, 1402f
Wasp stings, 481t
Watchful waiting, 1436, 1445
Water balance. *See also* Fluid and electrolyte balance
regulation of, **307–308**
adrenal cortical, 307–308
cardiac, 308
gastrointestinal, 308
hypothalamic-pituitary, 307
renal, 307
Water content, 303, 303f
Water deficit, 305
Water deprivation (restriction) (ADH stimulation) test, 1279t–1283t
Water excess, 305
Water imbalance, 565
Water loss, insensible, 307
Water retention, 800–801
Water-soluble vitamins, 1010
Water therapy, 1559, 1559f
Water vapor thermal therapy, 1439
Weakened immune system, images useful for, 101t
Weakness, 703b–704b
at end of life, 157b–158b
Weaning, from positive pressure ventilation**,** 567–568, 567t
Wearable artificial kidney**, 1255**
Web-based health information, 59
Weber test, 443t–444t
Wedge resection, 551t
Weight
classification of, 1035–1036
healthy, 1038b
Weight changes, 1276–1278
chronic heart failure and, 866
Weight loss
1200-calorie-restricted weight-reduction diet for, 1039t
for hypertension, 804
Weights, daily, 310
WelChol (colesevelam), 828b–829b
Wellbutrin (bupropion), 133t
Wernicke receptive speech area, 1464
Wernicke-Korsakoff syndrome, 167–168
Wernicke's aphasia, 1522t
West Nile virus, 239
Wet compresses, 487–489
Wet mounts, 1368t
Wheal, 464t
Wheal-and-flare reaction, 220
Wheezes, 527, 528b
Whipple procedure, 1166f
Whitaker study, 1190t–1192t
White blood cells
laboratory studies, 705–707
in shock, 964t
White coat hypertension, 804
"Whiteout", 684
Whooshing sound, 772
WHR. *See* Waist-to-hip ratio
Wilson disease, 1146
Window period, 253, 253t
Wind-up, 122
Withdrawal
alcohol, 168, 169t
opioid, 142t
stimulant, 168
Withdrawing treatment, 1260b
Women
acute coronary syndrome in, 822b
coronary artery disease in, 821, 822b
hypertension, 798b
osteoarthritis in, 1697b
osteoporosis, 1689b
risk factors for breast cancer, 1376
vascular disorders in, 933b
Wood's lamp (black light), 468t
Work of breathing (WOB), 676
Workplace violence, 401
Work-related musculoskeletal disorder, 1642
Wound care, 187t
for burns, 502–503, 503f, 503b
dressings, 187, 189t
Wound dehiscence, 379
Wound healing
complications of, 186, 187t
drug therapy for, 191
Wound healing **(Continued)**
factors delaying, 187, 188t
in fractures, 1645–1646
granulation phase, 185–186, 185t
hyperbaric oxygen therapy for, 191
initial phase, 185, 185t
maturation phase, 185t, 186
nursing and interprofessional management, **186–192**
nutrition therapy for, 191
patient teaching for, 192
primary intention, 185–186
process of, **185–186**
secondary intention, 186
tertiary intention, 186
types of, 185f
Wound management, tetanus vaccines and TIG for, 391t
Wound Ostomy Continence Nurses Society, 1123
Wounds
assessment, 188b
chronic, 187
classification of, 186, 186f, 188t
clean, 188–190
contaminated, 190
full-thickness, 186
measurements, 187, 188f
partial-thickness, 186
postoperative infection in, **379–380**
psychologic implications of, 192
superficial, 186
Wryneck, 1632b–1633b

X

Xalatan (latanoprost), 432t
Xalkori (crizotinib), 208t
Xarelto (rivaroxaban), 950t
Xeljanz. *See* Tofacitinib
Xenical (orlistat), 1041b
Xerostomia, 592
Xgeva (denosumab), 1692b
X-linked disorders, 202
X-linked gene, 200t
X-linked recessive disorders, 203, 203t
Xolair (omalizumab), 648b–650b
Xopenex (levalbuterol), 648b–650b
X-rays
basic, 1634t–1635t
chest, 534t–535t, 788t–790t, 790–791, 791f
in TB, 606
kidneys, ureters, bladder (KUB), 1190t–1192t
lower gastrointestinal series, 1001–1002, 1002t–1005t, 1006f
skeletal, 711t–712t
skull, 1479t–1480t
small bowel series, 1002t–1005t
spine, 1479t–1480t
upper gastrointestinal series, 1001, 1002t–1005t
Xtandi (enzalutamide), 1447b
Xyzal (levocetirizine), 582b–583b

Y

Y-linked disorders, 202
Young-old adult, 66

Z

Zafirlukast (Accolate), 582b–583b, 647–666, 648b–650b
Zanaflex (tizanidine), 133t
Zaroxolyn (metolazone), 808b
Zegerid (omeprazole and sodium bicarbonate), 1060b
Zenker diverticulum, 1065
Zeroing, 781
Zestril (lisinopril), 806b–807b, 834b–835b
Zetia (ezetimibe), 828b–829b
Ziagen (abacavir), 208t
Zileuton (Zyflo), 582b–583b, 647–666, 648b–650b
Zinc deficiency, 188t
Zocor (simvastatin), 827b
Zofran (ondansetron), 361b, 1052b
Zoladex (goserelin), 1447b
Zoledronic acid (Reclast, Zometa), 755, 755b, 1692b
Zollinger-Ellison syndrome, 1069
Zometa (zoledronic acid), 1692b
Zontivity (vorapaxar), 834b–835b
Zonule, 410
Zyban (bupropion), 165, 165b–166b
Zyflo (zileuton), 582b–583b, 647–666, 648b–650b
Zygomatic arch fracture, 1663t
Zyrtec (cetirizine), 582b–583b
Zytiga (abiraterone), 1447b

ABBREVIATIONS

ABG	arterial blood gas
ACE	angiotensin-converting enzyme
ACLS	advanced cardiac life support
ACS	acute coronary syndrome
ACTH	adrenocorticotropic hormone
ADH	antidiuretic hormone
AED	automatic external defibrillator
AIDS	acquired immunodeficiency syndrome
AKA	above-knee amputation
AKI	acute kidney injury
ALI	acute lung injury
ALL	acute lymphocytic leukemia
ALS	amyotrophic lateral sclerosis
AMI	acute myocardial infarction
ANA	antinuclear antibody
ANS	autonomic nervous system
AORN	Association of periOperative Room Nurses
APD	automated peritoneal dialysis
aPTT	activated partial thromboplastin time
ARDS	acute respiratory distress syndrome
ATN	acute tubular necrosis
BCLS	basic cardiac life support
BKA	below-knee amputation
BMI	body mass index
BMR	basal metabolic rate
BMT	bone marrow transplantation
BPH	benign prostatic hyperplasia
BSE	breast self-examination
BUN	blood urea nitrogen
CABG	coronary artery bypass graft
CAD	coronary artery disease; circulatory assist device
CAPD	continuous ambulatory peritoneal dialysis
CAVH	continuous arteriovenous hemofiltration
CBC	complete blood count
CCU	coronary care unit; critical care unit
CDC	Centers for Disease Control and Prevention
CIS	carcinoma in situ
CKD	chronic kidney disease
CLL	chronic lymphocytic leukemia
CML	chronic myelocytic leukemia
CMP	cardiomyopathy
CN	cranial nerve
CNS	central nervous system
CO	cardiac output
COPD	chronic obstructive pulmonary disease
CPAP	continuous positive airway pressure
CPR	cardiopulmonary resuscitation
CRRT	continuous renal replacement therapy
CRNA	certified registered nurse anesthetist
CSF	cerebrospinal fluid
CT	computed tomography
CVA	cerebrovascular accident; costovertebral angle
CVAD	central venous access device
CVI	chronic venous insufficiency
CVP	central venous pressure
D&C	dilation and curettage
DDD	degenerative disk disease
DI	diabetes insipidus
DIC	disseminated intravascular coagulation
DJD	degenerative joint disease
DKA	diabetic ketoacidosis
DM	diabetes mellitus; diastolic murmur
DRE	digital rectal examination
DVT	deep vein thrombosis
ECF	extracellular fluid
ECG	electrocardiogram
ED	emergency department; erectile dysfunction
EEG	electroencephalogram
EMG	electromyogram
EMS	emergency medical services
ENT	ear, nose, and throat
ERCP	endoscopic retrograde cholangiopancreatography
ERT	estrogen replacement therapy
ESKD	end-stage kidney disease
ESR	erythrocyte sedimentation rate
ET	endotracheal
FEV	forced expiratory volume
FRC	functional residual capacity
FUO	fever of unknown origin
GCS	Glasgow Coma Scale
GERD	gastroesophageal reflux disease
GFR	glomerular filtration rate
GH	growth hormone
GI	glycemic index
GTT	glucose tolerance test
GU	genitourinary
GYN, Gyn	gynecologic
HAI	health care–associated infection
HAV	hepatitis A virus
Hb, Hgb	hemoglobin
HBV	hepatitis B virus
Hct	hematocrit
HCV	hepatitis C virus
HD	hemodialysis, Huntington's disease
HDL	high-density lipoprotein
HF	heart failure
HIV	human immunodeficiency virus
H&P	history and physical examination
HPV	human papillomavirus
HSCT	hematopoietic stem cell transplantation
IABP	intraaortic balloon pump
IBS	irritable bowel syndrome
ICP	intracranial pressure
I&D	incision and drainage
IE	infective endocarditis
IFG	impaired fasting glucose
IGT	impaired glucose tolerance
INR	international normalized ratio
IOP	intraocular pressure
IPPB	intermittent positive-pressure breathing
ITP	idiopathic thrombocytopenic purpura
IUD	intrauterine device
IV	intravenous
IVP	intravenous push; intravenous pyelogram
JVD	jugular venous distention
KS	Kaposi sarcoma
KUB	kidney, ureters, and bladder (x-ray)
KVO	keep vein open
LAD	left anterior descending

LDL	low-density lipoprotein
LGV	lymphogranuloma venereum
LLQ	left lower quadrant
LMN	lower motor neuron
LMP	last menstrual period
LOC	level of consciousness; loss of consciousness
LP	lumbar puncture
LUQ	left upper quadrant
LVH	left ventricular hypertrophy
MAP	mean arterial pressure
MD	muscular dystrophy
MDS	myelodysplastic syndrome
MG	myasthenia gravis
MI	myocardial infarction
MICU	medical intensive care unit
MODS	multiple organ dysfunction syndrome
MRB	manual resuscitation bag
MS	multiple sclerosis
MVP	mitral valve prolapse
NAFLD	nonalcoholic fatty liver disease
NANDA-I	North American Nursing Diagnosis Association—International
NAP	nursing assistive personnel
NASH	nonalcoholic steatohepatitis
NG	nasogastric
NHL	non-Hodgkin's lymphoma
NPO	nothing by mouth
NS	normal saline
NSR	normal sinus rhythm
OA	osteoarthritis
OD	right eye; optical density; overdose
OOB	out of bed
OR	operating room
ORIF	open reduction and internal fixation
OS	left eye
OSA	obstructive sleep apnea
OTC	over-the-counter
PA	posteroanterior; physician's assistant
PAC	premature atrial contraction
$PaCO_2$	partial pressure of carbon dioxide in arterial blood
PACU	postanesthesia care unit
PAD	peripheral artery disease
PaO_2	partial pressure of oxygen in arterial blood
PAP	pulmonary artery pressure
PAWP	pulmonary artery wedge pressure
PCA	patient-controlled analgesia
PCI	percutaneous coronary intervention
PCWP	pulmonary capillary wedge pressure
PD	Parkinson's disease; peritoneal dialysis
PE	pulmonary embolism; physical examination
PEEP	positive end-expiratory pressure
PEFR	peak expiratory flow rate
PERRLA	pupils equal, round, and reactive to light and accommodation
PET	positron emission tomography
PICC	peripherally inserted central catheter
PID	pelvic inflammatory disease
PKD	polycystic kidney disease
PMH	past medical history
PMI	point of maximal impulse
PMS	premenstrual syndrome
PN	parenteral nutrition
PND	paroxysmal nocturnal dyspnea; postnasal drip
PNS	peripheral nervous system
PO, po	orally
POC	point-of-care
PPD	purified protein derivative
PSA	prostate-specific antigen
PSS	progressive systemic sclerosis
PT	prothrombin time
PTT	partial thromboplastin time
PUD	peptic ulcer disease
PVC	premature ventricular contraction
RA	rheumatoid arthritis
REM	rapid eye movement
RF	rheumatic fever
RHD	rheumatic heart disease
RLQ	right lower quadrant
RLS	restless legs syndrome
R/O	rule out
ROM	range of motion
ROS	review of systems
RUQ	right upper quadrant
SA	sinoatrial
SCI	spinal cord injury
SCD	sickle cell disease; sudden cardiac death
SDP	sleep-disordered breathing
SICU	surgical intensive care unit
SIRS	systemic inflammatory response syndrome
SLE	systemic lupus erythematosus
SNS	sympathetic nervous system
SOB	shortness of breath
STD	sexually transmitted disease
STSG	split-thickness skin graft
SVR	systemic vascular resistance
SVT	superficial vein thrombosis
TAH	total abdominal hysterectomy
TB	tuberculosis
TBSA	total body surface area
TCDB	turn, cough, and deep breathe
TENS	transcutaneous electrical nerve stimulation
THR	total hip replacement
TIA	transient ischemic attack
TJC	The Joint Commission
TKO	to keep open
TPR	temperature, pulse, and respirations
TURP	transurethral resection of the prostate
UA	unstable angina
UGI	upper gastrointestinal
UI	urinary incontinence
UMN	upper motor neuron
URI	upper respiratory infection
UTI	urinary tract infection
VAD	venous access device; ventricular assist device
VD	venereal disease
VF	ventricular fibrillation
VS	vital signs
VT	ventricular tachycardia
VTE	venous thromboembolism
WHR	waist-to-hip ratio
WNL	within normal limits
