Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner; the clinical treatments described and

recommended may not be considered absolute and universal recommendations.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with the current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in his or her clinical practice.

LWW.com

This book is lovingly dedicated to my husband Glenn, who is the wind beneath my wings, and I am thankful for his enduring love, encouragement, and confidence in me. Also to my children, Brian and Jennifer, who have always inspired me throughout their lives. And lastly, to my grandchildren—Leyton, Peyton, Alyssa, Wyatt, Michael, Rylan, and Brody who bring me life's greatest joys.

SUSAN SCOTT RICCI

This text is dedicated to my initial mentor into pediatric nursing, Gayle Maloney. She role-modeled and inspired my passion for excellence in the care of children and families. Thank you to my ever-faithful and consistently dedicated husband John and my amazing and delightful children, Christian and Caitlin.

TERRI KYLE

This book is dedicated to all the children out there and the wonderful nurses who care for them. They inspire me to become a better nurse, educator, and person. This book is also dedicated to my loving and supportive family. My husband Chris without whom I could not have reached this accomplishment. My four beautiful girls, Grace, Ella, Lily, and Maya, who have allowed me to learn firsthand about growth and development and who truly amaze me each and every day. My parents, Lene and Kishor Patel, who always taught me I could do whatever I put my mind to. To Terri Kyle, thank you for this opportunity, your endless support, and your incredible vision.

SUSAN CARMAN

About the Authors

Susan Scott Ricci

Susan Scott Ricci earned a diploma in nursing from the Washington Hospital Center School of Nursing, and went on to receive a BSN and MSN in Maternal—Infant Nursing, from the Catholic University of America in Washington, DC. She also obtained an MEd in Counseling from the University of Southern Mississippi, along with a recent national certification as a nurse educator. She has worked in a variety of women's health care settings, including labor and birth, postpartum, prenatal, and family planning ambulatory care clinics. Susan is a certified women's health care nurse practitioner who has spent 30+ years in nursing education teaching in LPN, ADN, and BSN programs. She is involved in several professional nursing organizations and holds application of knowledge within nursing practice.

Terri Kyle

Terri Kyle earned a Bachelor of Science in Nursing from the University of North Carolina at Chapel Hill and a Master of Science in Nursing from Emory University in Atlanta, Georgia. She is a certified pediatric nurse practitioner, and practicing pediatric nursing for over 30 years, she has had the opportunity to serve children and their families in a variety of diverse settings. Terri also holds the credential of certified nurse educator.

She has experience in inpatient pediatrics, in pediatric and neonatal intensive care units, newborn nursery, specialized pediatric units, and community hospitals. She has worked as a pediatric nurse practitioner in pediatric specialty clinics and primary care. She has been involved in teaching nursing for over 25 years with experience in both graduate and undergraduate education. Terri is a fellow in the National Association of Pediatric Nurse Practitioners and a member of the Sigma Theta Tau International Honor Society of Nursing, the National League for Nursing, and the Society of Pediatric Nurses.

With the limited time allotted to the topic of maternity and pediatric nursing in nursing programs, Terri recognized the need for a textbook that "got to the point." She strongly believes in a concept-based approach for learning nursing—that is, to teach the basics to students in a broad, contextual format so that they can apply that knowledge in a variety of situations. The concept-based approach to nursing education is time efficient for nursing educators and fosters the development of critical thinking skills in student nurses.

Susan Carman

Susan Carman earned a Bachelor of Science in Nursing from the University of Wisconsin-Madison and a Master of Science in Nursing and Master in Business Administration from the University of Colorado-Denver. As a pediatric nurse for

over 20 years, Susan has had the opportunity to care for children in a variety of diverse settings and in many of the major children's hospitals throughout the United States. She also has provided volunteer nursing care in a variety of settings including the Dominican Republic and India. She has been involved in teaching nursing for the past 15 years and enjoys watching students transform into competent nurses with strong critical thinking skills. She is a member of Sigma Theta tau and Beta Gamma Sigma.

Preface

Many nursing curricula combine and teach maternity and pediatrics in tandem. This can be viewed as a *natural fit* of two content areas that belong together. Nursing education in general is founded upon the principle of mastering simpler concepts first and incorporating those concepts into the student's knowledge base. The student is then able to progress to problem solving in more complex situations. In today's education climate with reduced class time devoted to specialty courses, it is particularly important for nursing educators to focus on key concepts, rather than attempting to cover everything within a specific topic.

The intent of *Maternity and Pediatric Nursing* is to provide the nurse the basis needed for sound nursing care of women and children. The content in the book will enable the reader to guide women and children toward higher levels of wellness throughout the life cycle. In addition, the focus of the textbook will allow the reader to anticipate, identify, and address common problems and provide timely, evidence-based interventions to reduce long-term sequelae.

This textbook is designed as a practical approach to understanding the health of women and children. The main objective is to help the student build a strong knowledge base and assist with the development of critical thinking skills. Women in our society are becoming empowered to make informed and responsible choices regarding their health and that of their children, but to do so they need the encouragement and support of nurses who care for them. This textbook focuses on women and children throughout their life span, covering a broad scope of topics with emphasis placed upon common issues. Maternity nursing content coverage is comprehensive, yet presented in a concise and straightforward manner. The pediatric nursing content presents the important differences when caring for children compared with caring for adults. A nursing process approach provides relevant information in a concise and nonredundant manner.[1] The content covered in the text arms the student or practicing nurse with essential information to care for women and their families, to assist them to make the right choices safely, intelligently, and with confidence.

Organization

Each chapter of *Maternity and Pediatric Nursing* focuses on a different aspect of maternity and/or pediatric nursing care. The book is divided into eleven units, beginning with general concepts related to maternity and pediatric nursing care, progressing from women's health, pregnancy and birth, through child health promotion and nursing management of alterations in children's health.

Unit 1: Introduction to Maternity and Pediatric Nursing

Unit 1 helps build a foundation for the student beginning the study of the care of

women, infants, and children. This unit explores contemporary issues and trends in maternity and pediatric nursing. Perspectives on women's health and pediatric nursing, core concepts of maternal and pediatric nursing, including, family-centered and atraumatic care, and communication, and community-based nursing are addressed.

Unit 2: Women's Health Throughout the Life Span

Unit 2 introduces the student to selected women's health topics, including structure and function of the reproductive system, common reproductive concerns, sexually transmitted infections, problems of the breast, and benign disorders and cancers of the female reproductive tract. This unit encourages the student to assist women in maintaining their quality of life, reducing their risk of disease, and becoming active partners with their health care professional.

Unit 3: Pregnancy

Unit 3 addresses topics related to normal pregnancy, including fetal development, genetics, and maternal adaptation to pregnancy. Nursing management during normal pregnancy is addressed, encouraging application of basic knowledge to nursing practice. Nursing management includes maternal and fetal assessment throughout pregnancy, interventions to promote self-care and minimize common discomforts, and patient education.

Unit 4: Labor and Birth

Unit 4 begins with an explanation of the normal labor and birth process, including maternal and fetal adaptations. This is followed by content focusing on the nurse's role during normal labor and birth, which includes maternal and fetal assessment, pharmacologic and nonpharmacologic comfort measures and pain management, and specific nursing interventions during each stage of labor and birth.

Unit 5: Postpartum Period

Unit 5 focuses on maternal adaptation during the normal postpartum period. Both physiologic and psychological aspects are explored. Paternal adaptation is also considered. This unit also presents related nursing management, including assessment of physical and emotional status, promoting comfort, assisting with elimination, counseling about sexuality and contraception, promoting nutrition, promoting family adaptation, and preparing for discharge.

Unit 6: The Newborn

Unit 6 covers physiologic and behavioral adaptations of the normal newborn. It also delves into nursing management of the normal newborn, including immediate assessment and specific interventions as well as ongoing assessment, physical examination, and specific interventions during the early newborn period.

Unit 7: Childbearing at Risk

Unit 7 shifts the focus to at-risk pregnancy, childbirth, and postpartum care. Pre-existing conditions of the woman, pregnancy-related complications, at-risk labor, emergencies associated with labor and birth, and medical conditions and

complications affecting the postpartum woman are all covered. Treatment and nursing management are presented for each medical condition. This organization allows the student to build on a solid foundation of normal material when studying the at-risk content.

Unit 8: The Newborn at Risk

Unit 8 continues to center on at-risk content. Issues of the newborn with birthweight variations, gestational age variations, congenital conditions, and acquired disorders are explored. Treatment and nursing management are presented for each medical condition. This organization helps cement the student's understanding of the material.

Unit 9: Health Promotion of the Growing Child and Family

Unit 9 provides information related to growth and development expectations of the well child from newborn through adolescence. Although not exhaustive in nature, this unit provides a broad knowledge base related to normal growth and development that the nurse can draw on in any situation. Common concerns related to growth and development and client/family education are included in each age-specific chapter.

Unit 10: Children and Their Families

Unit 10 covers broad concepts that provide the foundation for providing nursing care for children. Rather than reiterating all aspects of nursing care, the unit focuses on specific details needed to provide nursing care for children in general. The content remains focused upon differences in caring for children compared with adults. Topics covered in this unit include atraumatic care, anticipatory guidance and routine well child care (including immunization and safety), health assessment, nursing care of the child in diverse settings, including the hospital and at home, concerns common to special needs children, pediatric variations in medication and intravenous fluid delivery and nutritional support, and pain management in children.

Unit 11: Nursing Care of the Child With a Health Disorder

Unit 11 focuses on children's responses to health disorders. This unit provides comprehensive coverage of illnesses affecting children and is presented according to broad topics of disorders organized with a body systems approach. It also includes infectious, genetic, and mental health disorders as well as pediatric emergencies. Each chapter follows a similar format in order to facilitate presentation of the information as well as reduce repetition. The chapters begin with a nursing process overview for the particular broad topic, presenting differences in children and how the nursing process applies. The approach provides a general framework for addressing disorders within the chapter. Individual disorders are then addressed with attention to specifics related to pathophysiology, nursing assessment, nursing management, and special considerations. Common pediatric disorders are covered in greater depth than less common disorders. The format of the chapters allows for the building of a strong knowledge base and encourages critical thinking. Additionally, the format is nursing process driven and consistent from chapter to

chapter, providing a practical and sensible presentation of the information.

Recurring Features

In order to provide the instructor and student with an exciting and user-friendly text, a number of recurring features have been developed.

Key Terms

A list of terms that are considered essential to the chapter's understanding is presented at the beginning of each chapter. Each key term appears in boldface, with the definition included in the text. Key terms may also be accessed on thePoint.

Learning Objectives

Learning Objectives included at the beginning of each chapter guide the student in understanding what is important and why, leading the student to prioritize information for learning. These valuable learning tools also provide opportunities for self-testing or instructor evaluation of student knowledge and ability.

Words of Wisdom

Each chapter opens with inspiring Words of Wisdom (WOW), which offer helpful, timely, or interesting thoughts. These WOW statements set the stage for each chapter and give the student valuable insight into nursing care of women, children, and their families.

Threaded Case Studies

Real-life scenarios present relevant woman, child, and family information that are intended to perfect the student's caregiving skills. Questions about the scenario provide an opportunity for the student to critically evaluate the appropriate course of action.

Evidence-Based Practice

The consistent promotion of evidence-based practice is a key feature of the text. Throughout the chapters, pivotal questions addressed by current research have been incorporated into Evidence-Based Practice displays, which cite studies relevant to chapter content.

Healthy People 2020

Throughout the textbook, relevant *Healthy People 2020* objectives are outlined in box format. The nursing implications or guidance provided in the box serve as a roadmap for improving the health of women, mothers, and children.

Atraumatic Care

These highlights, located throughout the pediatric sections of the book, provide tips for providing atraumatic care to children in particular situations in relation to the topic being discussed.

Thinking About Development

The content featured in these boxes in chapters related to the care of children will

encourage student to think critically about special developmental concerns relating to the topic being discussed.

Teaching Guidelines

An important tool for achieving health promotion and disease prevention is health education. Throughout the textbook, Teaching Guidelines raise awareness, provide timely and accurate information, and are designed to ensure the student's preparation for educating women, children, and their families about various issues.

Consider This!

In every chapter the student is asked to *Consider This!* These first-person narratives engage the student in real-life scenarios experienced by their clients. The personal accounts evoke empathy and help the student to perfect caregiving skills. Each box ends with an opportunity for further contemplation, encouraging the student to think critically about the scenario.

Take Note!

The *Take Note!* feature draws the student's attention to points of critical emphasis throughout the chapter. This feature is often used to stress life-threatening or otherwise vitally important information.

Drug Guides

Drug guide tables summarize information about commonly used medications. The actions, indications, and significant nursing implications presented assist the student in providing optimum care to women, children, and their families.

Common Laboratory and Diagnostic Tests

The Common Laboratory and Diagnostic Tests tables in many of the chapters provide the student with a general understanding of how a broad range of disorders is diagnosed. Rather than reading the information repeatedly throughout the narrative, the student is then able to refer to the table as needed.

Common Medical Treatments

The Common Medical Treatments tables in many of the nursing management chapters provide the student with a broad awareness of how a common group of disorders is treated either medically or surgically. The tables serve as a reference point for common medical treatments.

Nursing Care Plans

Nursing Care Plans provide concrete examples of each step of the nursing process and are included in numerous chapters. The Nursing Care Plans summarize issue- or system-related content, thereby minimizing repetition.

Comparison Charts

These charts compare two or more disorders or other easily confused concepts. They serve to provide an explanation that clarifies the concepts for the student.

Nursing Procedures

Step-by-step Nursing Procedures are presented in a clear, concise format to facilitate competent performance of relevant procedures as well as to clarify pediatric variations when appropriate.

Icons

WATCH AND LEARN

A special icon throughout the book directs students to free video clips locate on thePoint that highlight growth and development, communicating with children, and providing nursing care to the child in the hospital.

CONCEPTS IN ACTION ANIMATIONS

These unique animations, also located on thePoint bring physiologic and pathophysiologic concepts to life and enhance student comprehension.

Tables, Boxes, Illustrations, and Photographs

Abundant tables and boxes summarize key content throughout the book. Additionally, beautiful illustrations and photographs help the student to visualize the content. These features allow the student to quickly and easily access information.

Key Concepts

At the end of each chapter, Key Concepts provide a quick review of essential chapter elements. These bulleted lists help the student focus on the important aspects of the chapter.

References and helpful Websites

References used in the development of the text are provided at the end of each chapter. These listings enable the student to further explore topics of interest. Many online resources are provided on thePoint as a means for the student to electronically explore relevant content material. These resources can be shared with women, children, and their families to enhance patient education and support.

Chapter Worksheets

Chapter worksheets at the end of each chapter assist the student in reviewing essential concepts. Chapter worksheets include:

- **Multiple Choice Questions**—These review questions are written to test the student's ability to apply chapter material. Questions cover maternal-newborn, women's health, and pediatric content that the student might encounter on the national licensing exam (NCLEX®).
- **Critical Thinking Exercises**—These exercises challenge the student to incorporate new knowledge with previously learned concepts and reach a satisfactory conclusion. They encourage the student to think critically, problem solve, and consider his or her own perspective on given topics.
- **Study Activities**—These interactive activities promote student participation in the learning process. This section encourages increased interaction/learning via

clinical, on-line, and community activities.

Teaching–Learning Package

Instructor's Resources

Tools to assist you with teaching your course are available upon adoption of this text on thePoint.

- An **E-Book** on thePoint gives you access to the book's full text and images online.
- A **Test Generator** that features hundreds of questions within a powerful tool to help the instructor create quizzes and tests.
- **PowerPoint presentations** with **Guided Lecture Notes** provide an easy way for you to integrate the textbook with our students' class-room experience, either via slide shows or handouts. Multiple choice and true/false questions are integrated into the presentations to promote class participation and allow you to use i-clicker technology.
- An **Image Bank** lets you use the photographs and illustrations from this textbook in your PowerPoint slides or as you see fit in your course.
- **Case Studies** with related questions (and suggested answers) give students an opportunity to apply their knowledge to a client case similar to one they might encounter in practice.
- **Pre-Lecture Quizzes** (and answers) are quick, knowledge-based assessments that allow you to check students' reading.
- **Discussion Topics** (and suggested answers) can be used as conversation starters or in online discussion boards.
- **Assignments** (and suggested answers) include group, written, clinical, and web assignments.
- Sample **Syllabi** provide guidance for structuring your pediatric nursing courses and are provided for four different course lengths: 4, 6, 8, and 10 weeks.
- **Journal Articles**, updated for the new edition, offer access to current research available in Lippincott Williams & Wilkins journals.

Contact your sales representative or check out LWW.com/Nursing for more details and ordering information.

Student Resources

An exciting set of free resources is available to help students review material and become even more familiar with vital concepts. Students can access all these resources on thePoint using the codes printed in the front of their textbooks.

- **NCLEX-Style Review Questions** for each chapter help students review important concepts and practice for NCLEX. **Over 700 questions** are included, more than twice as many as last edition!
- **Multimedia Resources** appeal to a variety of learning styles. Icons in the text direct readers to relevant videos and animations:
  - **Watch and Learn Videos** highlight growth and development, communicating with children, and providing nursing care to the child in the hospital.
  - **Concepts in Action Animations** bring physiologic and pathophysiologic concepts to life and enhance student comprehension.

- A **Spanish–English Audio Glossary** provides helpful terms and phrases for communicating with patients who speak Spanish.
- **Journal Articles** offer access to current research available in Lippincott Williams & Wilkins journals.

[1] Nursing Process Overview contains NANDA-I approved nursing diagnoses. Material related to nursing diagnoses is from Nursing Diagnoses—Definitions and Classification 2015-2017 © 2014, 2012 2009, 2007, 2005, 2003, 2001, 1998, 1996, 1994 NANDA International. Used by arrangement with Wiley-Blackwell Publishing, a company of John Wiley & Sons, Inc. In order to make safe and effective judgments using NANDA-I nursing diagnoses it is essential that nurses refer to the definitions and defining characteristics of the diagnoses listed in this work.

Contents in Brief

UNIT 1 INTRODUCTION TO MATERNITY AND PEDIATRIC NURSING

CHAPTER 1 Perspectives on Maternal and Child Health Care

CHAPTER 2 Family-Centered Community-Based Care

UNIT 2 Women's Health Throughout the Life Span

CHAPTER 3 Anatomy and Physiology of the Reproductive System

CHAPTER 4 Common Reproductive Issues

CHAPTER 5 Sexually Transmitted Infections

CHAPTER 6 Disorders of the Breasts

CHAPTER 7 Benign Disorders of the Female Reproductive Tract

CHAPTER 8 Cancers of the Female Reproductive Tract

CHAPTER 9 Violence and Abuse

UNIT 3 Pregnancy

CHAPTER 10 Fetal Development and Genetics

CHAPTER 11 Maternal Adaptation During Pregnancy

CHAPTER 12 Nursing Management During Pregnancy

UNIT 4 Labor and Birth

CHAPTER 13 Labor and Birth Process

CHAPTER 14 Nursing Management During Labor and Birth

UNIT 5 Postpartum Period

CHAPTER 15 Postpartum Adaptations

CHAPTER 16 Nursing Management During the Postpartum Period

Unit 1
Introduction to Maternity and Pediatric Nursing

1

Perspectives on Maternal and Child Health Care

WOW

Words of Wisdom

Being pregnant and giving birth is like crossing a narrow bridge: people can accompany you to the bridge, and they can greet you on the other side, but you walk that bridge alone. And the journey doesn't end there: children are the future of a society and special gifts to the world. Changes in our society and world require us to be attentive to and value them and their health.

KEY TERMS

Affordable Care Act (ACA)
assent
certified nurse midwife (CNM)
child abuse and neglect
childhood mortality rate
cultural competence
discipline

dissent
do not attempt resuscitate (DNAR) orders
doula

ethnocentrism
family structure
fetal mortality rate
foster care
infant mortality rate
maternal–fetal conflict
maternal mortality ratio
mature minor
morbidity
neonatal mortality rate
punishment
resilience
stem cells

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Analyze the key milestones in the history of maternal, newborn, and child health and health care.
2. Outline the evolution of maternal, newborn, and pediatric nursing.
3. Compare the past definitions of health and illness to the current definitions, as well as the measurements used to assess health and illness in children.
4. Assess the factors that affect maternal and child health.
5. Differentiate the structures, roles, and functions of the family and how they affect the health of women and children.
6. Evaluate how society and culture can influence the health of women, children, and families.
7. Appraise the health care barriers affecting women, children, and families.
8. Research the ethical and legal issues that may arise when caring for women, children, and families.

***Sophia Greenly,* a 38-year-old woman pregnant with her third child, comes to the prenatal clinic for a routine follow-up visit. Her mother, Betty, accompanies her because Sophia's husband is out of town. Sophia lives with her husband and two children, ages 4 and 9. She works part-time as a lunch aide in the local elementary school. What factors may play a role in influencing the health of Sophia and her family?**

INTRODUCTION

A person's ability to lead a fulfilling life and to participate fully in society depends largely on his or her health status. This is especially true for women, who commonly are responsible for not only their own health, but also that of others: their children and families. Thus, it is important to concentrate on the health of women, children, and families. Although the overall health of children has improved and the rates of death and illness in some areas have decreased, the need to focus on the health of women and children remains. Habits and practices established during pregnancy and early childhood can have profound effects on a person's health and illness throughout life. As a society, creating a population that cares about women, children, and families and promotes solid health care and lifestyle choices is crucial.

Maternity care is an integrated care process, which consists of different services (prenatal, intranatal, and postnatal), involves different professionals, and covers extended time frames. Maternal and newborn nursing encompasses a wide scope of practice typically associated with childbearing. It includes care of the woman before pregnancy, care of the woman and her fetus during pregnancy, care of the woman after pregnancy, and care of the newborn, usually during the first 6 weeks after birth. The overall goal of maternal and newborn nursing is to promote and maintain optimal health of the woman and her family. Providing quality maternity care includes client satisfaction and achieving best evidence-based outcomes with the fewest interventions. Child health nursing, commonly referred to as pediatric nursing, involves the care of the child from infancy through adolescence. In the United States, the number of children under age 18 years is approximately 73.6 million, accounting for 23.1% of the population (Federal Interagency Forum on Child and Family Statistics [FIFCFS], 2013). The overall goal of pediatric nursing practice is to promote and assist the child in maintaining optimal levels of health, while recognizing the influence of the family on the child's well-being. This goal involves health promotion and disease and injury prevention as well as assisting with care during illness. The common thread in both of these is the care of the family.

This chapter presents a general overview of the health care of women, children, and families and describes the major factors affecting maternal and child health. Nurses need to be knowledgeable about these concepts and factors to ensure that they provide professional care.

HISTORICAL DEVELOPMENT

The health care of women and children has changed over the years due in part to changes in childbirth methods, devastating epidemics, social trends in our country, changes in the health care system, and federal and state regulations. By reviewing historical events, nurses can gain a better understanding of the current and future status of maternal and child health and how maternal and pediatric nursing care has evolved.

The History of Maternal and Newborn Health and Health Care

Childbirth in colonial America was a difficult and dangerous experience. During the 17th and 18th centuries, women giving birth often died as a result of exhaustion, dehydration, infection, hemorrhage, or seizures (Foster, 2015). Approximately 50%

of all children died before age 5 (Norman, 2015), compared with the 0.06% **infant mortality rate** of today (Central Intelligence Agency, 2015).

There was a time when nearly every infant that came into this world was attended by a midwife. Centuries ago, "granny midwives" handled the normal birthing process for most women. They learned their skills through an apprenticeship with a more experienced midwife. Physicians usually were called only in extremely difficult cases, and all births took place at home. The rise of obstetrics in the 1800s drove midwifery to the periphery, but within the last century, midwifery has reemerged as an organized profession, appearing everywhere from home births to hospital labor units. Women who labored and gave birth at home were traditionally attended to by relatives and midwives. Having continuous support during childbirth yields better outcomes (see Evidence-Based Practice 1.1).

During the early 1900s, physicians attended about half the births in the United States. Midwives often cared for women who could not afford a doctor. Many women were attracted to hospitals because this showed affluence and they provided pain management, which was not available in home births. In the 1950s, "natural childbirth" practices advocating birth without medication and focusing on relaxation techniques were introduced. These techniques opened the door to childbirth education classes and helped bring the father back into the picture. Both partners could participate by taking an active role in pregnancy, childbirth, and parenting (Fig. 1.1).

Box 1.1 shows a time line of childbirth in America. In many ways, childbirth practices in the United States have come full circle, as we see the return of nurse midwives and **doulas**. Today, childbirth choices are often based on what works best for the mother, child, and family.

The History of Child Health and Child Health Care

In past centuries in the United States, the health of the country was poorer than it is today; mortality rates were high and life expectancy was short. Infectious diseases were rampant, and unsanitary food sources contributed to illness in children. Devastating epidemics of smallpox, diphtheria, scarlet fever, and measles hit children the hardest. During this period, the prevalent view was that children were a commodity; their role was to increase the population and share in the work to be done. This view changed over the years. Public schools were established and the court system began viewing children as minors. The health of children began to receive more and more attention.

EVIDENCE-BASED PRACTICE 1.1

CONTINUOUS SUPPORT FOR WOMEN DURING CHILDBIRTH

STUDY

Throughout history, women have been helping other women in labor by providing emotional support, comfort measures, information, and advocacy. However, in recent years this practice has waned, and facilities frequently adhere to strict specific routines that may leave women feeling "dehumanized." A study was done to assess the effects on mothers and their newborns of continuous, one-to-one intrapartum care in comparison

to usual care. The study also evaluated routine practices and policies in the birth environment that might affect a woman's autonomy, freedom of movement, and ability to cope with labor; who the caregiver was, whether or not a staff member of the facility; and when the support began, early or late in labor.

All published and unpublished randomized clinical trials (23) comparing continuous support during labor with usual care were examined involving 15,000 women. One author and one research assistant used standard methods for data collection and analysis and extracted the data independently. Clinical trial authors provided additional information. The researchers used relative risk for categorical data and weighted mean difference for continuous data.

Findings

Women receiving continuous intrapartum support had a greater chance of a spontaneous vaginal delivery (including without forceps or vacuum extraction). They also had a slight decrease in the length of labor and required less analgesia during this time. These women also reported increased satisfaction with their labor and childbirth experience. Overall, the support, when provided by someone other than a facility staff member and initiated early in labor, proved to be more effective.

Nursing Implications

Based on this research, it is clear that women in labor benefit from one-to-one support during labor. Nurses can use the information gained from this study to educate women about the importance of support persons during labor and delivery. Nurses can also act as client advocates in facilities where they work to foster an environment that encourages the use of support persons during the intrapartum period. The focus of nursing needs to be individualized, supportive, and collaborative with the family during their childbearing experience. In short, nurses should place the needs of the mother and her family first in providing a continuum of care.

Although the study found that support is more effective when provided by someone other than a staff member, support from an individual is essential. Assigning the same nurse to provide care to the couple throughout the birthing experience also fosters a one-to-one relationship that helps meet the couple's needs and promotes feelings of security. By meeting the couple's needs, the nurse is enhancing their birthing experience.

BOX 1.1

CHILDBIRTH IN AMERICA: A TIME LINE

1700s	Men did not attend births because it was considered indecent. Women faced birth not with joy and ecstasy but with fear of death. Female midwives attended the majority of all births at home.
1800s	There is a shift from using midwives to doctors among middle-class women. The word *obstetrician* was formed from the Latin, meaning "to stand before." Puerperal (childbed) fever was occurring in epidemic proportions. Louis Pasteur demonstrated that streptococci were the major cause of puerperal fever that was killing mothers after delivery. The first cesarean section was performed in Boston in 1894. The x-ray was developed in 1895 and was used to assess pelvic size for birthing purposes.
1900s	Twilight sleep (a heavy dose of narcotics and amnesiacs) was used on women during childbirth in the United States. The United States was 17th out of 20 nations in infant mortality rates. Of all women, 50–75% gave birth in hospitals by 1940. Nurseries were started because mothers could not care for their baby for several days after receiving chloroform gas. Dr. Grantley Dick-Reed (1933) wrote *Childbirth Without Fear,* which reduced the "fear-tension-pain" cycle women experienced during labor and birth. Dr. Fernand Lamaze (1984) wrote *Painless Childbirth: The Lamaze Method,* which advocated distraction and relaxation techniques to minimize the perception of pain. Amniocentesis was first performed to assess fetal growth in 1966. In the 1970s the cesarean section rate was about 5%. In 2011 it rose to 32%, where it stands currently. The 1970s and 1980s see a growing trend to return birthing back to the basics—nonmedicated, nonintervening childbirth. In the late 1900s, freestanding birthing centers—LDRPs—were designed, and the number of home births began to increase.
2000s	One in three women undergoes a surgical birth (cesarean). CNMs once again assist couples at home, in hospitals, or in freestanding facilities with natural childbirths. Research shows that midwives are the safest birth attendants for most women, with lower infant mortality and maternal rates, and fewer invasive interventions such as episiotomies and cesareans. Childbirth classes of every flavor abound in most communities. According to the latest available data, the United States ranks 48th in the world in maternal deaths. The maternal mortality ratio is approximately 28 in 100,000 live births. According to the latest available data, the United States ranks 55th in the world (compared to 224 other countries) in infant mortality rates. The infant mortality rate is approximately 6.17 in 1,000 live births.

Preventing primary cesarean births: Midwifery care. *Clinical Obstetrics and Gynecology, 58*(2), 282–293.

As the end of the 19th century neared, doctors and scientists gained a better

understanding of the root causes of illness. This knowledge helped fuel public health efforts such as the campaign for safe milk supply, which lead to pasteurizing milk and to dispensing free milk in some cities (U.S. Department of Health and Human Services [USDHHS], n. d.). Compulsory vaccination programs began during this time. In the late 1800s some states mandated smallpox vaccination as a condition of school attendance. These public health efforts led to a decrease in infant and child deaths (USDHHS, n. d.).

In the late 19th and early 20th centuries, cities became healthier places to live due to urban public health improvements such as sanitation services, treated municipal water, and improvements in hygiene (USDHHS, n. d.). Diseases such as diphtheria, cholera, polio, and yellow fever began to take less of a toll on children (USDHHS, n. d.). The turn of the 20th century brought new knowledge about nutrition, sanitation, bacteriology, pharmacology, medication, and psychology. Penicillin, corticosteroids, and increased numbers of vaccines, which were developed during this time, assisted with the fight against communicable diseases. Thus, by the end of the 20th century, unintentional injuries surpassed disease as the leading cause of death for children greater than 1-year old (Epstein, 2011).

Technologic advances have significantly affected all aspects of health care and led to increased survival rates in children. However, many children who survive illnesses that were previously considered fatal are left with chronic disabilities. For example, before the 1960s, extremely premature infants did not survive because of the immaturity of their lungs. Mechanical ventilation and the use of medications to foster lung development have increased survival rates in premature infants, but survivors are often faced with a myriad of chronic illnesses such as chronic lung disease (bronchopulmonary dysplasia), retinopathy of prematurity, cerebral palsy, or developmental delay. This increased survival has resulted in a significant increase in chronic illness relative to acute illness as a cause of hospitalization and mortality (Kelly, 2010).

In recent years advances in biomedicine have created a trend toward earlier diagnosis and treatment of disorders and diseases. Additionally, genetics have been linked with pathophysiologic processes. For example, female fetuses diagnosed with congenital adrenal hyperplasia, a genetic disorder resulting in a steroid enzyme deficiency leading to disfiguring anatomic abnormalities of sexual characteristics, are able to receive treatment before birth (Mayo Clinic Staff, 2015). In addition, early genetic defect identification allows for appropriate counseling.

In addition to improvement in technology and biomedicine, a number of national and international organizations have been formed in recent years to protect children's rights both in the United States and worldwide. These organizations focus on such issues as violence and abuse, child labor and soldiering, juvenile justice, child immigrants and orphaned children, and abandonment and homelessness—all of which have a negative impact on children's health. A child whose rights are restored and upheld has an improved opportunity for growth, development, education, and health.

The gains in child health have been huge but, unfortunately, these gains are not shared equally among all children. Certain health concerns such as asthma, obesity, poor nutrition, environmental toxin exposure, and learning or behavioral disorders affect poor children at higher rates than affluent and middle-class children (Seith & Isakson, 2011). Unintentional injuries continue to be the leading cause of death in

children greater than 1 year, but children's health remains threatened by illnesses and other health-related conditions in the 21st century (Centers for Disease Control and Prevention [CDC]/National Center for Health Statistics [NCHS], 2015). Obesity, environmental toxins, allergies, drug abuse, child abuse and neglect, and mental health problems are among some of the key issues that endanger children's health today.

Evolution of Maternal and Newborn Nursing

The history of maternity nursing is characterized by innovations that became common practice in later years. These innovations include fetal monitoring, mother/baby care, and early postpartum discharge. The driving forces behind changes in care within the social context of the times were scientific/medical developments and families' desires for the best possible childbearing experience.

Prior to World War II, American women moved from home to the hospital for childbirth in part because they were convinced that setting would improve birth outcomes. Hospitals were the major employers of maternity nurses. Early ambulation and rooming-in induced changes in the focus of care for the growing numbers of mothers and infants. Maternity nurses' focus shifted away from carrying out tasks and performing procedures to teaching mothers about self and infant care. Improved staffing patterns within hospitals meant longer hospital stays for the mothers, which allowed maternity nurses to spend more time with mothers for teaching purposes. Maternity nursing has changed dramatically since the Baby Boom era. The natural childbirth movement became a catalyst to bring about a change in nursing practice on the postpartum nursing units.

Other innovations that came later included breast-feeding and rooming-in to facilitate maternal–newborn bonding. Maternity nurses were then able to help the new mothers learn better how to care for their infants, to promote breast-feeding and bonding. The mid-1960s and early 1970s ushered in a consumer revolt which brought back home births, prepared childbirth, birth centers, the father's/partner's involvement in the birthing process, and nurse midwives—which had all but disappeared from the American health system (Stapleton & Rooks, 2015). Maternal–infant bonding became recognized as an essential part of postnatal care, and maternity nurses took a lead role to facilitate it.

With innovations becoming commonplace, maternity nursing practice has become more complex. How maternity nurses approach present-day challenges of increasing technology of birth, looming threats of litigation, and providing care under time and economic restraints is continuing to evolve.

A **certified nurse midwife (CNM)** has postgraduate training in the care of normal pregnancy and delivery and is certified by the American College of Nurse Midwives (ACNM). Midwives are primary care providers for women with a special emphasis on pregnancy, childbirth, and reproductive health. They are committed to providing ethical, individualized, evidence-based care for all women throughout their life cycle (American College of Nurse-Midwives, 2015).

A **doula** is a nonmedical birth companion who provides continuous emotional, physical, and educational support to the woman and family during childbirth and the postpartum period. Doulas do not perform clinical or medical tasks; they are there to comfort and support the mother and to enhance communication between

the mother and medical professionals (DONA International, n. d.). Many nurses working in labor and birth areas today are credentialed in their specialty so that they can provide optimal care to the woman and her newborn.

Evolution of Pediatric Nursing

In 1870, the first pediatric professorship for a physician was awarded in the United States to Abraham Jacobi, known as the father of pediatrics. For the first time, the medical community realized the need to provide specialized training and education about children to health care providers. In the early 1900s, Lillian Wald established the Henry Street Settlement House in New York City; this was the start of public health nursing. This facility provided medical and other services to poor families. These services included home nurse visits to teach mothers about health care.

During this time, health care personnel were trained to take care of children in hospitals, but parents of hospitalized children were discouraged from visiting to prevent the spread of infection. Restricting parents from being involved in their child's care was also thought to minimize emotional stress.

Nursing in public schools began in 1902 with the appointment of Lina Rogers as a full-time public school nurse in New York. A professional course in pediatric nursing was started in the early 1900s at Teachers' College of Columbia University.

In the 1960s, changes in the health care delivery system and shifts in the population's health status led to the development of the nurse practitioner role. Loretta Ford was the founder of the first nurse practitioner program. The 1970s brought cost-control systems from the federal government because of rapid escalation of health care expenditures. In addition, the considerable changes in the U.S. health care system in the 1980s have affected pediatric nursing and child health care. The emphasis of care was on quality outcomes and cost containment. Some of these changes brought more advanced practice nurses into the field of pediatrics.

In the 1980s, the Division of Maternal–Child Health Nursing Practice of the American Nurses Association developed maternal–child health standards to provide important guidelines for delivering nursing care.

In the 1990s the Health and Medicine Division published reports pointing out the need to improve quality and safety of the American health care system. This led to an increased focus on improving health care outcomes. As the health care environment continued to increase in complexity and patients hospitalized got sicker, programs were created for nurses to obtain a level of expertise and validate mastery of their skills and knowledge by passing a national standardized examination. Registered nurses and nurse practitioners can be certified in their specialty, such as pediatrics. These certifications show a commitment to lifelong learning and the ability to stay up to date in the rapidly changing health care environment. In recent years, pediatric nursing certifications have become increasingly specialized, such as a certified pediatric hematology/oncology nurse or a certified pediatric emergency nurse.

HEALTH STATUS OF WOMEN AND CHILDREN

At one time, health was defined simply as the absence of disease. Health was measured by monitoring the mortality and morbidity of a group. Over the past

century, however, the focus on health has shifted to disease prevention, health promotion, and wellness. The World Health Organization (WHO) (2015b) defines health as "a state of complete physical, mental, and social well-being, and not merely the absence of disease or infirmity." The definition of health is complex. It is not merely the absence of disease or an analysis of mortality and morbidity statistics.

In 1979, the US Surgeon General's Report, *Healthy People,* presented an agenda for the nation that identified the most significant preventable threats to health. With the series of updates that followed, including the present one, *Healthy People 2020,* the United States has a comprehensive health promotion and disease prevention agenda that is working toward improving the quantity and quality of life for all Americans (USDHHS, 2015). Overarching goals are to eliminate preventable disease, disability, injury, and premature death; achieve health equity, eliminate disparities, and improve the health of all groups; create physical and social environments that promote good health; and promote healthy development and behaviors across every stage of life (USDHHS, 2015). The principle behind this report is that setting national objectives and monitoring their progress can motivate action and change. In developing the health objectives, the report incorporates input from public health and prevention experts; federal, state, and local governments; over 2,000 organizations; and the public.

There are specific health topic areas, including women and children's health topics, which serve as a method for evaluation of progress made in public health. These topic areas also serve as focal points to coordinate the national health improvement efforts. For example, one objective under the physical activity topic is to increase the proportion of adolescents who meet current federal physical activity guidelines for aerobic physical activity and for muscle-strengthening activity (USDHHS, 2015). *Healthy People 2020* monitors four foundation health measures to assess the progress toward promoting health, preventing disease and disability, eliminating disparities, and improving quality of life (USDHHS, 2015). (See the *Healthy People 2020* feature for additional information on these health measures.)

Measuring health status is not always a simple process. For example, some women and children with chronic illnesses do not see themselves as "ill" if their disease is under control. A traditional method of measuring health is to examine mortality and morbidity data. This information is collected and analyzed to provide an objective description of the nation's health.

HEALTHY PEOPLE 2020

Four Foundation Health Measures

1. General Health Status
   - Measures include:
     - Life expectancy
     - Healthy life expectancy
     - Years of potential life lost
     - Physically and mentally unhealthy days
     - Self-assessed health status

    - Limitation of activity
    - Chronic disease prevalence
2. Health-Related Quality of Life and Well-Being
    - Measures include:
        - Physical, mental, and social health-related quality of life
        - Well-being/satisfaction
        - Participation in common activities
3. Determinants of Health (a range of personal, social, economic, and environmental factors that influence health status)
    - Include:
        - Biology
        - Genetics
        - Individual behavior
        - Access to health services
        - The environment in which people are born, live, learn, play, work, and age
4. Disparities
    - Measures include differences in health status based on:
        - Race/ethnicity
        - Gender
        - Physical and mental ability
        - Geography

U.S. Department of Health & Human Services, 2015.

Mortality

Mortality is the incidence or number of people who have died over a specific period. This statistic is presented as rates per 100,000 and is calculated from a sample of death certificates. The National Center for Health Statistics, under the DHHS, collects, analyzes, and disseminates the data on America's mortality rates.

Maternal Mortality

The **maternal mortality ratio** is the annual number of deaths from any cause related to or aggravated by pregnancy or its management (excluding accidental or incidental causes) during pregnancy and childbirth or within 42 days of termination of pregnancy, irrespective of the duration and site of the pregnancy, per 100,000 live births, for a specified year. In the United States, approximately 700 to 800 women die each year during pregnancy or shortly after childbirth. The rate of maternal mortality in the United States has more than doubled in the past few decades. A significant proportion of these deaths are preventable (Maron, 2015).

In the United States, the maternal mortality ratio is mixed depending on ethnic background. African American women suffer maternal mortality ratios far higher than any other ethnic group. The risk of maternal mortality has remained about three to four times higher among Black women when compared to White women during the past six decades. About 42.8 of 100,000 African American mothers die due to childbirth, as compared to much lower rates in Whites (12.5) and Hispanics (8.9) (CDC, 2015f). The federal government has pledged to improve maternal–child care outcomes and thus reduce mortality ratios for women and children by

endorsing the *Healthy People 2020,* but the WHO (2015c) data show that the United States ranks 48th in the world for maternal mortality. In fact, maternal mortality ratios are higher than almost all European countries, as well as several countries in Asia and the Middle East. For a country that spends more than any other country on health care and more on childbirth-related care than any other area of hospitalization, US $88 billion a year, this is a shockingly poor return on investment (Lu et al., 2015).

During the past several decades, mortality and morbidity have dramatically decreased as a result of an increased emphasis on hygiene, good nutrition, exercise, and prenatal care for all women. However, women are still experiencing complications at significant rates. The United States is one of the most medically and technologically advanced nations and has the highest per capita spending on health care in the world, but our current mortality rates indicate the need for improvement. For example:

- Approximately 700 to 800 women die each year in the United States as a result of pregnancy or a childbirth complication (CDC, 2015a).
- The United States ranks 48th (in other words, below 47 other countries) in rates of maternal deaths (deaths per 100,000 live births; WHO, 2015a).
- Most pregnancy-related complications are preventable. The leading causes of pregnancy-related mortality are hemorrhage, infection, preeclampsia–eclampsia, obstructed labor, and unsafe abortion (CDC, 2015e).

The maternal mortality and morbidity rates for African American women have been three to four times higher than for Whites (USDHHS, 2015). This major racial disparity has persisted for more than 60 years. Black women have at least double the risk of pregnancy-related death compared with White women. This striking difference in the pregnancy-related mortality ratio is the largest disparity in the area of maternal and child health. Researchers do not entirely understand what accounts for this disparity, but some suspected causes of the higher maternal mortality rates for minority women include low socioeconomic status, limited or no insurance coverage, bias among health care providers (which may foster distrust), and quality of care available in the community. Language and legal barriers may also explain why some immigrant women do not receive good prenatal care. Lack of care during pregnancy is a major factor contributing to a poor outcome. Prenatal care is well known to prevent complications of pregnancy and to support the birth of healthy infants, but not all women receive the same quality and quantity of health care during pregnancy. Pregnancy-related mortality is on the rise in the United States. The *Healthy People 2020* goal for maternal deaths is 11.4 per 100,000 live births (USDHHS, 2015). Black women had higher degrees of hypertension and lower hemoglobin levels on admission and had presented for prenatal care much later, on average, than White women or not at all (Stallings, 2015).

The CDC (2015f) has noted that the disparity in maternal mortality rates between women of color and White women represents one of the largest racial disparities among public health indicators. Eliminating racial and ethnic disparities in maternal–child health care requires enhanced efforts at preventing disease, promoting health, and delivering appropriate and timely care. The CDC has called for more research and monitoring to understand and address racial disparities, along with increased funding for prenatal and postpartum care. Research is needed to

identify causes and to design initiatives to reduce these disparities, and the CDC is calling on Congress to expand programs to provide preconception and prenatal care to underserved women.

Fetal Mortality

The **fetal mortality rate** or fetal death rate refers to the spontaneous intrauterine death of a fetus at any time during pregnancy per 1,000 live births. Fetal deaths later in pregnancy (>20 weeks of gestation) are also referred to as stillbirths. Fetal mortality may be attributable to maternal factors (e.g., malnutrition, disease, or preterm cervical dilation) or fetal factors (e.g., chromosomal abnormalities or poor placental attachment).

Fetal mortality is a major, but often overlooked, public health problem. Fetal mortality refers to spontaneous intrauterine death at any time during pregnancy. The fetal mortality rate in the United States is 6.2 per 1,000 live births (CDC, 2015c). *Healthy People 2020's* goal is to reduce it to 5.6 fetal deaths (USDHHS, 2015). Much of the public concern regarding reproductive loss has concentrated on infant mortality, as less is known about fetal mortality. However, the impact of fetal mortality on United States families is considerable, as it provides an overall picture of the quality of maternal health and prenatal care.

Neonatal and Infant Mortality

The **neonatal mortality rate** is the number of infant deaths occurring in the first 28 days of life per 1,000 live births. The United States now ranks 41st in the world in terms of neonatal mortality, the death rate of infants less than 1-month old. The neonatal mortality rate is 4.5 per 1000 live births (World Bank, 2015c). *Healthy People 2020's* goal is to reduce it to 4.1 per 1000 live births (USDHHS, 2015). Each year the deaths of 2 million babies are linked to complications during birth or within the first month. Furthermore, the burden is inequitably carried by the poor. Evidence-based strategies are urgently needed to reduce the burden of intrapartum-related deaths and effective interventions to address these problems must be incorporated into policy decisions (Oza et al., 2015). The reliability of the neonatal mortality estimates depends on accuracy and completeness of reporting and recording of births and deaths. Underreporting and misclassification are common, especially for deaths occurring early on in life.

Perinatal mortality encompasses late and early neonatal mortality and is defined as the number of stillbirths and deaths in the first week of life per 1,000 live births; it is also a useful indicator. The perinatal mortality is the sum of the fetal mortality and the neonatal mortality. Work is ongoing to improve estimates of stillbirth rates, a major component of perinatal mortality (WHO, 2015c).

The infant mortality rate is the number of deaths occurring in the first 12 months of life (Fig. 1.2). It also is documented as the number of deaths of infants younger than 1 year of age per 1,000 live births. Neonatal mortality and post neonatal mortality (covering the remaining 11 months of the first year of life) are reflected in the infant mortality rate. The infant mortality rate is used as an index of the general health of a country. Generally, this statistic is one of the most significant measures of children's health. The current infant mortality in the United States is 6.17 per 1000 live births (World Bank, 2015b).

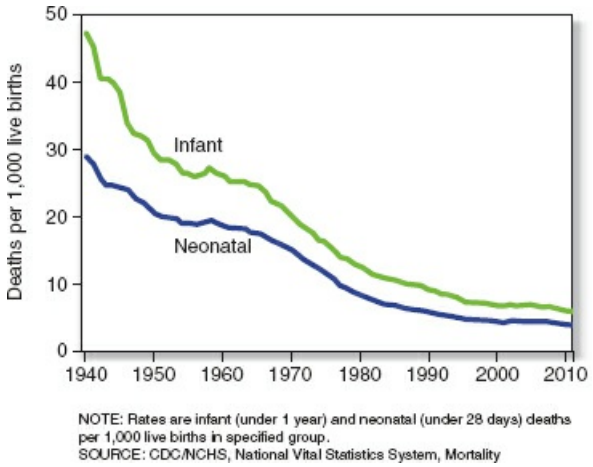

FIGURE 1.2 Infant and neonatal mortality from 1940 to 2011. (Adapted from Kochanek, K. D., Sherry, L., Murphy, S. L., & Xu, J. Q. (2015). Deaths: Final data for 2011. *National Vital Statistics Reports, 63*(3). Hyattsville, MD: National Center for Health Statistics. Retrieved from http://www.cdc.gov/nchs/data/nvsr/nvsr63/nvsr63_03.pdf.)

The infant mortality rate varies greatly from state to state as well as between ethnic groups. The United States has one of the highest gross national products in the world and is known for its technologic capabilities, but its infant mortality rate is much higher, in some cases double, than most other developed nations (Gissler, 2015). In 2014, the United States ranked 28th in infant mortality rates among industrialized nations (MacDorman et al., 2014). The main causes of early infant death in the United States include problems occurring at birth or shortly thereafter, such as prematurity, low birthweight, congenital and chromosomal anomalies, sudden infant death syndrome (SIDS), respiratory distress syndrome, unintentional injuries, bacterial sepsis, and necrotizing enterocolitis (Osterman et al., 2015).

Take Note!

Non-Hispanic, African American infants have consistently had higher infant mortality rates than other ethnic groups (Bediako, BeLue, & Hillemeier, 2015).

Congenital anomalies remain the leading cause of infant mortality in the United States (Egbe et al., 2015). In addition, low birthweight and prematurity are major indicators of infant health and significant predictors of infant mortality (Griffin et al., 2015). The lower the birthweight, the higher the risk of infant mortality. The percentage of infants born preterm in the United States is increasing, thus the impact of preterm-related causes of infant death has increased. Therefore, the high incidence of low birthweight (<2,500 g) in the United States is a significant reason why its infant mortality rate is higher than that of many other countries (March of Dimes, 2014).

After birth, other health promotion strategies can significantly improve an infant's health and chances of survival. Breast-feeding has been shown to reduce rates of infection in infants and to improve their long-term health. Human milk also reduces the risk for allergic and autoimmune diseases, and the risk of obesity and its complications (Wilson et al., 2016). Emphasizing the importance of placing an infant on his or her back to sleep will reduce the incidence of SIDS. In addition, parents/partners should not share a bed with an infant younger than 12 weeks old and should avoid exposing the infant to tobacco smoke (Adams, Ward, & Garcia,

2015). Encouraging mothers to join support groups to prevent postpartum depression and learn sound child-rearing practices will improve the health of both mothers and their infants.

Childhood Mortality

The **childhood mortality rate** is the number of deaths per 100,000 population in children 1 to 14 years of age. The childhood mortality rate in the United States has decreased significantly since 1980 but disparities by gender, age, race, and ethnicity persist (Child Trends DataBank, 2015a). The current mortality rate for children between ages 1 and 4 years is 25.5 per 100,000, with the leading cause of death being unintentional injuries followed by congenital malformations (CDC/NCHS, 2015). The mortality rate for children of ages 5 to 14 years is 13 per 100,000, with the leading cause being unintentional injuries followed by cancer (CDC/NCHS, 2015). Other causes of childhood mortality include suicide, homicide, diseases of the heart, influenza, and pneumonia.

Even as research continues into the preventable nature of childhood injuries, unintentional injury (e.g., motor vehicle accidents, fires, drowning, bicycle or pedestrian accidents, poisoning, falls) remains a leading cause of mortality and morbidity in children. These injuries have far-reaching consequences for children, families, and society in general. Risk factors associated with childhood injuries include young age, male gender, low socioeconomic status, parents who are unmarried or single, low maternal education level, poor housing, parental drug or alcohol abuse, and low support within the family. These deaths can often be prevented through education about the value of using car seats and seat belts, the dangers of driving under the influence of alcohol and other substances, and the importance of pedestrian and bicycle safety, fire safety, water safety, and home safety.

Take Note!

In the United States, American Indian/Alaska Natives children, followed by African American children, have the highest unintentional injury death rate (Gilchrist, Ballesteros, & Parker, 2012).

Morbidity

Morbidity is the measure of the prevalence of a specific illness in a population at a particular time. It is presented in rates per 1,000 population. Morbidity is often difficult to define and record because the definitions used vary widely. For example, morbidity may be defined as visits to the physician or diagnosis for hospital admission. Also, data may be difficult to obtain. Morbidity statistics are revised less frequently because of the difficulty in defining or obtaining the information.

Women's Health Indicators

Women today face not only diseases of genetic origin but also diseases that arise from poor personal habits. Even though women represent 51% of the population, only recently have researchers and the medical community focused on their special health needs. The USDHHS adopted the Health and Medicine Division's recommendations that eight preventive services for women be included in the defined list of preventive care services provided without cost sharing under the

Affordable Care Act (ACA) because they give women access to comprehensive preventive services to achieve health and wellness. Unfortunately, many women are unaware about what is covered, and thus don't take advantage of them. The National Women's Law Center (NWLC) has developed resources on well women visits to ensure that women are able to understand and access the preventive services now available to them under the ACA (Waxman & Johnson, 2015). A recent significant study identified an urgent need to improve women's access to health insurance and health care services, place a stronger emphasis on prevention, and invest in more research on women's health (National Women's Law Center, 2010). It identified 26 indicators of women's access to health care services, measuring the degree to which women receive preventive health care and engage in health-promoting activities (Box 1.2). The report card gave the nation an overall grade of "unsatisfactory," and not a single state received a grade of "satisfactory." In the 2010 National Report Card, the nation met three benchmarks since 2007: colorectal cancer screening, annual dental visits, and mammograms. However, the nation missed the other 23 benchmarks. Other substandard findings included the following:

- No state has focused enough attention on preventive measures, such as smoking cessation, exercise, nutrition, and screening for diseases.
- Too many women lack health insurance coverage: nationally, nearly one in five women has no health insurance.
- No state has adequately addressed women's health needs in the areas of reproductive health, mental health, and violence against women.
- Limited research has been done on health conditions that primarily affect women and that affect women differently than men (NWLC, 2010).

BOX 1.2

THE NATIONAL INDICATORS OF WOMEN'S HEALTH

- Lung cancer death rate
- Diabetes
- Heart disease death rate
- Binge drinking
- High school completion
- Poverty
- Wage gap
- Rate of AIDS
- Maternal mortality rate
- Rate of *Chlamydia* infection
- Breast cancer death rate
- Heart disease death rate
- Smoking
- Being overweight
- No physical activity during leisure time
- Eating five fruits and vegetables daily
- Colorectal screening
- Mammograms
- Pap smears

• First-trimester prenatal care
• Access to health insurance

Adapted from National Women's Law Center. (2010). *Making the grade on women's health: A national and state by state report card*. Washington, DC: National Women's Law Center.

Cardiovascular disease (CVD) is the number-one cause of death in women, regardless of racial or ethnic group. More women than men die each year from CVD. More than 500,000 women die annually in the United States of CVD—about one death per minute. More than 8.6 million women die from CVD globally each year (World Heart Federation [WHF], 2015). Women who have a heart attack are more likely than men to die. Heart attacks in women are often more difficult to diagnose than in men because of their vague and varied symptoms. Heart disease is still thought of as a "man's disease," and thus a heart attack may not be considered in the differential diagnosis when a woman presents to the emergency room.

Nurses need to look beyond the obvious "crushing chest pain" textbook symptom that heralds a heart attack in men. Risk factors of heart disease differ between men and women in several other ways—for example, menopause (associated with a significant rise in coronary events); diabetes, high cholesterol levels, and left ventricular hypertrophy; and repeated episodes of weight loss and gain (increased coronary morbidity and mortality) (WHF, 2015). Clinical manifestations of a heart attack observed in women include nausea, dizziness, irregular heartbeat, unusual fatigue, sleep disturbances, indigestion, anxiety, shortness of breath, pain or discomfort in one or both arms, and weakness (Brown, 2015). The prevalence, mortality, lack of warning signs in some women, and decreased awareness within this population make it imperative for nurses to assume an active role in assessing these clients, evaluating risk factors, and advocating for prevention of CVD in all women.

Cancer is a major public health problem in the United States and globally. It is the second leading cause of death among women, and is expected to surpass heart disease as the leading cause of death in the next few years (Siegel, Miller, & Jemal, 2015). Women have a one-in-three lifetime risk of developing cancer, and one out of every four deaths is from cancer (American Cancer Society [ACS], 2015a). Although much attention is focused on cancer of the reproductive system, lung cancer is the number-one killer of women. Lung cancer accounts for about 27% of all cancer deaths. More people die of lung cancer than of colon, breast, and prostate cancers combined. Lung cancer is largely the result of smoking and second-hand smoke. Lung cancer has no early symptoms, making early detection almost impossible. Thus, lung cancer has the lowest survival rate of any cancer; more than 90% of people who get lung cancer die of it (ACS, 2015c).

Breast cancer occurs in one in every seven women in a lifetime. It is estimated that in 2015 about 231,840 new cases of invasive breast cancer will be diagnosed among women in the United States. An estimated 40,290 women are expected to die from the disease in 2015 (ACS, 2015b). White women get breast cancer at a higher rate than African American women, but African American women are more likely to get breast cancer before they reach 40, and are more likely to die from it at any age. This is likely because the cancer is more advanced when it is found in African American women, and because survival at every cancer stage is worse among

African American women (ACS, 2015b).

Women living in North America have the highest rate of breast cancer in the world. At this time there are about 2.8 million breast cancer survivors in the United States. It is the most common malignancy in women and second only to lung cancer as a cause of cancer mortality in women (ACS, 2015b). Although a positive family history of breast cancer, aging, and irregularities in the menstrual cycle at an early age are major risk factors, other risk factors include excess weight or obesity, not having children, oral contraceptive use, excessive alcohol consumption, a high-fat diet, sedentary lifestyle, and long-term use of hormone therapy after menopause (ACS, 2015b). Breast cancer rates have dropped recently, possibly due to the decreased use of long-term menopausal hormone therapy that occurred after the Women's Health Initiative (WHI) report was released in 2002 and the Million Women Study in 2003 (Kyvernitakis et al., 2015). However, early detection and treatment continue to offer the best chance for a cure, and reducing the risk of cancer by decreasing avoidable risks continues to be the best preventive plan.

Pregnant women are by no means immune to any of the health issues presented thus far. Many women begin a pregnancy with existing health conditions, including hypertension, obesity, CVD, diabetes, inflammatory processes, autoimmune diseases, anemia, asthma, sexually transmitted infections, depression, or cancer. Although the majority of pregnant women are young and fairly healthy, the incidence of certain chronic health issues in them is increasing secondary to the obesity epidemic in the United States (Cancello, 2015).

Women's health is a complex issue, and no single policy is going to change the overall dismal state ratings. Although progress in science and technology has helped reduce the incidence of, and improve the survival rates for, several diseases, women's health issues continue to have an impact on our society. By eliminating or decreasing some of the risk factors and causes for prevalent diseases and illnesses, society and science could minimize certain chronic health problems. Focusing on the causes and effects of particular illnesses could help resolve many women's health issues of today.

Childhood Morbidity

In general, 56% of children in the United States enjoyed excellent health and 27% had very good health as reported in a summary of health statistics for children in 2011 (Bloom, Cohen, & Freeman, 2012). However, obesity, environmental toxins, allergies, drug abuse, child abuse and neglect, and mental health problems are among some of the key issues that endanger children's health today. Factors that may increase morbidity include homelessness, poverty, low birthweight, chronic health disorders, foreign-born adoption, attendance at daycare centers, and barriers to health care. For example, 21.8% of children live in poverty and have a higher incidence of disease, limited coordination of health services, and limited access to health care, except for visits to the emergency department (DeNavas-Walt, Proctor, & Smith, 2013). The overall poverty rate is 15%, which is the highest poverty rate since 1994 (DeNavas-Walt et al., 2013). However the poverty rate among African Americans and Hispanics is 27.2% and 26%, respectively. These children are particularly at increased risk for illness (DeNavas-Walt et al., 2013).

The most important aspect of morbidity is the degree of disability it produces, which is identified in children as the number of days missed from school or confined

to bed. In 2011, more than one quarter of schoolchildren, ages 5 to 17, did not miss any school due to illness or injury. However, approximately 5% missed 11 or more days of school because of injury or illness (Bloom et al., 2012).

Common health problems in children include respiratory disorders such as asthma; gastrointestinal disturbances, which lead to malnutrition and dehydration; and injuries. Asthma is the leading chronic disease in children affecting 14% of children in the United States (Bloom et al., 2012). Another 11% of children have respiratory allergies, 9% suffer from hay fever, 6% from food allergies, and 13% from skin allergies (Bloom et al., 2012). Diseases of the respiratory system, such as asthma and pneumonia, were the major cause of hospitalization for children of ages 1 to 9, while mental health disorders are the leading cause for children 10 to 14 years of age (USDHHS, Health Resources and Services Administration [HRSA], Maternal and Child Health Bureau [MCHB], 2013). In the United States during 2010, there were 3.5 hospital discharges for every 100 children (age 1 to 21 years) (USDHHS, HRSA, MCHB, 2013). Figure 1.3 shows the major causes of hospitalization by age in the United States.

As more immunizations become available, common childhood communicable diseases affect fewer children. The tracking of the leading topics from *Healthy People 2020* provides some positive information related to improving children's health. Improvements have occurred in child health but morbidity and disability from some conditions, such as asthma, diabetes, attention-deficit/hyperactivity disorder, and obesity, have increased in recent decades. Also, disparities in health status among children in the United States according to race and socioeconomic status demonstrate widening social inequalities.

One trend in the United States is the increasing number of children with mental health disorders and related emotional, social, or behavioral problems. The American Academy of Pediatrics (AAP) estimates that one in five children in the United States have mental health–related problems (American Academy of Pediatrics, n. d.; Office of Adolescent Health, 2015). These problems may limit the child's educational success. They also increase the child's risk for significant mental health problems later in life or emotional problems and possible use of firearms, reckless driving, promiscuous sexual activity, and substance abuse during adolescence. Overall, these behavioral, social, and educational problems can interfere with children's social and academic development. Often, insurance does not reimburse for these problems, leading to additional concerns such as lack of treatment.

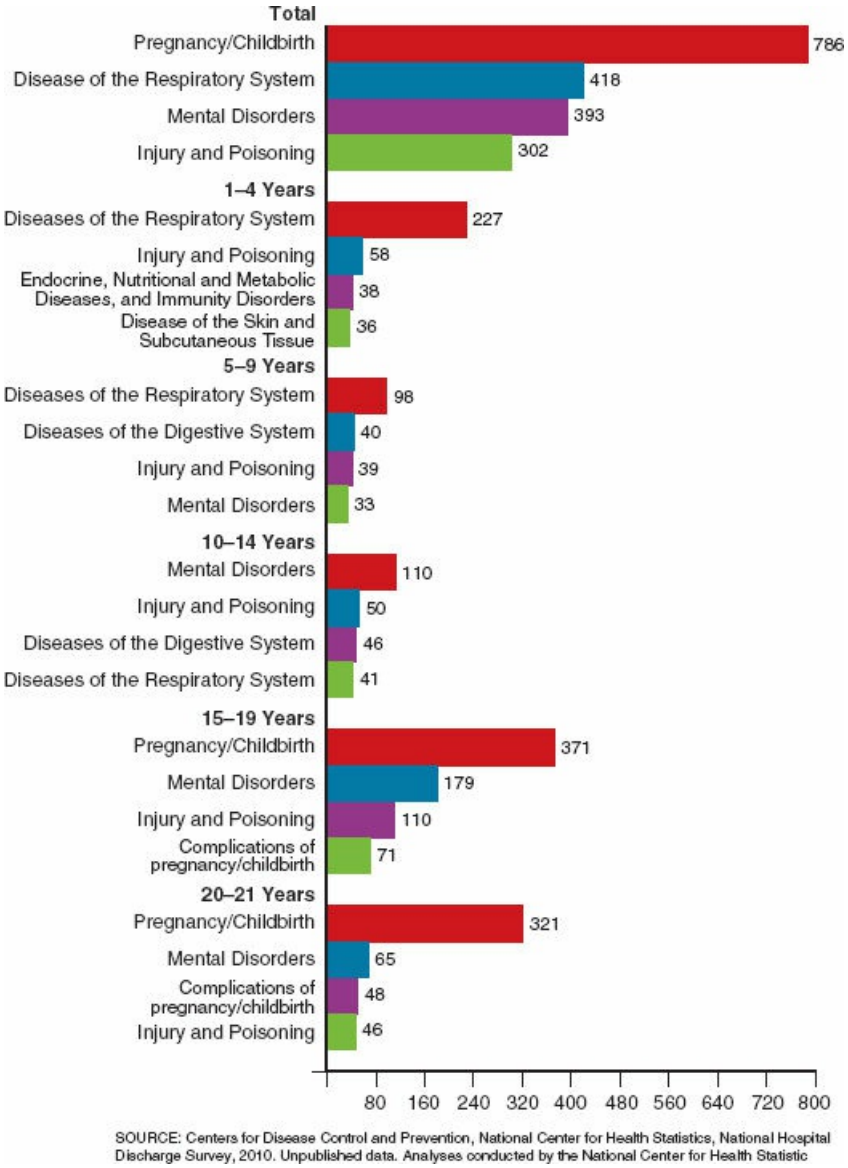

FIGURE 1.3 Causes of hospitalization in children, 2010. (From U.S. Department of Health and Human Services, Health Resources and Services Administration, Maternal and Child Health Bureau. (2013). *Child health USA 2012*. Rockville, MD: U.S. Department of Health and Human Services. Retrieved from http://mchb.hrsa.gov/chusa12/hs/hsc/downloads/img/hHa.gif.)

Environmental and psychosocial factors are now an area of concern in children.

These include academic difficulties, complex psychiatric disorders, self-harm and harm to others, use of firearms, hostility at school, substance abuse, HIV/AIDS, and adverse effects of the media.

FACTORS AFFECTING MATERNAL AND CHILD HEALTH

From conception, children are shaped by a myriad of factors, such as genetics and the environment. As members of a family, they are also members of a specific population, community, culture, and society. As they learn and grow, they are affected by multiple, complex, and ever-changing influences around them. For example, dramatic demographic changes in the United States have led to shifts in majority and minority population groups. Globalization has led to an international

focus on health. Access to health care and the types of health care available have changed due to modifications in health care delivery and financing. In addition, the United States is still grappling with issues such as immigration, poverty, environmental warming, homelessness, and violence (Alzola & Marino, 2015). The factors affecting maternal and child health discussed in this section include family, genetics, society, culture, health status and lifestyle, access to health care, improvements in diagnosis and treatments, and empowerment of health care consumers.

These factors may affect the person positively, by promoting healthy growth and development, or negatively, by increasing the person's health risks. Nurses, especially those working with women and children, need to understand how these influences affect the quality of nursing care and health outcomes. They must examine the impact of these variables to gain the knowledge and skills needed to plan effective care, thereby achieving the best possible outcomes for women, children, and families.

Family

The family is considered the basic social unit. The U.S. Census Bureau defines a family as a group of two or more persons related by birth, marriage, or adoption and living together (Vespa, Lewis, & Kreider, 2013). Earlier definitions of family emphasize the legal ties or genetic relationships of people living in the same household with specific roles. Given the diversity of families in today's society, however, some believe that family should be defined as whatever the client says it is (Holtzman, 2011; Patterson, 1995) (Fig. 1.4).

FIGURE 1.4 **Nurses must take into account family dynamics when providing health care. There are many different family structures, and they influence the client's needs. A. The traditional nuclear family is composed of two parents and their biologic or adopted children. B. The extended family includes the nuclear family plus other family members, such as grandparents, aunts, uncles, and cousins. C. Gay and lesbian families comprise two people of the same sex sharing a committed relationship with or without children.**

The family greatly influences the development and health of its members. For example, children learn health care activities, health beliefs, and health values from their family. The family's structure, the roles assumed by family members, and social changes that affect the family's life can influence the woman's and child's health status. Families are unique; each one has different views and requires distinct methods for support.

Various theories and models have been generated to explain the concept of family. They have influenced the definition of family, the understanding of the

structure and function of the family, and the way family coping and adaptation are assessed. Table 1.1 summarizes some of the major theories related to family.

Take Note!

The lifestyle of the parents basically is the lifestyle of the children. For instance, parents who are inactive and eat poorly will have children who do the same, and the problems associated with these unhealthy habits, such as diabetes, obesity, and early heart disease, are showing up earlier in children and adolescents. It is important for parents to serve as role models for proper nutrition and physical activity (through sports, hobbies, or other activities).

Family Structure

Family structure is the composition of people who interact with one another on a regular, recurring basis in socially sanctioned ways. It involves how the family unit is organized, which often influences the relationship of the members of the family. Family members can be gained or lost through events such as divorce, marriage, birth, death, abandonment, and incarceration. All of these events can alter the family structure, leading to roles being redefined or redistributed. Table 1.2 provides examples of the types of family structures found in today's society.

The traditional nuclear family is no longer considered the dominant family structure. From 1980 to 2012, the percentage of children who were living with their own married parents decreased steadily from 77% to 64% (FIFCFS, 2013). By understanding clients' family structure and any changes that may occur, nurses can provide them with support to alleviate or prevent dysfunctional alterations in family coping and adaptation.

Families today face complex challenges as they try to nurture, develop, and socialize their members. Family structure changes such as divorce, blending families, adoption, or **foster care** can have wide-ranging and lifelong effects. These special situations require astute assessment and proactive intervention to minimize the risk to the family.

DIVORCED FAMILY

Divorce is a common reason why the family structure changes. Today, over 40% of marriages end in divorce and many of these marriages include children (Serwint, 2011). Divorce can have a great impact on the child, with chronic and devastating results. Typically, divorce is not a single event. Changes have most likely been occurring in the family for years, and children may have been exposed to turmoil, violence, or changes in structure before the actual divorce. Children feel scared and confused by the threat divorce poses on their security. The initial response of children to divorce depends on their age; problems are most apparent the year after the divorce and diminish over the next couple of years (Kim, 2011). However, regardless of family type, children whose parents had a hostile interparental relationship during the marriage tended to have poorer emotional well-being than children whose parents had a nonhostile relationship (Baxter, Weston, & Lixia, 2011).

Parents need to understand the impact that divorce can have on their children so that they can place the children's interests in the forefront. The loss of a parent through divorce can leave children vulnerable to physical and mental illnesses (American Academy of Child and Adolescent Psychiatry [AACAP], 2012a).

However, by appropriately utilizing family strengths and providing care and attention, children can be helped to deal constructively with divorce (AACAP, 2012a). Parents can use the rules in Box 1.3 to help reduce tension and conflict, thereby minimizing the impact of separation and divorce on their children. Health care providers can offer support, guidance, and resources to help make the strain of divorce easier on the entire family.

SINGLE-PARENT FAMILIES

Single-parent families can result from divorce or separation, death of a spouse, an unmarried woman raising her own child, or adoption by an unmarried man or woman. In 2014 approximately 64% of children under age 18 live with two married parents, with 24% living in mother-only households and 4% living with the father only (Child Trends Databank, 2015b). In addition, one in three children born in the United States is to a single mother (Bembry, 2011).

Single-parent families have several concerns that can affect the health of the children. Life in a single-parent household can be stressful for both the adult and the children. The single parent may feel overwhelmed with no one to share the day-to-day responsibilities of juggling the care of the children, maintaining a job, and keeping up with the home and finances. These issues may be compounded by other pressures, such as custody problems, decreased time available to spend with children, continuing conflicts between parents who are separated or divorced, or changes in relationships with extended family members.

TABLE 1.1 SUMMARY OF MAJOR THEORIES RELATED TO FAMILY

Theory	Description	Key Components
Friedman's structural functional theory	Emphasizes the social system of family, such as the organization or structure of the family and how the structure relates to the function	Identified five functions of families: • Affective function: meeting the love and belonging needs of each member • Socialization and social placement function: teaching children how to function and assume adult roles in society • Reproductive role: continuing the family and society in general • Economic function: ensuring the family has necessary resources with appropriate allocation • Health care function: involving the provision of physical care to keep family healthy
Duvall's developmental theory	Emphasizes the developmental stages that all families go through, beginning with marriage; the longitudinal career of the family is also known as the family life cycle	Described eight chronologic stages with specific predictable tasks that each family completes: • Marriage: beginning of family • Childbearing stage • Family with preschool children • Family with school-age children • Family with adolescents • Family with young adults • Middle-age parents • Family in later years
Von Bertalanffy: general system theory applied to families	Emphasizes the family as a system with interdependent, interacting parts that endure over time to ensure the survival, continuity, and growth of its components; the family is not the sum of its parts but is characterized by wholeness and unity	Used to define how families interact with and are influenced by the members of their family and society and how to analyze the interrelationships of the members and the impact that change affecting one member will have on other members

Family stress theory	Addresses the way families respond to stress and how the family copes with the stress as a group and how each individual member copes	Described elements of stress as occurring internally within the family (e.g., values, beliefs, structure) that the family can control or change or externally from outside the family (e.g., culture of the surrounding community, genetics, the family's current time or place) over which the family has no control Mobilization of family resources resulting in either a positive response of constructive coping or negative response of a crisis Identified the main determinant of adequate coping based on the meaning of the stressful event to the family and its individual members
Resiliency model of family stress and family adjustment, and adaptation response model	Addresses the way families adapt to stress and can rebound from adversity	Identified the elements of risks and protective factors that aid a family in achieving positive outcomes

(2002). Integrating family resilience and family stress theory. *Journal of Marriage and Family, 64*(2), 349–360.

TABLE 1.2 TYPES OF FAMILY STRUCTURES

Structure	Description	Specific Issues
Nuclear family	Husband, wife, and children living in same household	May include natural or adopted children Once considered the traditional family structure; now decreased due to trends in divorce rates or other social situations such as nonmarital childbearing
Binuclear family	Child who is member of two families due to joint custody; parenting is considered a joint venture	Always works better when the interests of the child are put above the parents' needs and desires
Single-parent family	One parent responsible for care of children	May result from death, divorce, desertion, birth outside marriage, or adoption Likely to encounter several challenges because of economic, social, and personal restraints; one person as homemaker, caregiver, and financial provider
Commuter family	Adults in the family living and working apart for professional or financial reasons, often leaving the daily care of children to one parent	Similar to single-parent family, but without as much economic challenge
Step or blended family	Adults with children from previous marriages or from the new marriage	May lead to family conflict due to different expectations for the child and adults; may have different views and practices related to child care and health
Extended family	Nuclear family and grandparents, cousins, aunts, and uncles	Need to determine decision maker as well as primary caretaker of the children May be encouraged and supported by some cultures, such as Hispanic and Asian cultures

Same-sex family (also called homosexual or gay/lesbian family)	Adults of the same sex living together with or without children	May face prejudice against those with different lifestyles
Communal family	Group of people living together to raise children and manage household; unrelated by blood or marriage	May face prejudice against those with different lifestyles Need to determine the decision maker and caretaker of children
Foster family	A temporary family for children who are placed away from their parents to ensure their emotional and physical well-being	May include foster family's children and other foster children in the home Foster children are more likely to have unmet health needs and chronic health problems because they may have been living in a variety of settings (AAP, 2000)
Grandparents-as-parents families	Grandparents raising their grandchildren if parents are unable to do so	May increase the risk for physical, financial, and emotional stress on older adults May lead to confusion and emotional stress for child if biologic parents are in and out of the child's life
Adolescent families	Young parents still mastering the developmental tasks of their own childhood	Teenage girls have greater risk for health problems during pregnancy and delivery of premature infants, leading to risk of subsequent health and developmental problems Probably still need support from their family related to financial, emotional, and school issues

BOX 1.3

RULES FOR DIVORCING PARENTS

1. Tell your children about the divorce and the reasons for the divorce in terms that they can understand. Be sure that you and your spouse are present together when telling the children; tell all the children at the same time.
2. Reassure your children that the divorce is not their fault. Repeat this as often as possible and as necessary.
3. Inform the children well in advance of anyone moving out of the house (except when abuse is present or there are concerns for immediate safety).
4. Clearly inform the children about the family structure after the divorce, such as who will live with whom and where; also discuss visitation clearly and honestly.
5. Do not make your children be or act like adults. Seek support from other adults in your life.
6. Do not discuss money or finances with your children.
7. Minimize unpredictable schedules and maintain routines, rules, and discipline, and be consistent in this area.
8. Never force or allow your children to take sides.
9. Avoid belittling your former spouse when the children can hear. However, do not lie to cover up for irresponsible behavior by the other parent.
10. Never put your children in the middle between you and your ex-spouse.
11. Keep each parent involved in the child's life. Write letters, emails, phone calls, and text messages to continue communication. This shows the child they remain important to you even when they are with the other parent.
12. Communicate directly with the other parent. Avoid making the child your messenger.

Adapted from New, M. (2011). *Helping your child through divorce.* KidsHealth for Parents. Retrieved from http://kidshealth.org/parent/positive/talk/help_child_divorce.html#; and Kemp, G., Smith, M., & Segal, J. (2015). Children and divorce. Retrieved from http://www.helpguide.org/articles/family-divorce/children-and-divorce.htm.

Communication and support are essential to the optimal functioning of the single-parent family. The parent and children need to be able to express their feelings and work through the problems together. Single parents must provide greater support for their children. Even though a single parent may feel alone they need to ensure they treat their children as children and not a substitute for a partner. Support and comfort needs to come from outside resources. Community resources can be helpful. Parents Without Partners, for instance, is an international organization that has over 200 chapters in the United States and Canada. Links to these organizations' websites can be found under Web Resources on thePoint.

BLENDED FAMILIES

Before the age of 15, one third of children in the United States are anticipated to live in a stepfamily (Pew Research Center, 2011). Creating a blended family (parents and their stepchildren), even though considered a form of "normal" these days, can be stressful for the parents and children alike. Although it creates a structure and stability and reduces some of the financial stresses of single parenthood, making the transition to a blended family takes time. Children may feel jealous of the stepparent or feel disloyal toward the previous biologic parent. There may be competition or rivalry among the stepchildren. The child may fear that the stepparent is interfering with the child's relationship with the parent or taking away his or her source of love, affection, and attention.

Mutual respect and open, honest communication among all individuals involved are key, and this should include the previous biologic parent when possible. Responsibilities for parenting must be shared, including decisions about expectations, limits, and discipline. The continued role of the previous biologic parent and the role of the stepparent in the child's life are important to address.

ADOPTED FAMILIES

Adoption can occur domestically (through an agency or intermediary such as an attorney in the family's own area or country), or the family may choose to adopt a child from another country. The child may be of a different culture, race, or ethnicity (Fig. 1.5). Most children in need of adoption in the United States and overseas are not infants. In recent years there has been an increasing number of children adopted from the US child welfare systems and internationally (Simms & Wilson, 2011).

FIGURE 1.5 An adoptive family with children from a different culture.

The amount of contact between the child and the birth mother can vary greatly. In a closed adoption there is no contact between the adoptive parents, the adopted child, and the birth mother. In an open adoption there is as much contact among the individuals as desired. Regardless of the method used to adopt a child, adoptive families may be faced with unique issues. Some adopted children have complex medical, developmental, behavioral, educational, and psychological issues (Faver & Alanis, 2012). They may have been exposed to poverty, neglect, infectious diseases, and lack of adequate food, clothing, shelter, and nurturing, placing them at risk for medical problems, physical growth and development delays or abnormalities, and behavioral, cognitive, and emotional problems. The adoptive parents may know about these problems, but in other situations little if any history may be available.

Differences in culture, ethnicity, or race can further influence the adopted child's sense of identity (Faver & Alanis, 2012). Children may be subjected to racism or bigotry. Extended family members may not accept the child as part of the family. Parents need to emphasize that the adopted child is their child and is as much a part of the family as any other member. Parents need to openly recognize racial differences that exist between them and their child. Parents should encourage and assist the child to learn about their heritage, culture, and ethnic group (Jones et al., 2012). Adopted adolescents and adults may feel a need to identify their biologic parents. Children adopted from other countries may travel to the country of their birth, and children adopted domestically may search for biologic relatives. Although this search is an indicator of healthy emotional growth, it can upset the adoptive parents, who may feel rejected.

As the adopted child grows older, he or she may feel the loss of a birth family or may question what he or she did that led to the birth parents' decision to proceed with adoption. Attachment to the adoptive family is important. In order to attach in future relationships children must appropriately grieve past losses. This can be particularly complex and difficult for older children and children previously living in foster care or orphanages.

Take Note!

Adolescents face vast challenges adjusting to adoption at this age because of the added complexity of identity issues facing this age group (Jones et al., 2012).

Clear, open, honest communication and discussion are essential to promote a healthy, strong relationship. Support, guidance, and open communication are key for all parties involved. Open acknowledgment of the adoptive relationship helps to nurture trust, security, and a child's self-esteem as he or she learns to understand what it means to be part of a family through adoption (Jones et al., 2012).

The pediatric nurse needs to be sensitive, understanding, and supportive when interacting with adopted children and their families. "Positive" adoption language should be used. This includes saying "birth parent" when referring to biologic parents instead of "natural" or "real parent" and just parents when talking about adoptive parents (Jones et al., 2012). Also, do not refer to the child as their "adopted child" or other children as "natural child" (Jones et al., 2012). When discussing adoption using terms such as "make an adoption plan" instead of "give away" or "give up for adoption" are preferred (Jones et al., 2012). The nurse also needs to provide reassurance and understanding regarding missing health information and provide appropriate resources and referrals to resources that are knowledgeable about adoption and sensitive to the issues that may arise. Sources of information and support available are the Center for Adoption Support and Education and the North American Council on Adoptable Children, links to which are provided on thePoint.

FOSTER CARE FAMILY

Foster care is a situation in which a child is cared for in an alternative living situation apart from his or her parents or legal guardians. The child may be placed in this living situation due to difficulties in the family situation, such as abuse, neglect, abandonment, or the parents' inability to meet the child's needs, due to illness, substance abuse, or death. The child may be sent to live with relatives (kinship care) or foster parents, who are strangers providing protection and shelter in a state-approved foster home.

There are about 397,122 children in the United States currently living in some form of foster care (U.S. Department of Health and Human Services, Administration for Children & Families, Administration on Children, Youth and Families, Children's Bureau [USDHHS, ACF, ACYF, CB], 2013a). Since 2002 there has been a steady decline in children in foster care (USDHHS, ACF, ACYF, CB, 2013b). The goal of foster care is to provide temporary services until the child can return home to his or her family or be adopted. Unfortunately, children may remain in foster care for several years or longer and may be moved from one foster family to another.

Many children who are placed in foster care have been the victims of abuse or neglect. Children in foster care are more likely to exhibit a wide range of medical, emotional, behavioral, dental, educational, or developmental problems (Bernedo et al., 2012). However, children are very resilient and most children in foster care are determined to live their lives, but they may struggle with certain issues, including the following:

- Unmet health care needs
- Significant mental health problems, such as depression, social problems, anxiety, and posttraumatic stress disorder due to trauma, loss, and unpredictability
- Behavioral problems such as substance use, problems with the law, and self-destructive behaviors
- Interruptions in developmental stages and developmental delay

- Educational obstacles due to frequent moves and educational difficulties
- Self-blame and feelings of guilt
- Feelings of being unwanted
- Feelings of helplessness and powerlessness
- Insecurity about the future
- Ambivalent feelings related to foster parents; feelings of being disloyal to birth parents (Zlotnick, Tam, & Soman, 2012)

Individual attention to the child in foster care is essential. A multidisciplinary approach to care that includes the birth parents, foster parents, child, health care professionals, and support services is important to meet the child's needs for growth and development. Nurses play a key role in advocating for the child.

Family Roles and Functions

Regardless of the structure of the family, the role of the family in caring for the child includes not only providing physical and emotional care but also imparting the rules and expected behaviors of society through teaching and discipline techniques. These expected behaviors depend on the culture, values, and beliefs of the family and the child's developmental stage and physical and cognitive abilities. Roles and functions are further defined by each family's own traditions and values and the family's set of standards for interaction within and outside the family. For instance, some families may value privacy more than others. These family members may tend to be more self-protective and secretive.

CAREGIVER–CHILD INTERACTION

The caregiver–child interaction is critical to the survival and healthy development of a young child (WHO, 2012; Xu, 2011). Typically, the primary caregivers are the parents. Ideally, parents nurture their children and provide them with an environment in which they can become competent, productive, self-directed members of society. For young children in particular, growth, health, and their very personhood itself depend on the ability of the adults in their life to understand and respond to them (Groark & McCall, 2011; WHO, 2012).

PARENTAL ROLES

Parenting is an enormous responsibility and takes a lot of time as well as physical and mental energy. Parental roles are vast and numerous. Typical parental roles include nurturer/caregiver, financial provider, decision maker, schedule manager, financial manager, problem solver, counselor, teacher, behavior support and manager, and health manager.

CHANGES IN PARENTAL ROLES OVER TIME

Parental roles evolve due to societal and economic changes as well as individual family changes. Traditionally, the role of provider was assigned to the father. However, with increased numbers of women in the workplace and more households with two parents working, today both parents are often the providers as well as the nurturers to the children. Technologic innovations have provided parents with opportunities to work at home, allowing some parents to maintain the provider role while simultaneously fulfilling the nurturer and health manager roles. Fathers are

taking on greater responsibilities related to household management and child care. Also, the number of children being raised by their grandparents is increasing (AACAP, 2012b). Moreover, as baby boomers age, parents may find themselves caring for both their children and their aging parents.

Recall Sophia, the pregnant woman described at the beginning of the chapter. Identify the parental roles Sophia would assume. How might these roles be different from those of her mother when she was Sophia's age?

PARENTING STYLES

Beginning in the 1960s with Baumrind, a psychologist, and further research in the 1980s by Maccoby and Martin were the basis of the development of four major parenting styles seen in our society: authoritarian, authoritative, permissive, and uninvolved or rejecting-neglecting (as cited in Cherry, 2015). The styles are defined by the amount of support and control exerted over the child during parenting. Many parents may use more than one parenting style and may fall somewhere in between styles instead of adhering strictly to one style. Also some parents may change parenting styles as the child ages and matures. Whatever the style, sensitive and responsive caregiving is needed to promote appropriate physical, neurophysiologic, and psychological development (Beers, 2011). Nurses need to recognize different parenting styles and provide support to parents by discussing the effects of different parenting models and teaching parenting skills.

AUTHORITARIAN

The *authoritarian* parent expects obedience from the child and discourages the child from questioning the family's rules. The parent provides low support and high control over the child (Cherry, 2015). The rules and standards set forth by the parents are strictly enforced and firm. The parents expect the child to accept the family's beliefs and values and demand respect for these beliefs. The parents are the ultimate authority and allow little, if any, participation by the child in making decisions. Behavior that does not adhere to the family's rules and standards is punished. This parenting style is associated with negative effects on self-esteem, happiness and social skills, increased aggression, and defiance (Cherry, 2015; Hamon & Schrodt, 2012).

AUTHORITATIVE

The *authoritative* or democratic parent shows some respect for the child's opinions. Although parents still have the ultimate authority and expect the child to adhere to the rules, authoritative parents allow children to be different and believe that each child is an individual. They exhibit warmth and consistently, fairly, and firmly enforce the family's rules and standards without emphasizing punishment. This type of parenting is associated with increased independence, happiness, self-confidence, and socially responsible individuals (Cherry, 2015; Piko & Balázs, 2012).

PERMISSIVE

Permissive or laissez-faire parents have little control over the behavior of their

children. Rules or standards may be inconsistent, unclear, or nonexistent. Permissive parents allow their children to determine their own standards and rules for behavior. Discipline can be lax, inconsistent, or absent. Parents can be warm, cool, or uninvolved. There are more negative than positive effects associated with this style of parenting. Negative effects include children being impulsive, low happiness, poor school performance, problems with authority, lacking responsibility and independence (Cherry, 2015; Hamon & Schrodt, 2012).

UNINVOLVED OR REJECTING-NEGLECTING

Uninvolved parents are indifferent. They do not provide rules or standards. The child's basic needs are often met but the parent is disconnected from the child's life. In some cases the parents may neglect or reject the child. They can be cold and uninterested in meeting the child's needs. They minimize their interactions and time with the children. This type of parenting is associated with negative effects such as the child lacking interest in school, lacking interest in the future, and lacking emotional and self-control (Cherry, 2015). This type of parenting may also lead to lack of trust, low self-esteem, and anger toward others (Cherry, 2015; Kawabata et al., 2011).

DISCIPLINE

Much of parenting involves increasing desirable behavior and decreasing or eliminating undesirable behavior, a process generally known as **discipline**. There are various opinions in our society about the best or most effective method of discipline. Each child and family is unique. Discipline that works with one child or within one family may not work for another family. Discipline should focus on the development of the child while ensuring to preserve their self-esteem and dignity. It should be based on age-appropriate expectations with clear, consistent guidelines while offering meaningful choices when possible. Discipline involves teaching and it is ongoing, not something that is done just when the child misbehaves.

The AAP (2012a, 2015a) suggests three strategies for effective discipline (see also Teaching Guidelines 1.1):

- Maintaining a positive, supportive, nurturing caregiver–child relationship
- Using positive reinforcement to increase desirable behaviors
- Removing positive reinforcements or using punishment to reduce or eliminate undesirable behaviors

Teaching Guidelines 1.1

PROMOTING EFFECTIVE DISCIPLINE

- Set clear, consistent, and developmentally appropriate expected behaviors; offer choices whenever possible.
- Maintain consistency in responding to behaviors; provide encouragement and affection.
- Role-model appropriate behaviors.
- Provide an age-appropriate explanation of the consequence if the child demonstrates unacceptable behavior.

- Always administer the consequence soon after the unacceptable behavior.
- Keep the consequence appropriate to the age of the child and the situation.
- Stay calm but firm without showing anger when administering the consequence.
- Always praise the child for displaying appropriate behavior (positive reinforcement).
- Set the environment to assist the child in accomplishing the appropriate behavior; remove temptations that may lead to inappropriate behavior.
- Reinforce that the child's behavior was "bad" but the child was not "bad."
- Use extinction to reduce or eliminate reinforcement for an inappropriate behavior (e.g., ignore a temper tantrum).
- When using time-out, use 1 minute per year of the child's age. Do not exceed 5 minutes.
- Maintaining a positive, supportive, nurturing caregiver–child relationship
  - Using positive reinforcement to increase desirable behaviors
  - Using extinction or punishment to reduce or eliminate undesirable behaviors

POSITIVE REINFORCEMENT

Attention from parents is a very powerful form of positive reinforcement and can help increase desirable behaviors. The key is to focus on the child's appropriate behaviors rather than emphasize the inappropriate ones. Immediate, consistent, and frequent feedback is crucial. This feedback can be in the form of smiles, praise, special attention, or rewards such as extra privileges or a special token or activity. Providing the feedback immediately is important so that the child learns to associate the feedback with the appropriate behavior, thereby reinforcing the behavior.

EXTINCTION

Another form of discipline is extinction, which focuses on reducing or eliminating the positive reinforcement for inappropriate behavior. Examples are ignoring the temper tantrums of a toddler, withholding or removing privileges, and requiring "time-out." Withholding or removing privileges such as TV, music device, computer, or cell phone use is most effective for older children and adolescents. The adolescent may be grounded for a short time or not allowed to drive the car. To be effective, the privilege being withheld or removed must be something that the child values.

Time-out is an extinction discipline method that is most effective with toddlers, preschoolers, and early school-age children. It involves removing the child from the problem area and placing him or her in a neutral, nonthreatening, safe area where no interaction occurs between the child and parents or others for a specifically determined period (Fig. 1.6).

Take Note!

The amount of time that a child spends in time-out is typically 1 minute per year of age. For example, a 3-year-old would spend 3 minutes in time-out (AAP, 2013b).

PUNISHMENT

Discipline is often confused with punishment, but **punishment** involves a negative or unpleasant experience or consequence for doing or not doing something.

Although punishment is sometimes a necessary element of discipline, to be an effective tool it must be coupled with rewards for good behavior (AAP, 2012a, 2015a; Flaskerud, 2011).

FIGURE 1.6 **Although he might not like it, quiet solitude helps the child develop inner control.**

Punishment may be verbal or corporal. Verbal punishment commonly takes the form of reprimands or scolding (the use of disapproving statements). The statements are intended to change or eliminate the inappropriate behavior. Verbal reprimands can be effective in the short term if they are used sparingly and are focused on the child's specific behavior. If verbal reprimands are used frequently and indiscriminately, they lose their effectiveness, can provoke anxiety in the child, and encourage the child to ignore the parent. Frequent use also may reinforce the behavior by providing the child with attention (AAP, 2012a, 2015a; Flaskerud, 2011).

Corporal punishment involves the use of physical pain as a means to decrease inappropriate behavior. The most common form of corporal punishment is spanking (the use of an open hand to the buttocks or an extremity with the intention of modifying behavior without causing injury) (Flaskerud, 2011). Research shows that many parents have spanked their children at some point, with 90% of parents having spanked their child at least once (AAP, 2012a, 2015a; Larzelere, 2011). Spanking decreases as children age, but is still used as a discipline strategy in adolescents. Over the past two decades a growing body of research has suggested that corporal punishment can cause an increase in behavior problems and have lasting effects into adulthood (Lansford et al., 2012).

Initially, spanking may be effective because of its sudden and shocking nature. However, over time it loses its effectiveness because its shock value declines. Spanking may stop the negative behavior, but it also increases the chance for physical injury, especially for infants and young children, and may lead to altered caregiver–child relationships (AAP, 2012a, 2015a; Flaskerud, 2011). Because the effects of spanking diminish, the intensity of the spanking must be increased to achieve the same effects. Thus, it is important for parents to understand the

consequences of its use.

Spanking is a controversial issue. Some argue that it provides children with a model of aggressive behavior as a solution for conflict, that it has been associated with increased aggression in children, and that it can lead to an altered parent–child relationship. Various studies have linked spanking in childhood with physical aggression and violence in childhood and persistent anger in adulthood (AAP, 2013b; Lansford et al., 2012). Because of the negative consequences of spanking, and because it has been shown to be no more effective than other methods for managing inappropriate behavior, the AAP recommends that parents use methods other than spanking to respond to inappropriate behavior (AAP, 2012a, 2015a).

Take Note!

Other forms of discipline, if used incorrectly, can also cause problems for the child and interfere with the caregiver–child relationship. For example, disapproval using tone of voice, facial expression, or gestures can be effective in stopping inappropriate behavior, but if the disapproval comes in the form of verbal statements that attack the child rather than the behavior, negative consequences may occur (AAP, 2012a, 2015a; Flaskerud, 2011).

Genetics

Genetics, the study of heredity and its variations, is a field that has applications to all stages of life and all types of diseases. The child's biologic traits, including gender, race, some behavioral traits, and the presence of certain diseases or illnesses, are directly linked to genetic inheritance. Heredity is the process of transmitting genetic characteristics from parent to offspring.

Gender

Gender is established when the sex chromosomes join. A person's gender can influence many aspects, such as physical characteristics and personal attributes, attitudes, and behaviors. Some diseases or illnesses are more common in one gender; for example, scoliosis is more common in females and color blindness in males (Lewis, 2011).

In addition to the specific biologic and physical traits related to gender are the social effects. The child develops specific gender attitudes and behaviors that are appropriate in his or her own culture. Interactions with family members and peers as well as activities and societal values affect how children perceive themselves as a specific gender (Fig. 1.7).

FIGURE 1.7 Interactions with family members and peers as well as activities and societal values affect how children

perceive themselves as a certain gender.

Race

Race refers to the physical features that distinguish members of a particular group, such as skin color, bone structure, or blood type. Some of the physical variations may be normal in a particular race but may be considered an identifying characteristic of a disorder in other races. For example, epicanthal folds (the vertical folds of skin that partially or completely cover the inner canthi of the eye) are normal in Asian children but may occur with Down syndrome or renal agenesis in other races. In addition, certain malformations and diseases are found more commonly in specific races. For example, sickle cell anemia occurs more often in African Americans (Long et al., 2011).

Public awareness is important in educating couples at genetic risk about the benefits of screening programs and proactively seeking preconceptual genetic counseling to consider options that could include preimplantation genetic diagnosis (the use of in vitro fertilization technology to screen for unaffected embryos) (Rafi & Kai, 2011). The lack of engagement by ethnic minorities might simply reflect a lack of genetic awareness. Nurses can take the lead in assisting couples to gain that needed awareness to be empowered to make intelligent reproductive decisions.

Temperament

Temperament is the manner in which a child interacts with the environment. The way a child experiences a particular event will be influenced by his or her temperament, and the child's temperament will influence the responses of others, including the parents, to the child. Early on, infants demonstrate differences in their behavior in response to stimuli. These responses are an integral part of the infant's developing personality and individuality. Although a child's temperament is intrinsic and relatively resistant to change, it does stabilize as the child matures (Crawford, Schrock, & Woodruff-Borden, 2011). Knowing a child's temperament can help parents understand and accept the characteristics of the child without feeling responsible for having caused them.

The classic temperament theory proposes nine parameters of temperament: activity level, rhythmicity, approach and withdrawal, adaptability, threshold of responsiveness, intensity of reaction, quality of mood, distractibility, and attention span and persistence (Feigelman, 2011). This theory seeks to identify behavioral characteristics that lead the child to respond to the world in specific ways. Using the nine parameters, children's temperaments may be categorized into three major groups: easy, difficult, and slow to warm up; various temperaments are a combination of these groups (Kiff, Lengua, & Zalewski, 2011; Feigelman, 2011). Easy children are even-tempered and have regular biologic functions, predictable behavior, and a positive attitude toward new experiences. Difficult children are irritable, highly active, and intense; they react to new experiences by withdrawing and are frustrated easily. Children in the slow-to-warm-up category are moody and less active and have more irregular reactions; they react to new experiences with mild but passive resistance and need extra time to adjust to new situations.

A child's temperament may cause problems in the family if it conflicts with that of the parents (e.g., a difficult 2-year-old with slow-to-warm-up parents). If parents want and expect their child to be predictable but that is not the child's style, parents

may perceive the child to have problems; this conflict may then affect the child's health. The key is not to label the child but to recognize the strengths and limitations of each group. Understanding a child's temperament can help parents understand a child's characteristics and behaviors and allow parents to adjust their parenting style.

Genetically Linked Diseases

New technologies in molecular biology and biochemistry have led to better understanding of the mechanisms involved in hereditary transmission, including those associated with genetic disorders. These advances are now leading to better diagnostic tests and management options.

Reproductive genetic testing, counseling, and other genetic services can be valuable components in the reproductive health care of women and their families. These services have the potential to increase knowledge about possible pregnancy outcomes that may occur if a woman decides to reproduce; to provide reassurance during pregnancy; and to enhance the developing relationship between the woman, her expected child, and others (Edwards et al., 2015). This awareness can provide each woman with an opportunity to have access to desired genetic services in a way that will improve her control over the circumstances of her reproductive life, her pregnancies, childbearing, and parenting, within a framework that is sensitive to her needs and values. Nurses can be a vital facilitator in this process and to these services.

Two major areas of study in genetics that are important to pediatrics are cytogenetics and the Human Genome Project. Cytogenetics is the study of genetics at the chromosome level. Since the genetic code was deciphered, much has been learned about the chromosomal structure shared by all human organisms. Chromosomal anomalies occur in 0.4% of all live births and are the most prevalent cause of cognitive impairment and congenital anomalies or birth defects (Ferguson-Smith, 2015). Anomalies are even more common among spontaneous abortions and stillbirths. The Human Genome Project was an international research effort involving the localization, isolation, and characterization of human genes and investigation of the function of the gene products and their interaction with one another. It was considered one of the most ambitious and successful international research collaborations in the history of biology. Completion of this project provided scientists with greatly enhanced information about how DNA shapes species development and genetic diseases to aid in developing new ways to identify, treat, cure, or even prevent them. Chapters 10 and 49 offer a more detailed discussion of genetics.

Society

Society has a major impact on the health of women, children, and families. Major components of a society that influence children and their health include social roles, socioeconomic status, the media, and the expanding global nature of society. Each of these areas may influence a person's self-concept, the communities where they live, their choice of lifestyle, and their health. Nurses need to assess these areas and their influence on the child and family so that individualized strategies can be designed and implemented to enhance the positive effects and minimize the

negative effects on the child's and family's health.

Social Roles

Society often prescribes specific patterns of behaviors: certain behaviors are permitted and others are prohibited. These social roles are often an important factor in the development of self-concept. Social roles influence a person's ideas about self. Social roles are generally carried out in groups with which the individual has intimate daily contact, such as the family, school, workplace, or peer groups.

Socioeconomic Status

Another dominant influence is a person's socioeconomic status, meaning his or her relative position in society. This includes the family's economic, occupational, and educational levels. Children are raised differently by parents of different educational levels, occupations, and incomes. Low socioeconomic status typically has an adverse influence on an individual's health. Health care costs are continuing to rise, as are health insurance premiums. The family may not be able to afford food, health care, and housing; meals may be unbalanced, erratic, or insufficient. Housing may be overcrowded or have poor sanitation. These families may not understand the importance of preventive care or may simply not be able to afford it. As a result, they may be exposed to health risks such as lead poisoning or may not be immunized against communicable diseases. Studies have documented that children who come from low socioeconomic status are more likely to suffer from acute and chronic conditions experiencing more limitations from these, as well as injuries and mental health conditions (Allin & Stabile, 2012).

Take Note!

A recent research study showed that lower socioeconomic status was associated with increased cortisol levels over time (Chen, Cohen, & Miller, 2010). Cortisol plays a role in psychiatric and physical illnesses; therefore, findings of elevated cortisol levels in children from a low socioeconomic status may help explain why low socioeconomic status is negatively related to health (Chen et al., 2010).

POVERTY

Poverty is a measurement based on the specific monetary income of a family. The poverty threshold is the dollar amount that the U.S. Census Bureau uses to determine whether a family is living in poverty. It is based on the family's size and income (Table 1.3). If the individual's or family's income is below the threshold, then that person or family is said to be living in poverty.

Despite the many global economic gains that have been made during the past century, poverty continues to grow and the gap between rich and poor is widening. Major gaps continue between the economic opportunities and status afforded to women and those offered to men. A disproportionate share of the burden of poverty rests on women's shoulders, and this undermines their health. However, poverty, particularly for women, is more than monetary deficiency. Women continue to lag behind men in control of cash, credit, and collateral. Other forms of impoverishment may include deficiencies in literacy, health care access, education, skills, employment opportunities, mobility, and political representation, as well as pressures on time and energy linked to their responsibilities. These poverty factors

may affect a woman's health (Robinson, Stoffel, & Haider, 2015).

TABLE 1.3 2013 US POVERTY GUIDELINES

Size of Family Unit	48 Contiguous States and D.C.	Alaska	Hawaii
1	$11,490	$14,350	$13,230
2	$15,510	$19,380	$17,850
3	$19,530	$24,410	$22,470
4	$23,550	$29,440	$27,090
5	$27,570	$34,470	$31,710

Adapted from U.S. Department of Health and Human Services (2013). *2013 Poverty Guidelines.* Retrieved from http://aspe.hhs.gov/poverty/13poverty.cfm#thresholds; Federal Register, Vol. 78, No. 16, January 24, 2013, pp. 5182–5183.

Over the past decade the number and rate of children living in poverty has risen. According to the Children's Defense Fund (2012), 16.4 million American children live in poverty, with 7.4 million living in extreme poverty. The rate of poverty is closely tied to the overall health of the economy; therefore, in times of recession, a rise is usually seen. Family structure is an important factor associated with poverty rates for children. The poverty rate for married-couple families is much less than that for families headed by a single parent. Of the families living below poverty level, 30.9% were single-mother families with no husband present, 16.4% were single-father families with no wife present, and 6.3% were married couples (Denavas-Walt et al., 2013). Educational level is another important factor: as education increases, unemployment declines and annual income rises. However, a chronic physical or emotional problem in any wage earner may lead to unemployment, and this can cause the family to spiral downward into poverty.

The effects of poverty on children's health can be wide-ranging. The family may be able to afford only substandard housing or a house or apartment in a dangerous neighborhood (e.g., unsanitary conditions, toxins, violence). Poverty may also lead to homelessness.

Basic financial stability enhances the general health and well-being of children, and thus an important negative influence on children's health is poverty. Children living in poverty are more likely to have poor health, be retained in a grade or drop out of school, become teen parents, experience violent crimes, and become poor adults (Da Fonseca, 2012). They have greater rates of death and illness from almost all causes, except suicide and motor vehicle accidents (Da Fonseca, 2012).

HOMELESSNESS

It is impossible to measure homelessness with 100% accuracy. Therefore, looking at trends is important to demonstrate if progress is being made or not. Recent research suggests that homelessness among families is increasing. In a given year,

approximately 1.6 million (1 in 45) children are likely to experience homelessness in America (National Center on Family Homelessness [NCFH], 2015). Over 60% of homeless families are ethnic minorities and the typical homeless family is headed by a single mother with two children (NCFH, 2015).

Homelessness occurs in large urban areas and midsize cities as well as suburban and rural areas. The principal causes of homelessness in families are poverty and lack of affordable housing. Other causes include cutbacks in public welfare programs, mental health issues, and traumatic events such as unemployment, illness, or accidents and personal crises such as divorce, domestic violence, or substance abuse. Children may be forced out of their house or choose to run away and become homeless because they have been abused or neglected, lived in foster homes, or were placed in residential treatment or juvenile detention centers.

Homelessness can have a negative impact on health and well-being in numerous ways, including the following:

- Increased mental health issues such as anxiety, depression, or aggressive behavior
- Higher incidence of chronic health problems and trauma-related injuries
- Problems related to nutritional deficiencies, affecting fetal or child growth and development
- Participation in behaviors such as illegal substance use or unprotected sex with multiple partners
- Limited access to health care services such as preventive care, prenatal care, or dental care
- Inability to attend school consistently, because the environment is not conducive to learning; may result in learning problems, socialization issues, or behavioral issues (NCFH, 2015).

Media

Prolonged sitting and watching television or surfing the Internet while pregnant impairs the blood return in the legs and causes swelling. This immobility may also increase the risk of blood clot formation. Nurses can instruct their pregnant clients that it is important to improve circulation to the legs by not crossing them at the knees and to keep the legs moving by rotating the feet at the ankles. Sitting with the feet up with support to the ankles is also helpful. Changing the sitting position and getting up at least every hour is essential to prevent complications.

FIGURE 1.8 Computer games can be fun and educational, but the child should be monitored while using the computer and other forms of media to minimize negative effects.

Today's children are inundated with various forms of media, such as television, video and computer games, iPods, iPads, the Internet, social media, such as Facebook, movies, magazines, books, and newspapers (Fig. 1.8). Media has both positive and negative effects on the development of children and much depends on the content to which they are exposed (AAP, 2013a). Some of the images and information are not always in the best interests of children. Children may identify with, and mimic, characters who engage in risk-taking behaviors or lifestyles. Health risk behaviors, such as excessive caloric intake, physical inactivity, smoking, underage drinking, and violent behavior have been linked to media exposure (AAP, 2013a; Strasburger, 2011). Research has established a strong link between media violence and violent, aggressive behavior (Martins & Wilson, 2012). If an image or type of behavior is portrayed as the norm, children may view this as acceptable behavior without examining the potential health risks or other long-term consequences. For example, thinness is portrayed as the body type that is identified with beauty, leading some children to develop unhealthy dieting or other behaviors to develop that body type. For the child who has a body type that does not fit the ideal, depression or self-esteem issues may develop.

Overall, the images children view every day will affect their behavior and possibly their health, and pediatric nurses should take this into account when working with children and their families.

The media's influence relates not only to the content but also to the total viewing time. For example, excessive TV viewing has been linked to obesity, poor cognitive skills, and irregular sleep patterns. Overuse of computer or video games may lead to poor school performance. Media has become a major factor in children's lives with TV remaining the dominant medium (AAP, 2013a). Young children spend more time on media then they do in school. It is the leading activity other than sleeping (AAP, 2013a). Media can be a positive influence, such as when it offers educational programming or public service messages on the negative effects of substance abuse, smoking, or gang involvement. Also, public broadcasting networks offer valuable programming.

Obtaining a media history provides helpful and important information. The nurse is encouraged to ask questions regarding the amount of recreational screen time and if the child has a television or Internet-connected device in their bedroom (AAP, 2013a). It is important for parents to set limits and know what their children are viewing, whether it is on the TV, computer, iPod, tablet, or phone.

Take Note!

The American Academy of Pediatrics discourages any screen media before the age of 2 (AAP, 2013a).

Widespread access to the Internet has fostered a connection to other areas of the world that would not have been possible in previous years. Children are no longer limited to their immediate surroundings, and they have access to a wealth of information. The Internet can be a valuable resource for parents and children to access information, learn new things, and communicate with friends and family. However, online threats exist that can affect the child's health and safety such as sexual predators, pornography, violence, and racism. Parents need to be alert to these hazards and set up safety guidelines (see Teaching Guidelines 1.2).

Teaching Guidelines 1.2
PROMOTING SAFE INTERNET USE

- Determine a specific time limit that your child can spend online each day or week. Be consistent in enforcing this time limit.
- Ensure that Internet use does not replace or interfere with homework, friends, or household or school activities.
- Tell your child NEVER to share personal information with anyone online unless you are sure of the person and the child has your permission to do so.
- Urge your child NEVER to share his or her password with anyone, even friends.
- Review Internet sites with your child, and explain what information and websites are appropriate. Use safety and parental controls offered by your Internet service provider.
- Avoid placing the computer in the child's room. Instead, place the computer in a public area of your home, such as the den or kitchen, so that you can monitor your child's use.
- Discuss with your child the need for maintaining safety while using the Internet. Explain potential hazards in terms the child can understand.
- Advise your child to immediately close any sites or stop any communication that makes him or her confused or uncomfortable. Tell your child NEVER to arrange any face-to-face meeting with persons he or she meets online. Urge your child to seek you out if he or she encounters such a situation.
- Teach the child NEVER to open email from any unknown senders.
- Be aware of computer use policies in your child's school.

Global Society

The world is connected in many ways today: people travel from one nation to another easily, new products and immigrants arrive each day, and the Internet makes worldwide communication simple. The United Nations Children's Fund and the WHO lead the world in dealing with the issues of children. Every year about 7.6 million children die around the world, over 21,000 every day (Shah, 2011). Hundreds of thousands of children born in developing countries and their families are moving to more developed nations such as the United States as refugees, immigrants, or international adoptees. These families become part of this nation.

Nurses need to be aware of the impact of worldwide events, such as natural and man-made disasters, on families. Families can be displaced by events such as hurricanes or wars, placing them at increased risk for problems such as infectious diseases, malnutrition, and psychological trauma.

Young children bear the brunt of the global burden of disease but progress has been made in reducing mortality in children less than 5 years old (WHO, 2014). The United Nations Children's Fund (UNICEF) and the World Health Organization (WHO) have identified major problems affecting child growth and development and survival:

- Acute respiratory infections, such as pneumonia
- Malnutrition, including micronutrient deficiency

• HIV/AIDS
• Diarrhea related to lack of clean water and sanitation
• Vaccine-preventable diseases such as measles
• Malaria
• Preterm birth complications
• Poor health care of pregnant and nursing mothers (WHO, 2014; UNICEF, 2015)

These organizations work to propose ways to eradicate these conditions by improving the case management skills of providers with adapted guidelines; improving the health systems with good district health planning and management as well as appropriate supplies, medications, information systems, and referral systems; and improving the family and community practices (WHO, 2012).

Today, families, children, and society as a whole have concerns over world threats and safety. Disasters such as the terrorist attacks of September 11, 2001, the killings at Columbine High School and Sandy Hook Elementary School, and devastating weather events such as Hurricane Katrina can have a significant impact on the well-being of women and children. The increase in stressors such as war, terrorism, school violence, and natural disasters puts women, children, and their families at risk for experiencing mental health difficulties. Children who have experienced these events are at risk for issues such as posttraumatic stress disorder, behavioral problems, depression, anxiety, sleep disturbances, restlessness, irritability, aggression, bullying, physiologic responses such as gastrointestinal symptoms, changes in academic performance, social isolation, and safety and security concerns (American Psychological Association, 2015). Children's coping abilities may be reduced and alterations in growth and development may be seen. Children's reactions depend on age and developmental level and are highly influenced by the emotional state of their caregivers. Nurses must be aware of the effects of world threats on women and children so that they can assess for alterations and intervene to promote security and stability.

Violence

Violence can occur in any setting and can involve any person. Violence against women is a major health concern—it affects thousands of lives and costs the health care system millions of dollars. Violence affects families, women, and children of all ages, ethnic backgrounds, races, educational levels, and socioeconomic levels. Pregnancy is often a time when physical abuse starts or escalates, resulting in poorer outcomes for the mother and the baby. The effects of intimate partner violence (IPV) on maternal health include insufficient or inconsistent prenatal care, poor nutrition, substance abuse, inadequate weight gain, and depression. Adverse neonatal outcomes include low birthweight, preterm birth, and small for gestational age infants (Alhusen et al., 2015). Many of these can lead to maternal or neonatal morbidity or mortality.

There are many opportunities within the current health care system for screening and early intervention during routine prenatal care or during episodic care in a hospital setting. The nurse is responsible for assessing for and following up on any abuse. Due to the potential impact of violence on women, children, and families, it is essential to identify any violent situation via a thorough assessment. All nurses need to include "RADAR" in every client visit (Box 1.4). Nurses serve their clients

best not by trying to rescue them, but by helping them build on their strengths and providing support. Essentially, nurses empower their clients to help themselves. Providing referrals to shelters and child advocacy centers and intervening to assist women and children in dealing with this issue are paramount.

BOX 1.4

RADAR

R—Routinely screen every client for abuse.
A—Ask direct, supportive, and nonjudgmental questions.
D—Document all findings.
A—Assess your client's safety.
R—Review options and provide referrals.

INTIMATE PARTNER VIOLENCE

Violence in the home environment, known as intimate partner violence, affects many lives in the United States. The U.S. Bureau of Justice Office on Violence against Women (2015) estimates that over 1 million violent crimes are committed by former spouses, boyfriends, or girlfriends each year; about 85% of the victims are women. This violence is known as intimate partner abuse, family violence, wife beating, battering, marital abuse, or partner abuse, but regardless of the term used, its effects are widespread.

Children exposed to family violence are more likely to be physically, sexually, or emotionally abused themselves (Child Trends, 2013). The federal Child Abuse Prevention and Treatment Act (CAPTA) defines **child abuse and neglect** as "any recent act or failure to act on the part of a parent or caretaker that results in death, serious physical or emotional harm, sexual abuse or exploitation, or an act or failure to act that presents an imminent risk of serious harm to a child" (Child Welfare Information Gateway, 2013).

In 2012, approximately 686,000 cases of child maltreatment occurred in the United States (CDC, 2014b). Of the number of children identified as being maltreated, 78% were victims of neglect, 18% were victims of physical abuse, 9% were victims of sexual abuse, and 11% were victims of other maltreatment, such as emotional or psychological abuse (CDC, 2014b). Approximately 1,640 children died from abuse and neglect in 2012; nearly 70% of those children were less than 3 years of age (CDC, 2014b).

Take Note!

Children of African American and American Indian or Alaska Native descent have higher rates of abuse and neglect (CDC, 2014b).

Children who are exposed to stressors such as domestic violence or who are victims of childhood abuse or neglect are at high risk for short- and long-term problems. These problems manifest differently based on the child's age and developmental ability; the younger the child, and the longer the exposure, the more serious the problems seen. Short-term problems include sleep disturbances,

headaches, stomachaches, depression, asthma, enuresis, aggressive behaviors, such as increased peer aggression and bullying, decreased social competencies, withdrawal, avoidance attachment, developmental regression, fears, anxiety, and learning problems. Long-term problems may include poor school performance, truancy, absenteeism, and difficulty with adult relationships and tasks. There is a strong correlation between the number of exposures to adverse events and negative behaviors such as early initiation of smoking, sexual activity, and illicit drug use, adolescent pregnancies, and suicide attempts (CDC, 2014a).

Take Note!

Witnessing and being exposed to violence in childhood results in a higher tolerance, and greater use, of violence as an adult (Child Trends, 2013).

Not all children exposed to violence suffer negative consequences. Children have resilience, and preliminary studies have identified protective factors that can help buffer children from the effects of violence and reduce the risk that the child will develop violent behaviors (Futures Without Violence, 2012). Examples of protective factors include the following:

- Feelings of connectedness or a secure attachment to a nonviolent parent or caregiver
- Strong commitment to school and academic performance
- Involvement in social activities
- Social and community support
- Positive sibling and peer relationships
- Ability to discuss problems with parents or a supportive adult
- Consistent presence of a parent at least once during the day, such as in the morning on awakening, when getting home from school, at dinnertime, or when going to bed
- Positive view of self
- Strong cultural and/or spiritual identity

Thus, interventions need to focus on reducing children's exposure to violence and fostering protective factors.

YOUTH VIOLENCE

Youth violence affects the community as well as the child and family. Studies have shown that youth violence is associated with a disruption in social services, an increase in health care costs, and a decline in property values (CDC, 2015c). Research continues to show that children exposed to violence suffer serious consequences, such as problems with development, behavior, and physical and mental health issues, that last a lifetime (Finkelhor et al., 2013).

VIOLENT CRIMES

Violent crimes include murder, rape, robbery, and aggravated assault. Statistics from the Centers for Disease Control and Prevention (2012) show that for people of ages 10 to 24 years:

- Approximately 4,828 people were murdered in 2011; of those deaths, firearms accounted for 83%.

- More than 707,212 people were treated in emergency departments for injuries due to violence in 2011.
- Homicide remained the leading cause of death for African Americans, the second-leading cause of death for Hispanics, and the third-leading cause of death for American Indians and Alaska Natives.

Suicide is a serious public health problem affecting young people today. Suicide is the third-leading cause of death in people of ages 10 to 14 years, with 56.9% due to firearms and 34.8% due to poisoning (CDC, 2015h). Of these reported suicides, boys (77.9%) were much more likely than girls to die from suicide (CDC, 2015h).

In 2013, a nationwide survey of students in grades 9 to 12 in public and private schools found that 17% reported seriously considering suicide in the previous 12 months (CDC, 2015h).

Take Note!

Cultural variations in youth suicide rates are present; American Indian/Alaskan Natives youths have the highest rate of suicide while Hispanic youth are more likely to report attempting suicide (CDC, 2015h).

SCHOOL VIOLENCE

In recent years, due to several high-profile cases of school shootings, much attention has been directed at school violence and concern for student safety. However, statistically, between 1% and 2% of school-age homicides occur on the way to or from school, at school events, or during school hours (CDC, 2014c). Students are much less likely to be victims of crime at school than away, but some schools continue to have serious crime and violence problems (CDC, 2014c). In a 2013 nationwide survey, 8% of high school students reported being involved in a physical altercation at least once in the previous year (CDC, 2015j). The percentage of youths who reported carrying a weapon (gun, knife, or club) for at least one of the days in the month prior to the survey was about 5% (CDC, 2015j).

Much of school violence involves bullying, which is repeated negative actions that are clearly malicious and unwarranted, by one or more persons directed at a victim. Among 9th to 12th graders, nearly 20% report being a target of bullying (CDC, 2015i). Many cases of bullying go unreported, but bullying can affect school performance and social relationships and have long-lasting traumatic effects such as depression, low self-esteem, anxiety, academic problems and violence later in adolescence and adulthood (CDC, 2015i). School nurses need to be aware of bullying and offer support, guidance, and intervention when necessary to the students and staff.

Safe schools are essential for proper learning, growth and development, development of healthy relationships, and overall health of our children. Violence in schools has a negative effect not only on students but also on the school and the entire community. The continued coordination among schools, law enforcement, social services, and mental health systems and the development of effective programs will help to reduce these risk behaviors.

Community

Community encompasses a broad range of concepts, from the nation where a person lives, to a particular neighborhood or group. The surrounding community affects

many aspects of a person's health and general welfare. The quality of life within the community has a great influence on a person's ability to develop and become a functional member of society. Community influences include the school, which is a community in itself, and peer groups. The support and assistance offered to women, children, and families from other areas of the community, such as school programs and community centers, can improve the person's overall health and well-being.

SCHOOLS AND OTHER COMMUNITY CENTERS

Children today start school at an earlier age, spend more time in child care settings, and are involved in various community centers and activities. By age 3 or 4, many children are in a preschool setting for several hours a day. Some children spend more awake time in school and child care settings than in their family home. Thus, schools and child care settings have become major influences on children.

School also provides a means of socialization. School rules about attendance and authority relationships and the system of sanctions and rewards based on achievement help to teach children behavioral expectations that they will need for future employment and relationships in the adult world. Although the primary role of schools has always been academic education, today schools are performing more health-related functions. Schools play an important role in promoting healthy behaviors and educating children about proper exercise, nutrition, safety, sex, drugs, and mental health.

Academic success is linked to healthy behaviors. Academic success is a good indicator of child well-being and is a predictor of adult health outcomes (CDC, 2015a). Academic failure is linked to health risk behaviors such as substance use, violence, and physical inactivity. School health programs have positive impacts on health outcomes and health risk behaviors along with educational outcomes (CDC, 2015a).

FIGURE 1.9 **Daycare centers provide socialization and support for young children.**

Because in many families both parents need to work, many children are enrolled in child care and after-school programs. Thus, the socialization process begins earlier and involves a larger percentage of the child's waking hours (Fig. 1.9).

After-school hours are a critical time where children may participate in risky health behaviors if they are not provided with supervised, structured activity where they can learn and grow. Community centers and after-school programs can provide

an opportunity for children to learn new skills, have new experiences, and develop relationships with caring adults in a safe and supportive environment.

PEER GROUPS

A child's friends can have a major influence, positive or negative, on his or her growth and development. Peer group relationships often begin early and are a large part of the child's world, particularly with school-age children and adolescents. This influence starts in playgroups in preschool or elementary school. The child is confronted with a variety of values and belief systems from interactions with friends. To be accepted, the child must conform to the specific values and beliefs of the group. When these values and beliefs differ from those of the adults in the child's world, conflicts can occur, possibly separating children from the adults and strengthening their sense of belonging to the peer group.

When the child's friends are successful in school or other activities, the growth and development of the child continues in a healthy and positive way. When these groups demonstrate healthy behaviors, the influence is very positive, but peer groups can also exert negative influences on the child. Thus, it is vital to identify the important peer groups in a child's life and the positive or negative behaviors connected with these groups.

Culture

Culture (the view of the world and implementation of a set of traditions that are used by a specific social group in order to pass these traditions along to the next generation) plays a critical role in shaping a woman, child, or family including their health and health practices (Stanhope & Lancaster, 2011). Culture is a complex phenomenon involving the integration of many components such as beliefs, values, language, time, personal space, and view of the world, all of which shape a person's actions and behavior. Individuals learn these patterns of cultural behaviors from their family and community through a process called **enculturation**, which involves acquiring knowledge and internalizing values (Adams-Leander & Rector, 2014; Yoon et al., 2012).

Culture is learned first in the family, then in school, and then in the community and other social organizations. Culture influences every aspect of development and is reflected in childbearing and child-rearing beliefs and practices designed to promote healthy adaptation (Andrews & Boyle, 2015).

With today's changing demographic patterns, nurses must be able to incorporate cultural knowledge into their interventions so that they can care effectively for culturally diverse women, children, and families. They must be aware of the wide range of cultural traditions, values, and ethics that exist in the United States today. All nurses must establish **cultural competence**, the ability to apply knowledge about a client's culture so that health care interventions can be adapted to meet the needs of the client. Cultural competence refers to the process by which individuals and systems respond respectfully and effectively to people of all cultures, languages, ethnic backgrounds, disabilities, religions, sexual orientation, and other diversity factors in a manner that recognizes, and values the worth of individuals, families, and communities (Oregon Department of Education, 2015).

The nurse should know about various cultural groups, ethnicity, culture-based

health practices and how they may affect children, as well as the demographics of the local population. The goal is for the nurse to view culture as a point of congruence rather than a potential source of conflict.

Cultural Groups

A cultural group is a self-defined group of people who share a commonality such as religion, language, nationality, ethnicity, race, or a physical trait. In a society there are typically dominant and minority groups. The dominant group, often the largest group, has the greatest authority to control the values and sanctions of the society (Adams-Leander & Rector, 2014; Kersey-Matusiak, 2012). As a result, the dominant culture may have the largest impact on the individual's health, whereas minority cultural groups may still maintain some of their own traditions and values.

The relationship of culture to health care can become obscured by the use of broad group titles. In reality, there are many distinct cultural groups, and within a group there may be many subcultures. Geographic differences also can occur. For example, the Latin Americans living in New York may be quite different from the Latin Americans living in Florida. Nurses must be aware of these distinct cultural groups so they can provide culturally competent care.

Nurses should also be aware of the traditional health care values and practices that are passed along from one generation to the next. For example, some cultures believe in consulting folk healers, and this belief may have a major influence on children's health (Table 1.4). The nurse must remember that diversity exists within cultures and this is as important as the diversity between cultures. Every person is a unique individual with his or her own beliefs, values, and history. Nurses must avoid stereotyping, which can lead to misconceptions.

Ethnicity

Ethnicity, a term sometimes used synonymously with culture, involves group membership by virtue of common ancestry shared culture and identity. The basic groups are differentiated by their customs, characteristics, language, or similar distinguishing factors. Ethnic groups have their own family structures, languages, food preferences, moral codes, and health care practices. Children learn the accepted mode of behavior by observing and imitating those around them. The influences of culture and ethnicity on women, children, and families are highly variable and dynamic. Probably the most important characteristic of ethnicity is the sense of shared identity felt by members (Nagle & Clancy, 2012).

Children who come from a minority group may experience conflict and difficulties with interactions, including health care providers, because their native customs are different from those of the dominant culture. Many Americans in the dominant culture do not view themselves as belonging to a specific ethnic group, but many minority groups still identify closely with their ethnicity and emphasize their cultural or racial differences (Nagle & Clancy, 2012).

Stereotyping or labeling can result from **ethnocentrism**, a belief that one's own ethnic group is superior to other ethnic groups. This attitude can lead to a slanted view of the world, and it may hinder the nurse's ability to provide culturally competent care.

TABLE 1.4 BELIEFS AND PRACTICES OF SELECTED CULTURAL GROUPS

Cultural Group	Beliefs and Practices Affecting Children's Health
African Americans	Strong extended family relationships; mother as head of household; elder family members valued and respected Food as a symbol of health and wealth View of health as harmony with nature, illness as disruption in harmony Use of folk healing and home remedies common to treat body, mind, and spirit Strong church/religious affiliation Belief in illnesses as natural (due to natural forces that the person hasn't protected self against) and unnatural (due to person or spirit) Individuals vulnerable to external forces
Asian Americans	Strong loyalty to the family, father head of household Family as the center, with members expected to care for one another Preserving family pride and dignity is important Use of complementary modalities with Western health care practices View of life as a cycle, with everything connected to health Health viewed as a balance between the forces of *yang (hot)* and *yin (cold)* resulting in *qi* (pronounced chee), which is a balanced state of harmony Respect for authority emphasized
Arab Americans	Women subordinate to men; young individuals subordinate to older persons Family loyalty is primary Modesty is a core value Disease and illness attributed to the will of Allah Good health associated with eating properly, consuming nutritious foods, and fasting to cure disease Illness due to inadequate diet, shifts in hot and cold, exposure of stomach while sleeping, emotional or spiritual distress, and "evil eye" Cleanliness important for prayer
American Indian/ Alaska Native	High value on family and tribe; respect for elders Family as an extended network providing care for newborns and children Women as the verbal decision makers Celebrations to mark the stages of growth and development Use of food to celebrate life events and in healing and religious ceremonies Health as harmony with nature; illness due to disharmony, evil spirits; purification rituals (immersion in water, sweat lodges) to cleanse the body and spirit and maintain harmony with nature Prefer restoration of physical, mental, and spiritual balance through herbal medicines and healing ceremonies
Hispanics	Family important; father as the source of strength, wisdom, and self-confidence Mother as the caretaker and decision maker for health View of children as persons to continue the family and culture Use of food for celebrations and socialization Health as God's will maintainable with a balance of hot and cold food intake Cope with illness through prayer and faith in God Freedom from pain indicative of good health; pain tolerated stoically due to belief that it is God's will Folk medicine practices and prayers, herbal teas, and poultices for illness treatment

Adapted from Adams-Leander, S. & Rector, C. (2014). Chapter 5: Transcultural nursing in the community. In J. A. Allender, C. Rector, & K. D. Warner (Eds.), *Community & public health nursing. Promoting the public's health* (8th ed., pp. 115–149). Philadephia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins.

Cultural Health Practices

Health practices are often the result of health beliefs derived from a person's culture. For example, do the child and family view health and illness as the result of natural forces, supernatural forces, or the imbalance of forces? Most cultures have remedies that people may use or consider before they seek professional health care. People from some cultures may go to folk healers who they believe can cure certain illnesses. For example, the *curandero* (male) or the *curandera* (female) of the Mexican American community is believed to have healing powers as a gift from God. Asian Americans may consult a practitioner who specializes in traditional Asian therapies such as acupuncture, acupressure, and moxibustion. These folk healers are often very powerful in their community, speak the language, and are

very familiar with the culture's spiritual or religious aspects.

If the folk remedies or practices of the folk healers are compatible with the health regimen and support appropriate health practices, these practices and beliefs do no harm; in fact, they may even benefit the child and family. However, use of a folk healer can lead to a delay in beneficial treatment or create other problems. Some traditional health practices may be misinterpreted as being harmful, and some actually are harmful. For example, the Vietnamese practice of coining, which involves rubbing the edge of a coin on an oiled symptomatic body area to rid the body of disease, may be misinterpreted as a sign of physical abuse (Adams-Leander & Rector, 2014). This practice also can lead to burns, bruising, or welt-like lesions on the child's skin if it is done frequently. *Azarcon* and *greta,* powders containing high amounts of lead, are used as a folk remedy in Mexico to treat *empacho,* digestive problems such as diarrhea, and indigestion; and in some cases have resulted in lead toxicity (Adams-Leander & Rector, 2014).

Take Note!

Nurses can help to shape a person's lifelong perceptions of health and health services. An understanding of how the woman's, child's, and family's culture affects their health practices gives the nurse an opportunity to incorporate appropriate and beneficial health practices into the family's cultural milieu, providing sources of strength rather than areas of conflict.

Changing Cultural Demographics

The United States is no longer a melting pot of various cultures and ethnicities but a society with each individual bringing a diversity and richness that enriches the country as a whole. In 2012, 53% of the population is White, 14% is Black or African American, 24% is Hispanic, 5% is Asian, and 5% is non-Hispanic other races (FIFCFS, 2013). The Hispanic population has increased substantially over the past decade (FIFCFS, 2013). It is projected by 2050 that 36% of the US population of children will be Hispanic and 36% will be White, non-Hispanic (FIFCFS, 2013). In addition, the increasing number of intermarriages between individuals from different ethnic origins is producing an increasing number of children who have a heritage that represents more than one cultural group.

Immigration

Employment and economic opportunities, expanded human rights, educational opportunities, and other types of freedoms and opportunities encourage many foreigners to move to the United States. There are a growing number of immigrants with approximately one in five children in the United States being immigrants or members of an immigrant family (Stanton & Behrman, 2011). This includes both children born outside the United States or with at least one foreign-born parent. Some communities welcome the new members, but others do not. Partly due to fears of terrorism, the United States is evaluating, enforcing, and changing many of its immigration laws.

Immigration can affect the health, educational, and social services provided in the United States. It also presents issues related to access to care and the types of care that need to be offered. Immigration imposes stresses on women, children, and families, including the following:

- Depression, grief, or anxiety due to migration and adoption of a new culture
- Separation from support systems
- Inadequate language skills
- Differences in social, professional, and economic status between the country of origin and the United States
- Traumatic events such as war that may have occurred in their homeland (AAP, 2010)

Inability to speak English can hinder an immigrant's educational attainment, economic opportunities, and ability to join the mainstream of society. Twenty-two percent of children living in the United States speak a language other than English at home and 22% of children in immigrant families live in a linguistically isolated home (i.e., no person 14 years or older speaks fluent English) (Kids Count Data Center, 2014a, 2014b). Immigrant parents who do not speak English may have trouble accessing health care and health insurance, enrolling their children in school or becoming involved in school activities, and accessing work or better-paying jobs.

Immigrant families also may arrive in the United States with significant health problems. They may present with diseases that are more common in their country of origin but rarely seen in the United States, such as malaria. The health status of immigrant children may be compromised due to the lack of at-birth and early childhood screenings, which may manifest with problems such as inborn errors of metabolism, lack of preventive care, no immunizations, and no dental care. Due to financial, language, cultural, and other types of barriers that immigrant families sometimes face, they may not receive the necessary preventive care or receive care for minor conditions until they become more serious. Stresses experienced by immigrant children and their families, such as those associated with relocation, separation, and traumatic events, also can have a negative impact on their psychological health.

Spirituality and Religion

Spirituality is a basic human quality involving the belief in something greater than oneself and a faith that affirms life positively. It is a major influence in many people's lives, providing a meaning or purpose to life and a foundation for and source of love, relationships, and service. Spirituality is considered a universal human phenomenon with an assumption of the wholeness of people and their connectedness to a higher being. During life-changing events and crises, such as a serious illness or the birth of a child with a congenital defect, families often turn to spirituality for hope, comfort, and relief.

The word *religion* is often used interchangeably with spirituality in our society. However, spirituality is a more private and individual belief, whereas religion is an organized way of sharing beliefs and practicing worship. Over 90% of Americans believe in God (Bohon, 2011). Therefore, spirituality and religion are an important focus when working with women, children, and their families. A person's reaction to health and illness may be affected by these beliefs. In some religions, illness is seen as a punishment for sin or wrongdoing. Other religions view illness as a test of strength (Adams-Leander & Rector, 2014).

People appreciate the recognition of, and respect for, their beliefs. Therefore, identifying the individual's and family's religious beliefs and customs is important.

People may adhere to special dietary restrictions, rituals such as baptism or holy communion, use of amulets or icons, or practices related to dying that can be incorporated into the plan of care. Using open-ended questions and observing for the use of religious articles during assessment can provide clues to the family's beliefs and practices. Visits from spiritual leaders may also be noted. Table 1.5 identifies some of the ways in which tenets of major religious beliefs may affect children's health.

Take Note!

Never make assumptions about a family's religious or spiritual affiliation. Although they may belong to a particular religion, family members may not adhere to all of its beliefs or participate in all aspects of the religion. Be alert for clues that would provide insight into their specific beliefs.

Health Status and Lifestyle

Obviously, the general health status of a person and specific lifestyle can influence a person's health. Health status may be a factor soon after birth. Societal shifts, triggered by a greater focus on education and careers, have resulted in a trend toward delayed childbearing in American women. This timing has increased the incidence of multiple births due to the increased use of in vitro fertilization and other assisted reproductive technologies along with women delaying childbearing until they are older (Crawford & Steiner, 2015). Potential complications of multiple births include prematurity and intrauterine growth retardation, which may lead to chronic health problems in the child. Children with chronic health conditions may also have developmental delays, especially in acquiring skills related to cognition, communication, adaptation, social functioning, and motor functioning. Thus, the beginning health status of a child may affect his or her long-term health and development.

Developmental Level and Disease Distribution

Developmental level has a major impact on a person's health status. In general, the distribution of diseases or illnesses varies with age. For example, adolescents who become pregnant are at a higher risk for certain complications, such as anemia, hypertension, preterm labor, cephalopelvic disproportion, and postpartum hemorrhage. Pregnant adolescents also experience higher rates of intimate partner violence and substance abuse. Moreover, substance abuse can contribute to low birthweight, intrauterine growth restriction, preterm births, newborn addiction, and sepsis (Wong, Ordean, & Kahan, 2011). Women who become pregnant after age 35 are at risk for hypertension, dystocia, and postpartum hemorrhage. Older pregnant women are also more likely to have a pre-existing condition that could complicate the pregnancy. Moreover, fetuses of older pregnant women are at risk for chromosomal abnormalities.

Certain communicable diseases are more commonly associated with certain age groups. Roseola, which is a viral illness resulting in high fevers and rash, is most often seen in infants 6 to 15 months; scarlet fever, a group A streptococci infection, is a disease that primarily affects children between 4 and 8 years of age. The physiologic immaturity of an infant's body systems increases the risk for infection. Ingestion of toxic substances and poisoning are major health concerns for toddlers

as they become more mobile and inquisitive. Because preschool and school-age children are generally quite active, they are more prone to injury and accidents. Adolescents are establishing their identity, which may lead them to distance themselves from their family values and traditions for a period of time and conform more with their peers. This journey may lead to risky behaviors, resulting in injuries or other situations that may impair their health.

Nutrition

Nutrition provides the body with the calories and nutrients to sustain life and promote growth, as well as the essentials required to maintain health and prevent illness.

TABLE 1.5 SELECTED RELIGIOUS BELIEFS AFFECTING CHILDREN'S HEALTH

Religion	Beliefs About Health and Illness	Dietary Practices	Beliefs About Birth and Death
Buddhism	Illness from karmic causes (ignorant craving) Illness as an opportunity to develop the soul Ultimate goal of achieving nirvana (state of supreme tranquility, purity, and stability) No restrictions for medications, vaccines, nutritional therapies, or other therapeutic interventions	Moderation in diet encouraged Some sects vegetarian; some branches have strict dietary regulation; therefore, it is important to inquire about client's preferences	No baptism Last rite chanting at bedside soon after death; if there is hope for recovery and continuing the pursuit of enlightenment all means of intervention are encouraged Organ donation acceptable Cremation common
Christian Science	Disease viewed as error of human mind that can be dispelled by spiritual truth Health viewed within a spiritual framework; healing through prayer and spiritual regeneration Possible contact of own healing ministry (Christian Science practitioners) if child is hospitalized General opposition to human interventions with drugs or other therapies except for legally required immunizations Usually do not use blood or blood components, seek transplants or act as donors, seek biopsies or physical examination	No special requirements or restrictions	No baptism or last rites Unlikely to seek medical means to prolong life, use of prayer for recovery. Disposal of body in death left to family to decide

Hindu	Illness due to sins committed in previous life Acceptance of most medical practice/care Nonviolent approach to life	Meat consumption forbidden (especially beef) Some are strict vegetarians	No baptism View of death as a step in an ongoing cycle to reach nirvana Certain prescribed rites after death, such as washing the body by family and restrictions on who touches the body Cremation common
Islam	Belief that God cures but will accept treatment Compulsory prayers at dawn, noon, afternoon, after sunset, and after nightfall	Ingestion of pork and pork products and alcohol forbidden Fasting (by boys from age 7, girls from age 9, and adults) required during Ramadan (ninth month of Islamic year) (exceptions for pregnant/nursing mothers, elderly, or very ill)	No baptism Special party (*Aqeeqa*) to celebrate birth Specific burial rituals (rinsing and washing, wrapping, special prayers, and burial)
Judaism (orthodox and conservative)	Illness as possible reason for violating some dietary restrictions No treatments or procedures on Sabbath (which begins 18 minutes before sunset on Friday and ends 42 minutes after sunset on Saturday) or holy days	Ingestion of blood (such as raw meat) prohibited Kosher dietary laws; highly individualized observance Abstinence from ingestion of pork and predatory fowl and no mixing of milk dishes with meat dishes; ingestion of only fish with fins and scales; no shellfish (strict followers) Fasting during Yom Kippur, and matzo replaces leavened bread during Passover week	No baptism Ritual circumcision of male infants on eighth day of life Ritual of washing body after death; family and close friends remain with the deceased for a period of time No cremation
Mormon (Church of Jesus Christ of Latter-Day Saints)	Belief in divine health via laying on of hands. Medical therapy not prohibited Common use of herbal folk remedies	Ingestion of caffeinated tea, coffee, and alcohol and use of tobacco prohibited Fasting (no food or drink including water) once a month for 24 hours on a designated day, exceptions made (pregnant women, very young or old, and ill)	Baptism at older age (approximately 8 years old); infant blessed by church official after the birth Death believed to be another step in eternal progression Cremation discouraged, but not forbidden
Roman Catholic	Care of sick encouraged Misuse of any substance considered harmful to the body and a sin Eucharist as the food of healing and health	Moderation in diet encouraged Fasting and abstinence from meat and meat products on Ash Wednesday and Good Friday Abstinence on Fridays during Lent, but exceptions made if ill	Infant baptism; sacrament of the sick if prognosis is poor while child is alive; anointing of the sick Burial and treatment of the body with respect and honor Cremation is acceptable in certain circumstances

Adapted from Andrews, M. M., & Boyle, J. (2015). *Transcultural concepts in nursing care* (7th ed.). Philadelphia, PA: Lippincott Williams & Wilkins; Hanson, P. A., & Andrews, M. M. (2012). Chapter 13: Religion, culture and nursing. In M. M. Andrews, & J. S. Boyle (Eds.), *Transcultural concepts in nursing care* (6th ed., pp. 351–402). Philadelphia, PA: Wolters Kluwer Health/ Lippincott Williams & Wilkins.

Nutritional deficiencies, such as iron-deficiency anemia, or excesses, such as the increasing incidence of childhood obesity, are still common problems in the United States. Effective obesity prevention and treatment interventions targeting children and their families are needed to help curb the obesity epidemic (Seburg et al., 2015). Some factors contributing to poor nutrition include inadequate food intake,

nutritionally unsound social and cultural food practices, the easy accessibility of processed and nutritionally inadequate foods, lack of nutrition education in homes and schools, and the presence of illness that interferes with ingestion, digestion, and absorption of food.

During pregnancy, a woman needs additional calories to support fetal growth and development as well as to support her own needs, and an adequate intake of folic acid is important to prevent neural tube defects (Fig. 1.10). For the child, inadequate nutrition is associated with lowered cognitive ability, poor or altered emotional and mental health, increased susceptibility to childhood illnesses, and stunted physical growth (Miller & Scott, 2015). The so-called fast food or junk food that is prevalent in today's society is a key factor in the epidemic of childhood obesity and increases in the prevalence of childhood type 2 diabetes. Nutrition and its effects on health status are integrated throughout this text.

FIGURE 1.10 A. This pregnant client is eating a healthy meal to ensure adequate nutrition. B. The dietary habits established early in life can have a long-lasting impact on the child's health and quality of life.

Lifestyle Choices

Lifestyle choices that affect a person's health include patterns of eating; amount and type of exercise; use of tobacco, drugs, or alcohol; and methods of coping with stress. Most health problems that arise today are due to a person's lifestyle. For children, the lifestyle of the parents basically is the lifestyle of the child. Inactive parents who eat poorly commonly have children with the same habits, which can result in diabetes, obesity, and early heart disease. These typically adult problems are being diagnosed more frequently in children and adolescents today. Parents should first self-evaluate their own dietary and activity habits, make changes where necessary, and then strive to encourage healthy eating habits and an appropriate level of physical activity in the child's life through sports, hobbies such as dancing, or family activities.

Environmental Exposure

Some environmental exposures can jeopardize health. In utero, the child can be affected by poor maternal nutrition, maternal infections, or maternal use of alcohol, tobacco, and drugs. Nurses caring for pregnant women should be aware of the risks to the fetus posed by certain drugs, chemicals, and dietary agents, as well as maternal illnesses. These agents, known as teratogens, may be linked to birth defects in children. Not all drugs or agents are associated with fetal effects, however, and research is necessary to identify the correlations between teratogens and other variables.

The environment continues to affect a child's health after birth. Exposure to air pollution, tobacco, and water or food contaminants can impair a child's health status. Safety hazards in the home or community can contribute to falls, burns, drowning, or other accidents. Exposure to second-hand smoke and other pollutants, such as from radiation or chemicals, is a health hazard for children. Because children are smaller and still developing, environmental exposures can cause them additional health problems. For example, lead exposure is a common preventable poisoning in children, especially children less than 6 years of age. Due to their rapidly developing nervous system, young children are more sensitive to the effects of lead. Sources include lead paint, lead-contaminated dust, and lead contained in soil and water. Lead exposure can result in developmental and behavioral problems ranging from inattentiveness and hyperactivity to permanent brain damage and death, depending on the level of exposure.

Take Note!

A recent study found that residual tobacco smoke and carcinogens remain after a cigarette is extinguished (referred to as third-hand smoke). These toxins cling to the smoker's hair and clothes and can be present on any surface in the house, such as carpet and cushions. Children are particularly susceptible to third-hand smoke since they breathe near, crawl, touch, and mouth contaminated surfaces (Karim et al., 2015).

Stress and Coping

Disasters, such as the terrorist attacks of September 11, 2001, or Hurricane Katrina, can have a significant impact on the well-being of women, children, and families. Stressors such as war, terrorism, school violence, and natural disasters may decrease a person's coping ability (Yahav, 2011) and lead to alterations in growth and development (Masten & Narayan, 2012). Exposure to traumatic events and violence may have long-term effects on an individual's psychosocial development and status. Some children can adapt and respond to the stress, while others do not. The term **resilience** refers to the qualities that enable a person to cope with significant adverse events or stresses and still function competently (Masten & Narayan, 2012).

Exposure to stress is not limited to disasters or traumatic events, however. Stress can also include areas such as inadequate finances, family crises such as divorce, inadequate support systems, illness, or violence. Stress can also be associated with the normal problems associated with growth and development, such as entering a new classroom, learning a new skill, or being teased by a classmate. Similar to disasters and traumatic events, the effects of these stressors can dramatically affect the health status of a woman, child, or family.

Recall Sophia, the 38-year-old pregnant woman who has come to the prenatal clinic for a visit. While talking with the nurse, Sophia mentions that her children are very involved in activities. She says, "My husband is busy at work, so I do most of the running around. Sometimes I feel like the people at the drive-thru know me by name! My husband helps out on the weekends, but during the week, it's all me." What factors may be influencing Sophia's health? How might these factors be influencing the health of the children and the family?

Access to Health Care

The health care system, including the delivery and financing of this system, continues to change and evolve. In the United States, changes in the health care system result from pressures from many directions. These changes reflect shifts in social and economic realities and the results of the biomedical and technologic progress over the past several decades. Every person who seeks health care in any form feels the effects. Access to health care is affected negatively by lack of health insurance. People without health insurance typically cannot afford to seek health care for maintenance and prevention interventions. The "working poor" may not earn enough money to afford health insurance or medical care, and part-time workers do not always receive benefits such as health insurance. In most states, a man and a woman of the same age and health status will be charged different rates for exactly the same individual health insurance policy, a practice called "gender rating." Women continue to pay a much higher health insurance rate for the same coverage versus men in the United States, an inequality that continues today. This causes women more psychological distress than men (Weissman et al., 2015).

Parents with uninsured children often delay care for their children and are less likely to have a usual place of care for their children (FIFCFS, 2013). The percentage of children without health insurance has dropped slightly over the past 2 years to 9.7% in 2011 (FIFCFS, 2013). This decrease is attributed to the stabilization of private employer–based insurance plans and the states' ability to improve enrollment in Medicaid and the State Children's Health Insurance Program (The Kaiser Commission on Medicaid and the Uninsured [KCMU], 2013). Medicaid is a joint federal and state program that provides health insurance to low-income children and their parents. It is state administered and each state has its own set of guidelines. In 1997, Congress passed legislation that led to the creation of the State Children's Health Insurance Program (S-CHIP) (now known as Children's Health Insurance Programs [CHIP]). The purpose of this program is to help insure low-income children who are ineligible for Medicaid, but cannot afford private health insurance. This program is also funded jointly by the federal and state governments, but administered by the individual states. In recent years Medicaid and CHIP have focused on increasing enrollment by increasing outreach, simplifying enrollment procedures, and retaining eligible enrollees. Legislation, such as The Children's Health Insurance Program Reauthorization Act of 2009 (CHIPRA) and the ACA, has helped support this (KCMU, 2012). Despite these efforts, half of uninsured children are eligible for these public programs but not enrolled (Children's Defense Fund, 2012). During the recent economic downturn and recession the uninsured rate for

children has actually declined with the majority of the uninsured coming from low-income working families (KCMU, 2013). Medicaid and CHIP provide a good base of coverage for low-income children, but unfortunately eligibility for parents is much more limited.

These programs rely on adequate state and federal funding. Therefore, the continued success of these programs depends on future legislation. Tough economic times along with changes in employer-based health insurance will continue to challenge the nation to ensure adequate health care for all children.

Preventive Care Focus

The emphasis on cost reduction also led to an emphasis on preventive care and services. Anticipatory guidance is vital during each health contact with women, children, and families. Education of the family includes everything from keeping the home safe to preventing illness.

The Continuum of Care Emphasis

A "continuum of care" strategy is cost-effective and provides more efficient and effective services. This continuum extends from acute care settings such as hospitals to outpatient settings such as ambulatory care clinics, primary care offices, rehabilitative units, community care settings, long-term facilities, homes, and even schools. For example, the hospital stay is now integrated into a continuum that allows the client to complete therapy at home, school, or other community settings, while reentering the hospital for short periods for specific treatments or illnesses.

Improvements in Diagnosis and Treatments

Because of the tremendous improvements that have been made in technology and biomedicine, disorders and diseases are being diagnosed and treated earlier. The 1990s witnessed a remarkable and productive connection between genetics and various pathophysiologic processes. For example, female fetuses with congenital adrenal hyperplasia, a genetic disorder resulting in a steroid enzyme deficiency that can lead to disfiguring anatomic abnormalities, are beginning to receive treatment before birth. In addition, many genetic defects are being identified so counseling and treatment may occur early. With these improved diagnoses and treatments, nurses may now be caring for people who have survived situations that once would have been fatal, who are living well beyond their life expectancy for a specific illness, or who are functioning with chronic disabilities (CDC, 2015b). For example, at one time women with congenital heart disease did not live long enough to become pregnant. However, with new surgical techniques to correct the defects, many of these women survive and become pregnant, progressing through their pregnancy without significant problems.

While positive and exciting, these advances and trends also pose new challenges for the health care community. For example, as health care for premature newborns improves and survival rates increase, the incidence of long-term chronic conditions such as respiratory airway dysfunction or developmental delays has also increased. As a result, nurses are faced with caring for clients at all stages along the health–illness continuum, such as well children, those who are occasionally ill, and women, children, and families with chronic and sometimes disabling conditions.

Empowerment of Health Care Consumers

Due to the influence of managed care, the focus on prevention, a more educated population, and technologic advances, individuals and families have taken an increased responsibility for their own health. Health consumers are now better informed, and they want to play a greater role in managing health and illness. Families want information about illnesses and they want to participate in making decisions about treatment options. As client advocates valuing family-centered care, nurses are instrumental in promoting this empowerment. To do this, the nurse should respect the family's views and concerns, address all issues and concerns, consider the family members as important participants, and always include the woman, child, and family in the decision-making process.

BARRIERS TO HEALTH CARE

Women are major consumers of health care services, in many cases arranging not only their own care but also that of family members. Compared with men, women have more health problems, longer life spans, and more significant reproductive health needs (Davis, 2014). Access to care can be jeopardized by lower incomes and greater responsibilities (juggling work and family). Barriers to health care include lack of finances; sociocultural barriers, including lack of transportation, no babysitters, and language; and health care delivery system barriers, including inconvenient clinic hours and poor attitudes by health care workers. These barriers often discourage clients from seeking health care (Patel & Rushefsky, 2015).

Finances

Financial barriers are one of the most important factors that limit care. Childbirth is the leading reason for hospitalization in the United States. For both private insurers and Medicaid, hospital maternity and newborn charges exceed those for any other condition. In US hospitals, vaginal and cesarean deliveries cost approximately $10,000 to $17,000 and $16,000 to $25,000, respectively (Lincoln, 2015). Many women have limited or no health insurance and cannot afford to pay for maternity care. The intent of the ACA is to provide access to health care services for many (Crissman et al., 2015). Although Medicaid covers prenatal care in most states, the paperwork and enrollment process can be so overwhelming that many women do not register.

After a decade of decline, the percentage of children living in low-income families has again been on the rise. In 2011, 45% of children were living in low-income families and 22% were living in poor families (Addy, Engelhardt, & Skinner, 2013). Many children and families do not have insurance, do not have enough insurance to cover services obtained, or cannot pay for services. Nurses need to assess for financial barriers to health care and be aware of resources available to help families overcome these barriers.

Sociocultural Barriers

Lack of transportation and the need for both parents to work also pose barriers to seeking health care. It can be difficult to attend all recommended prenatal health care visits or well-child visits, especially if the woman has other small children who

must be taken along on the visit. These challenges can reduce the adherence to scheduled appointments and follow-up. Knowledge barriers (e.g., lack of understanding of the importance of prenatal care or preventive health care), language barriers (e.g., speaking a different language than the health care providers), or spiritual barriers (e.g., religious beliefs discouraging some forms of treatment) also exist.

Health Care Delivery System Barriers

The health care delivery system itself can create barriers, such as the cost containment movement. Fifty-eight percent of employed families with insurance are covered by some type of managed health care plan or health maintenance organization (HMO), but millions of Americans remain uninsured (Douthit et al., 2015). This prospective payment system based on diagnosis-related groups (DRGs) limits the amounts of health care the family may receive. This also includes Medicaid reimbursement. Due to cost-containment efforts, the trend is to discharge clients as soon as possible from the hospital and to deliver care in the home or through community-based services (Riggs & Alexander, 2015). Although overall insurance plans may improve access to preventive services, they may limit access to specialty care—which greatly affects clients with chronic or long-term illnesses.

Clinic hours must meet the needs of the clients, not the health care providers who work there. Evening or weekend hours might be needed to meet the schedules of working clients. Clinic personnel should evaluate the availability and accessibility of the services they offer.

Unfortunately, some health care workers exhibit negative attitudes toward poor or culturally diverse families, and this could deter these clients from seeking health care. Long delays, hurried examinations, and rude comments by staff discourage clients from returning.

Consider This

I was a 17-year-old pregnant migrant worker needing prenatal care. Although my English wasn't good, I was able to show the receptionist my "big belly" and ask for services. All the receptionist seemed interested in was a social security number and health insurance—neither of which I had. She proceeded to ask me personal questions concerning who the father was and commented on how young I looked. The receptionist then "ordered" me in a loud voice to sit down and wait for an answer by someone in the back, but never contacted anyone that I could see. It seemed to me like all eyes were on me while I found an empty seat in the waiting room. After sitting there quietly for over an hour without any attention or answer, I left.

Thoughts: Why did she leave before receiving any health care service? What must she have been feeling during her wait? Would you come back to this clinic again? Why or why not?

LEGAL AND ETHICAL ISSUES IN MATERNAL AND CHILD HEALTH CARE

Law and ethics are interrelated and affect all of nursing. Professional nurses must understand their scope of practice, standards of care, institutional or agency policies, and state laws. Every nurse is responsible for knowing current information

regarding ethics and laws related to their practice. Numerous federal programs have had a major impact on women's and children's health (Table 1.6).

Several areas are of particular importance to the health care of women and children. These include abortion, substance abuse, fetal therapy, maternal–fetal conflict, stem cell research, umbilical cord blood banking, informed consent, client rights, and confidentiality.

Abortion

Abortion was a volatile legal, social, and political issue even before *Roe v. Wade,* the 1973 Supreme Court decision that legalized abortion. Nearly half of pregnancies among American women are unintended, and about 4 in 10 of these are terminated by abortion. Twenty-two percent of all pregnancies (excluding miscarriages) end in abortion (Alan Guttmacher Institute [AGI], 2014). In September 2000, the U.S. Food and Drug Administration approved mifepristone to be marketed in the United States as an alternative to surgical abortion. Medication abortion using mifepristone or a similar medication accounted for 38% of all nonhospital abortions, and about one quarter of abortions before 9 weeks' gestation (AGI, 2014).

TABLE 1.6 MILESTONES IN FEDERAL PROGRAMS IN SUPPORT OF THE HEALTH OF WOMEN AND CHILDREN

Date	Action	Impact
1909	First White House Conference on Care of Dependent Children (convened by President Theodore Roosevelt) Prevention of Infant Mortality Association formed	Addressed the poor working and living conditions of many children in the United States Aimed at improving the lives of children The Association played a major role in creating a new registration procedure for all infant births and deaths nationally
1912/1913	U.S. Children's Bureau	Established the first governmental agency to oversee children's health and environmental conditions Purpose is to research and report all issues pertaining to all children's well-being; to assist states and local government in preventing child abuse and neglect
1921	Maternity & Infancy (Sheppard–Towner) Act	Provided grants to states to establish maternal and child health divisions in state health departments
1930	White House Conference on Child Welfare Standards	Produced the Children's Charter, documenting the child's need for health, education, welfare, and protection
1935	The Social Security Act Introduction of vitamin K to newborns	Established federal–state partnership and provided Aid to Dependent Families and Children (ADFC), maternal–child health services, and child welfare services This discovery led to the prevention of hemorrhagic disease in newborns
1938	Initiation of the March of Dimes	Through research, defeated polio and now improves lives through the prevention of birth defects, prematurity, and infant mortality

1946	National School Lunch Program	Provides nutritious, well-balanced lunches to children each day at school for free or at low cost. It also provides meal supplements for children in afterschool care and nutrition programs for homeless children.
	Centers for Disease Control and Prevention established	The CDC is globally recognized as a leading force in public health expertise
1962	National Institute of Child Health and Human Development (NICHD)	Supports and performs research on child, maternal, adult, and family health issues
1964	Head Start Developed	Head Start provides child development programs to pregnant women, families, and children from birth to age 5 with the overarching goal of increasing school readiness for children from low-income families.
1965	Medicaid Program under Title XIX of Social Security Act; special programs such as Child Health Assessment Program	Provided state block grants to reduce financial barriers to health care for the poor and special services to pregnant women, young children, and people with disabilities
1966/ 1974	Women, Infants, Children (WIC) program	Provided nutritional supplementation and education to low-income families; pregnant, postpartum, and lactating women; and infants and children up to age 5
1968	Expansion of Lunch & Nutrition Act	Provide food for low-income, school-age children year-round along with low-income children in day care and Head Start programs
1969	U.S. Children's Bureau moves to Office of Health, Education, & Welfare (HEW)	Established greater presence for the programs
1972	Head Start to Serve Handicapped Children	Congress mandated that at least 10% of the children enrolled in Head Start must be handicapped children.
1975	Education for All Handicapped Children Act (Public Law 94–142)	Established federally mandated special education in public schools
	Title XX Social Services	Provided block grants to day care, emergency shelters, counseling, family planning, and other services for children
1976	Improved Pregnancy Outcome Projects	Raised awareness of the importance of maternal health during pregnancy to reduce infant mortality
1976	The Supplemental Security Income (SSI) Disabled Children's Program	Provided cash to low-income children with disabilities to help their families manage their healthcare costs.
1979	National health objectives for 1990	These early efforts resulted in *Healthy People 2010* and *2020*
1981	Alcohol, Drug Abuse, & Mental Health block grants	Began funding services for children and adolescents with mental health issues
	Healthy Mothers, Healthy Babies Coalition	Raised public awareness of prenatal care, good nutrition, avoidance of drugs, and promotion of breast-feeding
1986	Education of Handicapped Act Amendments (Public Law 99–457)	Established federal funding for states to create statewide, comprehensive, coordinated, and multidisciplinary early-intervention services for handicapped infants and toddlers
1990	Omnibus Budget Reconciliation Act	Extended Medicaid coverage to all children (6 to 18 years) with family income below 133% of poverty level
1990	Bright Futures Initiated	Provided a comprehensive set of child health supervision guidelines for health professionals, families, and communities and train these groups to work toward optimal child health

1991	Healthy Start initiated	Is a community-based program that serves at-risk women to reduce infant mortality during and after their pregnancy
1993	Family & Medical Leave Act (FMLA)	Allowed eligible employees to take up to 12 weeks of unpaid leave from their jobs every year to care for newborns or newly adopted children or children, parents, or spouses who have a serious health condition; employee can return to previous job or a comparable job with the same conditions
1994	Back to Sleep Campaign	A national campaign to prevent sudden infant death syndrome (SIDS) by placing infants on their backs to sleep
1995	Early Head Start Program	Federally funded community-based program for low-income families (infants, toddlers, and pregnant women) that focuses on child development
1997	Children's Health Insurance Program (CHIP) (formerly known as State Children's Health Insurance Program [SCHIP]) (National Conference of State Legislatures, 2015)	Offers federal assistance to state-based health insurance for low-income families that are not eligible for Medicaid but cannot afford private insurance
2000	Children's Health Act	Lead to increased research and treatment of health issues concerning children such as autism, asthma, epilepsy, and oral health
2002	No Child Left Behind Act	To ensure that all children in all classrooms receive research-based curriculum, well-prepared teachers, and a safe learning environment
2006	Combating Autism Act	Lead to increasing autism awareness by increasing funding for research, surveillance, diagnosis, and treatment
2007	WIC Food Package Revised	Designed to improve nutritional intake of WIC recipients by supporting and promoting long-term breast-feeding and adding fruits and vegetables, whole grains, soy-based foods, and a variety of culturally appropriate foods
2008	Newborn Screening Saving Lives Act	Provided increased funding for newborn screening grants and provided more education and outreach, coordination of follow-up care after screening and evaluation of newborn screening programs effectiveness
2009	Children's Health Insurance Program Reauthorization Act	Expanded the program to cover more uninsured children
2009	American Recovery and Reinvestment Act	Designated money to fund and expand programs such as Head Start, foster care, and the Supplemental Nutrition Assistance Program (Food Stamp Program) as well as creating new jobs and improving services such as community health centers and unemployment benefits during the economic recession
2010	Affordable Care Act (Patient Protection & Affordable Care Act); Health Care & Education Reconciliation Act	Increases coverage by expanding Medicaid, ends pre-existing conditions exclusion for children; holds insurance companies accountable by ending lifetime coverage limits, requiring insurance companies to publicly justify premium increases; decreases healthcare costs; increases choice and enhances quality of care for all Americans by covering all preventative care

Abortion has become a hotly debated political issue that separates people into two camps: pro-choice and pro-life. The pro-choice group supports the right of any woman to make decisions about her reproductive functions based on her own moral and ethical beliefs. The pro-life group feels strongly that abortion is murder and deprives the fetus of the basic right to life. Both sides will continue to debate this very emotional issue for years to come.

Medical and surgical modalities are available to terminate a pregnancy,

depending on how far the pregnancy has developed. A surgical intervention can be performed up to 12 weeks' gestation; a medical intervention can be performed up to 9 weeks' gestation (King et al., 2015). All women undergoing abortion need emotional support, a stable environment in which to recover, and nonjudgmental care throughout the experience.

Abortion is a complex issue, and the controversy is not only in the public arena; many nurses struggle with the conflict between their personal convictions and their professional duty. Nurses are taught to be supportive client advocates and to interact with a nonjudgmental attitude under all circumstances even when personal and political views differ from those of their clients.

With all the advances in abortion care, this points toward greater nursing involvement. Although this bodes well for woman-centered care, the burden on nurses is likely to increase incrementally. This may have an adverse effect on the affective attributes or emotions that those nurses possess (McLemore, Levi, & James, 2015).

Nurses need to clarify their personal values and beliefs on this issue and must be able to provide nonbiased care before assuming responsibility for clients who might be in a position to consider abortion. Their decision to care for or refuse to care for such clients affects staff unity, influences staffing decisions, and challenges the ethical concept of duty (McLemore, Kools, & Levi, 2015).

The American Nurses Association's updated Code of Ethics for Nurses upholds the nurse's right to refuse to care for a client undergoing an abortion if the nurse ethically opposes the procedure (ANA, 2016). Nurses need to make their values and beliefs known to their managers before the situation occurs so that alternative staffing arrangements can be made. Open communication and acceptance of the personal beliefs of others can promote a comfortable working environment.

Substance Abuse

Substance abuse for any person is a problem, but when it involves a pregnant woman, substance abuse can cause fetal injury and thus has legal and ethical implications. Substance abuse during pregnancy may cause fetal anomalies, preterm birth, placenta abruption, and central nervous system developmental alterations (Viteri et al., 2015). Many state laws require reporting evidence of prenatal drug exposure, which may lead to charges of negligence and child endangerment against the pregnant woman. It has been found that incarceration, or threat of it, has no effect in reducing cases of alcohol or drug abuse (Malinowska-Semprunch & Rychkova, 2015). This punitive approach to fetal injury raises ethical and legal questions about the degree of governmental control that is appropriate in the interests of child safety. All pregnant women and women of childbearing age should be screened periodically for alcohol, tobacco, and prescription and illicit drug use. Nurses should employ a flexible approach to the care of women who have substance use problems, and they should encourage the use of all available community resources. Nurses should counsel women about the risks of preconception, antepartum, and postpartum substance abuse in a calm, nonjudgmental manner (Galante, French, & Grace, 2015).

Intrauterine Therapy

Progress in prenatal diagnosis can lead to the diagnosis of severe fetal abnormalities for which previously one would anticipate a fatal outcome or the development of severe disability despite optimal postnatal care. Intrauterine therapy can now be offered in these selected cases and also in the treatment of fetal obstructive uropathy, intrauterine transfusions for fetal anemia, spina bifida repair, and stem cell transplantation. Intrauterine therapy is a procedure that involves opening the uterus during pregnancy, performing a surgery, and replacing the fetus in the uterus. Although the risks to the fetus and the mother are both great, fetal therapy may be used to correct anatomic lesions (Yuan, 2015). Some argue that medical technology should not interfere with nature, and thus this intervention should not take place. Others would argue that the surgical intervention improves the child's quality of life. For many people, these are the subjects of debates and intellectual discussions, but for nurses, these procedures may be part of their daily routine.

Nurses play an important supportive role in caring and advocating for clients and their families. As the use of technology grows, situations will surface more frequently that test a nurse's belief system. Encouraging open discussions to address emotional issues and differences of opinion among staff members is healthy and increases tolerance for differing points of view.

Maternal–Fetal Conflict

In maternity nursing, the ethical principles of beneficence and autonomy provide the fundamental framework that guides the management of all pregnant women. As there is the need for consideration of the fetus, autonomy can become a complex issue, which gives rise to what is sometimes called the **maternal–fetal conflict**.

Fetal care becomes problematic when what is required to benefit one member of the dyad will cause an unacceptable harm to the other. When a fetal condition poses no health threat to the mother, caring for the fetal client will always carry some degree of risk to the mother, without direct therapeutic benefit for her. The ethical principles of beneficence ("be of benefit") and nonmaleficence ("do no harm") can come into conflict.

Because the clients are biologically linked, both, or neither, must be treated alike. It would be unethical to recommend fetal therapy as if it were medically indicated for both clients. Still, given a recommendation for fetal therapy, pregnant women, in most cases, will consent to treatment, which promotes fetal health. When pregnant women refuse therapy, health care providers must remember that the ethical injunction against harming one client in order to benefit another is virtually absolute.

The use of court orders to force treatment on pregnant women raises many ethical concerns. Court orders force pregnant women to forfeit their autonomy in ways not required of competent men or nonpregnant women. There is an inconsistency in allowing competent adults to refuse therapy in all cases but pregnancy. The American College of Obstetricians and Gynecologists (ACOG) advocates counseling and education to convince a mother to follow her doctor's advice and condemns the use of coercion on a pregnant woman, as this violates the intent of the informed consent process. Faced with a continuing disagreement with a pregnant woman, a physician should turn to an institutional ethics committee. Resorting to the legal system is almost never justified (Avci, 2015).

Stem Cell Research

Stem cells constitute one of the most promising tools for regenerative medicine. They can grow into any cell type in the body and have been touted as a potential cure for everything from type 1 diabetes to stroke. The goal of stem cell research is a relief of human suffering, which ethically is good. Benefits of stem cell research include therapies for Parkinson disease, regeneration of diseased body tissues, repair of spinal cord injuries, and the growing of needed organs for transplant.

It would seem morally compelling to explore all the sources that might provide us with them, but the ethical concerns surrounding stem cell research vary depending on the origin of the stem cells. Adult stem cells are found in adults, who can replace old cells by reproducing new ones (e.g., blood and liver cells). Bone marrow transplants are examples of the use of adult stem cells in medical therapy. Embryonic stem cells are derived from the inner cell mass of an early embryo. They aren't without controversy; the process of obtaining these cells results in the destruction of the embryo. However, they hold huge promise too (de Miguel-Beriain, 2015).

Some people feel that the destruction of the human embryo constitutes the killing of a human being and reject this practice on religious grounds. Views about when life begins and whether the early embryo is considered a person with moral status are the heart of the ethical deliberations related to embryonic stem cells. Everyone has to decide based on their own personal values and ethical background.

Umbilical Cord Blood Banking

Umbilical cord blood, the remaining blood in the umbilical cord at birth, can be collected and be a source of stem cells for an individual in need of a bone marrow transplant later in life. It can also be used for admission laboratory studies in neonates and also for a transfusion if needed (Carroll & Christensen, 2015). The extraordinary scientific and technologic advance of contemporary medicine constantly leads toward the introduction of new treatments. Umbilical cord blood is a potential vast source of primitive hematopoietic stem and progenitor cells available for clinical application. Cord blood can be used as an alternative source for bone marrow transplantation and its use is developing into a new field of treatment for pediatric and adult clients presenting with hematologic disorders, immunologic defects, and specific genetic diseases (Roura et al., 2015).

Blood from a newborn's umbilical cord, once considered a waste product that was routinely discarded along with the placenta, is now considered to contain potentially life-saving stem cells. Banks were initially developed to store cord blood stem cells from newborns, for a fee, for potential future use by the same child or a family member if the child developed disease later in life. Today, there are public banks that store, for free, stem cells that can be used by anyone needing them, similar to how public blood banks work.

Pregnant women should be aware that stem cells from cord blood cannot currently be used to treat inborn errors of metabolism or other genetic diseases in the same individual from which they were collected because the cord blood would have the same genetic mutation. Cord blood collected from a newborn that later develops childhood leukemia cannot be used to treat that leukemia for much the same reason. Umbilical cord banks are a central component, as umbilical cord tissue

providers, in both medical treatment and scientific research with stem cells. But, whereas the creation of umbilical cord banks is seen as successful practice, others perceive it as ethically risky.

The fact that private cord banks offer their services as "biologic insurance" in order to obtain informed consent by promising the parents that the tissue that will be stored to insure the health of their child in the future raises the issue of whether the consent is freely given or given under coercion. Another consideration that must be made in relation to privately owned cord banks involves the ownership of the stored umbilical cord. Conflicts between moral principles and economic interests (many physicians own private blood banks) cause dilemmas in the clinical practice of umbilical cord blood storage and use, especially in privately owned banks (Ballen, Verter, & Kurtzberg, 2015).

Both the ACOG (2012) and AAP (2012) have reaffirmed previously issued statements opposing the use of for-profit banks and criticizing their marketing tactics. Instead, they recommended that parents donate cord blood to public banks, which make it available for free to anyone who needs it. Globally, other organizations have done the same. Private umbilical cord blood banking raises a question of special legal regulation. This practice promises the safe storage of biologic material on the assumption that it may be useful, at a certain moment in future, for its own donor (or for a donor's close family member) for curing serious blood diseases (Kim, Han, & Shin, 2015). Nurses need to provide unbiased education about this topic with all pregnant women and their families to allow informed choices to be made.

Informed Consent

Most care given in a health care setting is covered by the initial consent for treatment signed when the person becomes a client at that office or clinic, or by the consent to treatment signed upon admission to the hospital or other inpatient facility. Certain procedures, however, require a specific process of informed consent. Procedures that require informed consent include major and minor surgery; invasive procedures such as amniocentesis, internal fetal monitoring, lumbar puncture, or bone marrow aspiration; treatments placing the person at higher risk, such as chemotherapy or radiation therapy; procedures or treatments involving research; application of restraints; and photography involving the person.

Generally, only people over the age of majority (18 years of age) can legally provide consent for health care. Because children are minors, the process of consent involves obtaining written permission from a parent or legal guardian. In cases requiring a signature for consent, usually the parent gives consent for care of children less than 18 years of age except in certain situations (see discussion that follows).

Take Note!

Never assume that the adult accompanying the child is the parent or legal guardian. Always clarify the relationship of the accompanying adult.

The informed consent process, which must be done before the procedure or specific care, addresses the legal and ethical requirement of informing the person

about the procedure. It originates from the right of the child and family to direct their care and the ethical responsibility of health care providers to involve the child and family in health care decisions. Nurses should involve children and adolescents in the decision-making process to the extent possible, though the parent is still ultimately responsible for giving consent. The physician or advanced practitioner providing or performing the treatment and/or procedure is responsible for informing the child and family about the procedure and obtaining consent by providing a detailed description of the procedure or treatment, the potential risks and benefits, and alternative methods available.

The nurse's responsibility related to informed consent includes the following:

- Ensuring that the consent form is completed with signatures from the client (or parents or legal guardians if the client is a child)
- Serving as a witness to the signature process
- Determining whether the client or parents or legal guardians understand what they are signing by asking them pertinent questions

Box 1.5 describes the key elements of informed consent, although laws vary from state to state.

Nurses must become familiar with state laws as well as the policies and procedures of the health care agency. Treating children without obtaining proper informed consent violates their rights, and the physician and/or facility may be held liable for any damages (Murray, 2012).

BOX 1.5

KEY ELEMENTS OF INFORMED CONSENT

- The decision maker must be of legal age in that state, with full civil rights, and must be competent (have the ability to make the decision).
- Present information that is simple, concise, and appropriate to the level of education and language of the individual responsible for making the decision.
- The decision must be voluntary, and without coercion, force, or influence of duress.
- Have a witness to the process of informed consent.
- Have the witness sign the consent form.

Special Situations to Informed Consent

There are special situations related to informed consent. If the parent is not available, then the person in charge (relative, babysitter, or teacher) may give consent for emergency treatment if that person has a signed form from the parent or legal guardian allowing him or her to do so. During an emergency situation, a verbal consent via the telephone may be obtained. Two witnesses must be listening simultaneously and will sign the consent form, indicating that consent was received via telephone. Health care providers can provide emergency treatment to a child without consent if they have made reasonable attempts to contact the child's parent or legal guardian (AAP, Committee on Pediatric Emergency Medicine, & Committee on Bioethics [CPEMCB], 2011; Wright, 2011). In urgent or emergent situations,

appropriate medical care never should be delayed or withheld due to an inability to obtain consent (AAP, CPEMCB, 2011; Wright, 2011). Certain federal laws, such as the Emergency Medical Treatment and Labor Act (EMTALA), require that every client who presents at an emergency department is given a medical examination regardless of informed consent or reimbursement ability (AAP, CPEMCB, 2011; Wright, 2011). Table 1.7 gives further information about other special situations.

Exceptions to Parental Consent Requirement

In some states, a **mature minor** may give consent to certain medical treatment. The health care provider must determine that the adolescent (usually over 14 years of age) is sufficiently mature and intelligent to make the decision for treatment. The provider also considers the complexity of the treatment, its risks and benefits, and whether the treatment is necessary or elective before obtaining consent from a mature minor (AAP, CPEMCB, 2011; Wright, 2011).

TABLE 1.7 SPECIAL CONSIDERATIONS RELATED TO INFORMED CONSENT

Issue	Definition	Nursing Considerations
Child not living with biologic or adoptive parents	Child living: • In foster care • With potential adoptive parent • With a relative	Legally appointed guardian must provide consent Verify authority and include documentation of legally appointed guardian in child's medical record
Parent consent after divorce	Ability to give consent for health care rests with parent who has legal custody by divorce degree	Determine if the parents have joint custody or if there is sole custody by one parent Even the parent with only physical custody may give consent for emergency care May need to seek court involvement if there is joint legal custody but parents disagree on care
Consent for organ donation	For a minor to donate, the parents must be aware of the risks and benefits and must provide emotional support to the child. There should be a close relationship between the donor and recipient, if living-related donation is occurring The minor must agree to donate without coercion in live organ donation	Potential donors should be referred to local organ procurement organization Educate family about policies related to organ donation Legal guardian or parent consents to organ donation (AAP, 2013)
Consent for medical experimentation	Requirements include consent of parents, assent of child, and a perceived benefit to the child (USDHHS, n.d.)	Comply with all federal regulations if federal funds are received (refer to section on assent)

Adapted from American Academy of Pediatrics, Committee on Hospital Care, Section on Surgery, and Section on Critical Care. (2010). Pediatric organ donation and transplantation. *Pediatrics, 125*(4), 822–828; and U.S. Department of Health and Human Services. (n.d.). *Special protections for children as research subjects.* Retrieved from http://www.hhs.gov/ohrp/policy/populations/children.html

State laws vary in relation to the definition of an **emancipated minor** and the types of treatment that may be obtained by an emancipated minor (without parental consent). The nurse must be familiar with the particular state's law. Emancipation may be considered in any of the following situations, depending on the state's laws:

- Membership in a branch of the armed services
- Marriage
- Court-determined emancipation
- Financial independence and living apart from parents

• Pregnancy
• Mother less than 18 years of age

The emancipated minor is considered to have the legal capacity of an adult and may make his or her own health care decisions (AAP, Committee on Bioethics [CB], 2012; Wright, 2011).

Many states do not require consent or notification of parents or legal guardians when providing specific care to minors. Depending on the state law, health care may be provided to minors for certain conditions, in a confidential manner, without including the parents. These types of care may include pregnancy counseling, prenatal care, contraception, testing for and treatment of sexually transmitted infections and communicable diseases (including HIV), substance abuse, and mental illness counseling and treatment (AAP, CB, 2012; Brooke, 2011). These exceptions allow children to seek help in a confidential manner in situations where they might otherwise avoid care if they were required to inform their parents or legal guardian. Again, laws vary by state, so the nurse must be knowledgeable about the laws in the state where he or she is licensed to practice.

Assent

Assent means agreeing to something. In pediatric health care, the term **assent** refers to the child's participation in the decision-making process about health care (AAP, 2012). The age of assent depends on the child's developmental level, maturity, and psychological state. The AAP recommends that children and adolescents be involved in the discussions about their health care and kept informed in an age-appropriate manner (AAP, CB, 2012; Sirbaugh & Diekema, 2011). As a child gets older, assent or dissent should be given more serious consideration. The pediatric client needs to be empowered by health care providers to the extent of their capabilities and as children mature and develop over time they should become the primary decision maker regarding their own health care (AAP, CB, 2012; Sirbaugh & Diekema, 2011). The AAP recommends that if a health care provider asks the child's opinion about the direction of treatment or participation in research, then the child's view and desires should be seriously considered (AAP, CB, 2012; Sirbaugh & Diekema, 2011).

When obtaining assent, first help the child to understand his or her health condition, depending on the child's developmental level. Next, inform the child of the treatment planned and discuss what he or she should expect. Then determine what the child understands about the situation and make sure he or she is not being unduly influenced to make a decision one way or another. Finally, ascertain the child's willingness to participate in the treatment or research (AAP, CB, 2012 Sirbaugh & Diekema, 2011). Assent is a process and should continue throughout the course of treatment or research protocol.

The converse of assent is **dissent** (disagreeing with the treatment plan), and it may be ethically binding (AAP, CB, 2012). If the health care provider is not going to honor the pediatric client's dissent, then the argument can be made that the provider should not ask for the client's assent. In some cases, such as in those of significant morbidity or mortality, dissent may need to be overridden. These cases need to be looked at on an individual basis. If the decision is made to move forward with treatment despite the child's dissent, then this decision must be explained to the child in developmentally appropriate terms.

There has been an increased emphasis on including children in research studies. Children are not little adults but 70% of medicines given to children have only been tested on adults (National Institutes of Health, 2012). In research studies investigators and investigation review boards (IRBs) are responsible for ensuring measures are taken to protect the children in the studies. The nurse caring for these children also has the responsibility to ensure protection at all stages of the research process. Nurses can become members of the IRB; they should also become familiar with studies that have been approved in their work setting to help ensure their pediatric clients are protected.

Take Note!

Whenever possible, obtain assent for participation from the child.

Refusal of Medical Treatment

All clients have the right to refuse medical treatment, based on the American Hospital Association's Bill of Rights. Ideally, medical care without informed consent should be used only when the client's life is in danger. Clients may refuse treatment if it conflicts with their religious or cultural beliefs (Brudney & Lantos, 2011). An example would be a Jehovah's Witness. Individuals of this faith have strong beliefs based upon passages from the Bible that are interpreted as prohibiting the "consumption" of blood. Their beliefs prevent them from accepting transfusion of whole blood or its primary components. With recent advances and use of biologic hemostats that aid coagulation and reduce blood loss, major surgery can be performed safely in the Jehovah's Witness who refuses blood transfusion by utilizing these devices (Darwish, 2011). In these cases, it is important to educate the client and family about the importance of the recommended treatment without coercing or forcing the client to agree. Sometimes common ground may be reached between the family's religious or cultural beliefs and the health care team's recommendations. Communication and education are the keys in this situation.

In the case of a child, parental autonomy (the right to decide for or against medical treatment) is a fundamental, constitutionally protected right, but not an absolute one. The general assumption is that parents act in the best interests of their children. Ideally, medical care without informed consent should be given only when the child's life is in danger. In some cases parents may refuse medical treatment for their child. This refusal may arise when treatment conflicts with their religious or cultural beliefs, and the nurse should be aware of some of these common beliefs. Some religions, such as Christian Science, Pentecostal, Church of the First Born, and Followers of Christ, prefer prayer or faith healing over allopathic medicine (Bingham, 2012; Hall, 2013). The Black Muslim culture advocates vegan diets and refuses pork-based medicines or treatments. Hindus may refuse beef-based foods and medicines. People from an Islamic background may refuse the use of any potentially addictive substances such as narcotics or medicines containing alcohol (Leever, 2011). Sometimes common ground may be reached between the family's religious or cultural beliefs and the health care team's recommendations.

Take Note!

Do not assume what a family's beliefs are based on religious affiliation. Assess each family and child views on an

individual basis.

In other cases, parents may refuse treatment if they perceive that their child's quality of life may be significantly impaired by the medical care that is offered. The health care team must appropriately educate the family and communicate with them on a level that they can understand. The child and family should be informed of what to expect with certain tests or treatments. The health care team should make a clinical assessment of the child's and family's understanding of the situation and their reasons for refusing treatment. Active listening may allow the health care provider to address the concerns, fears, or reservations the family may have regarding their child's care.

Refusal of medical care may be considered a form of child neglect. If providing medical treatment may prevent substantial harm and suffering, or save a child's life, health care providers and the judicial system strive to advocate for the child. The state has an overriding interest in the health and welfare of the child and can order that medical treatment to proceed without signed informed consent; this is referred to as *parens patriae* (the state has a right and a duty to protect children). If the parents refuse treatment and the health care team feels the treatment is reasonable and warranted, the case should be referred to the institution's ethics committee. If the issue remains unresolved, or in complex cases, the judicial system may become involved (AAP, 2012).

Advance Directives

The Patient Self-Determination Act of 1990 established the concept of advance directives. Advance directives determine the child's and family's wishes should life-sustaining care become necessary. Parents are generally the surrogate decision makers for children. If the child's interests are not served by prolonged survival, then the physician or advanced practitioner should educate the parents about the extent of the child's illness and potential for ongoing quality of life (Edwards et al., 2012). After discussion with other family members, friends, and spiritual advisors, the parents may make the decision to forego life-sustaining medical treatment, either withdrawing treatment or deciding to withhold further treatment or opt not to resuscitate in the event of cardiopulmonary arrest (McGowan, 2011).

Life-sustaining care may include antibiotics, chemotherapy, dialysis, ventilation, cardiopulmonary resuscitation, and artificial nutrition and hydration. Some families may choose to withdraw these treatments if they are already in place or to not begin them should the need arise. **Do not attempt resuscitation (DNAR)** orders are in place for some children, particularly the terminally ill. Some institutions have started using the term AND (Allow Natural Death). No matter what term is used, these orders should include specific instructions regarding the child's and family's wishes (e.g., some families may desire oxygen but not chest compressions or code medications). When the child is hospitalized, the DNAR order must be documented in the physician orders and updated according to the facility's policy. DNAR orders may also be in place in the home, but only a few states allow emergency medical services to honor a child's DNAR order in the home. Children with DNAR orders may also still be attending school. In that case, the health care professionals involved should meet with the school officials (the board of education and its legal

counsel) to discuss how the DNAR request can be upheld in the school setting (McGowan, 2011). The health care provider should help educate the school about the child's condition, potential complications, and health care goals (AAP, Committee on School Health and Committee on Bioethics [CSHCB], 2013). They should work with the school and family on developing an individualized health care plan that will include what to do instead of CPR such as comfort measures (AAP, CSHCB, 2013).

The Baby Doe regulations, which are an amendment to the United States Child Abuse Protection and Treatment Act, provide specific guidelines on how to treat extremely ill, premature, terminally ill, and/or disabled infants regardless of the parents' wishes (Tucker et al., 2011).

Health care providers must continue to work with parents of extremely sick or premature infants to ensure they are accurately informed about the condition of their child and the risks and benefits to treatment. Health care providers must also be aware of federal, state, and hospital policy regarding care of very ill, premature, and/or disabled newborns.

The nurse must be knowledgeable about the laws related to health care of children in the state where he or she practices as well as the policies of the health care institution. The nurse must be sensitive to the various ethical situations that he or she may become involved in and should apply knowledge of laws as well as concepts of ethics to provide appropriate care.

Client Rights

The American Hospital Association first established a Patient's Bill of Rights in 1972 as a way to promote the value and dignity of the client. This information is updated periodically. Most health care agencies and professional organizations have developed some type of document that addresses client rights.

Ensuring that client rights are upheld is a key aspect in the care of any client. For the pregnant woman, two clients must be considered—the pregnant woman and her fetus. The American Foundation for Maternal and Child Health developed the Pregnant Patient's Bill of Rights to address specific concerns and situations involving the health and well-being of the mother and her fetus. In addition, the U.S. Department of Health and Human Services has issued laws related to protecting the welfare of newborns (the Baby Doe law). A child, due to his or her age and developmental level, may lack mature decision-making abilities. Many pediatric institutions have adopted a bill of rights for children's health care specific to that institution. This might include the following rights:

- To be called by name
- To receive compassionate health care in a careful, prompt, and courteous manner
- To know the names of all providers caring for the child
- To have basic needs met and usual schedules or routines honored
- To make choices whenever possible
- To be kept without food or drink when necessary for the shortest time possible
- To be unrestrained if able
- To have parents or other important persons with the child
- To have an interpreter for the child and family when needed
- To object noisily if desired

- To be educated honestly about the child's health care
- To be respected as a person (not having people talk about the child within earshot unless the child knows what is happening)
- For all health care providers, to respect the child's confidentiality about his or her illness at all times (adapted from Children's Hospital Los Angeles, 2012)

Confidentiality

With the establishment of the Health Insurance Portability and Accountability Act (HIPAA) of 1996, the confidentiality of health care information is now mandated by law. The primary intent of the law is to maintain health insurance coverage for workers and their families when they change or lose jobs. Another aspect of the law requires the Department of Health and Human Services to establish national standards for electronic transmission of health information. With the increased use of electronic medical records (EMRs) and electronic billing came the increased possibility that personal health information might be inappropriately distributed. Client confidentiality and privacy must be maintained in the same manner as it is with paper documentation. Nurses can ensure that privacy is maintained when using computerized documentation and EMRs by doing the following:

- Always maintain the security of personal log-in information; nurses should never share it with other health care providers or other persons.
- Always log off when leaving the computer.
- Do not leave client information visible on a monitor screen when the computer/monitor is unattended.
- Use safeguards, such as encryption, when using alternative means of communication such as email.

Exceptions to confidentiality exist. For example, suspicion of physical or sexual abuse and injuries caused by a weapon or criminal act must be reported to the proper authorities. Abuse cases are reported to the appropriate welfare authorities, whereas criminal acts are reported to the police. In addition, if the minor is a threat to self, then information may need to be disclosed to protect the child. The health care provider must also follow public health laws that require reporting certain infectious diseases to the local health department (e.g., tuberculosis, hepatitis, HIV, and other sexually transmitted infections). Finally, there is a duty to warn third parties when a specific threat is made to an identifiable person.

Health care providers must strike a balance between confidentiality and required disclosure. Even if disclosure is required it is recommended that the health care provider attempt to gain consent for the disclosure and when possible inform the minor of the limits to confidentiality and consent prior to the initiation of care (Murray, Calhoun, & Philipsen, 2011).

IMPLICATIONS FOR NURSES

The health care system is intricately woven into the political and social structure of our society, and nurses should understand social, legal, and ethical health care issues so that they can play an active role in meeting the health care needs of women, children, and families. Nurses need to take a proactive role in advocating for and empowering their clients. For example, nurses can help women to increase control over the factors that affect health, thereby improving their health status. A

woman may become empowered by developing skills not only to cope with her environment, but also to change it. Nurses also can assume this mentoring role with children and families, thus helping them to improve their overall health status and health outcomes.

Nurses must have a solid knowledge base about the factors affecting maternal and child health and barriers to health care. They can use this information to provide anticipatory guidance, health counseling, and teaching for women, children, and families. It also is useful in identifying high-risk groups so that interventions can be initiated early on, before problems occur.

When caring for women, children, and families, the nurse operates within the framework of the nursing process, which is applicable to all health care settings. Maternal and child health nursing is everchanging as globalization and the exchange of information expands. Nurses must remain up to date about new technologies and treatments and integrate high-quality, evidence-based interventions into the care they provide.

KEY CONCEPTS

- *Healthy People 2020* presents a national set of health goals and objectives for adults and children that focus on health promotion and disease prevention.
- One method to establish the aggregate health status of women, infants, and children is with statistical data, such as mortality and morbidity rates.
- The infant mortality rate is the lowest in the history of the United States, but it is still higher when compared with other industrialized countries. This high rate may be the result of the increase in low-birth-weight infants born in this country.
- The family is considered the basic social unit. The family greatly influences the development and health of its members. Members learn health care activities, health beliefs, and health values from their family.
- Social roles are often an important factor in the development of one's self-concept, which can have a very positive influence on health or present various limitations and problems, possibly resulting in a negative influence on health.
- Culture influences every aspect of development and is reflected in childbearing and child-rearing beliefs and practices designed to promote healthy adaptation.
- Spirituality, a major influence for many individuals, provides a meaning and purpose to life and is a foundation for and a source of love, relationships, and service. Spiritual and religious beliefs and views can provide strength and support to women, children, and their families during times of stress and illness.
- Other factors impacting the health of women and children include health status and lifestyles, improved diagnosis and treatment, and health care consumer empowerment. Finances, transportation, language, culture, and the health care delivery system can provide barriers to health care.
- Advances in science and technology have led to increased ethical dilemmas in health care.
- All clients have the right to refuse medical treatment based on the American Hospital Association's Bill of Rights. For a child, the parents have the legal right to decide for or against medical treatment. Minor children (under the age of 18 years) must have their parents or legal guardians provide consent for health care in most cases.
- In certain states, mature minors and emancipated minors may consent to their own health care and certain health care may be provided to adolescents without parental notification, including contraception, pregnancy counseling, prenatal care, testing and treatment of sexually transmitted infections and communicable diseases (including HIV), substance abuse and mental illness counseling and treatment, and health care required as a result of a crime-related injury.

- The nurse must be knowledgeable about the laws related to health care of women and children in the specific state of nursing practice as well as the specific policies of the health care institution.

CHAPTER WORKSHEET

MULTIPLE-CHOICE QUESTIONS

1. When preparing a presentation for a local woman's group on women's health problems, what would the nurse include as the number-one cause of mortality for women in the United States?
   a. Breast cancer
   b. Childbirth complications
   c. Injury resulting from violence
   d. Heart disease
2. Which factor would most likely be responsible for a pregnant women's failure to receive adequate prenatal care in the United States?
   a. Belief that it is not necessary in a normal pregnancy
   b. Use of denial to cope with pregnancy
   c. Lack of health insurance to cover expenses
   d. Inability to trust traditional medical practices
3. When caring for an adolescent, in which instance must the nurse share information with the parents, no matter which state care is provided in?
   a. Pregnancy counseling
   b. Depression
   c. Contraception
   d. Tuberculosis
4. The following events were milestones in the support of women's and children's health. Place the events in the correct sequence, from oldest to most recent.
   a. Declaration of the Rights of the Child approved
   b. WIC program established
   c. U.S. Children's Bureau established
   d. Sheppard–Towner Act passed
   e. Family and Medical Leave Act passed
   f. Education for All Handicapped Children Act passed
5. The nurse is preparing a class for a group of students about homelessness. Which factors contribute to homelessness? Select all that apply.
   a. Decrease in the number of people living in poverty
   b. Rises in unemployment
   c. Exposure to abuse or neglect
   d. Cutbacks in public welfare programs
   e. Development of community crisis centers

CRITICAL THINKING EXERCISES

1. As a nurse working in a federally funded low-income clinic offering women's

health services, you are becoming increasingly frustrated with the number of "no-shows," or appointments missed in your maternity clinic. Some clients come for their initial prenatal intake appointment and never come back. You realize that some just forget their appointments, but most don't even call to notify you. Many of the clients are high risk and thus are jeopardizing their health and the health of their future child.
   a. What changes might be helpful to address this situation?
   b. Outline what you might say at your next staff meeting to address the issue of clients making one clinic visit and then never returning.
   c. What strategies might you use to improve attendance and notification?
   d. Describe what cultural and customer service techniques might be needed.
2. A couple has adopted an 11-month-old infant girl from China and brought her to the health care facility for a checkup. The couple had no contact with the infant's birth parents. The infant spent 7 months in an orphanage before being adopted. Describe the family structure and the issues that may affect this family.
3. You have been asked by the local school district to speak to a group of middle-school children and their parents about Internet safety. Describe the topics that you should address.
4. A 12-year-old is to undergo research treatment for a serious illness. Explain the concept of assent as it relates to this situation.

STUDY ACTIVITIES

1. Research a current policy, bill, or issue being debated on the community, state, or national level that pertains to the health and welfare of women or children. Summarize the major facts and supporting and opposing arguments, and prepare an oral report on your findings.
2. Within your clinical group, debate the following statement: Should access to health care be a right or a privilege?
3. Visit a local community health center that offers services to women and children from various cultures. Interview the staff about any barriers to health care that they have identified. Investigate what the staff has done to minimize these barriers.

BRINGING IT ALL TOGETHER: A CASE STUDY

Maali, a 19-year-old Arab immigrant, presents at the local prenatal clinic accompanied by her husband Labib. The couple and their 18-month-old daughter, Labiba, have lived with relatives since arriving in America 5 months ago. During the prenatal interview, Maali reports that she is 4 months pregnant and is the primary caregiver for their daughter as well as caring for Labib's sister's toddler son while her sister-in-law is at work during the day.

Go to thePoint to find questions to consider about this case.

2

Family-Centered Community-Based Care

WOW

Words of Wisdom

To recognize diversity in others and respect it, we must first have some awareness of who we are.

KEY TERMS

atraumatic care
case management
community
cultural competence
epidemiology
evidence-based nursing practice
family-centered care
health literacy
nonverbal communication
population
verbal communication

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Identify the core concepts associated with the nursing management of women, children, and families.
2. Examine the major components and key elements of family-centered care.
3. Explain the different levels of prevention in nursing, providing examples of each.
4. Give examples of cultural issues that may be faced when providing nursing care.
5. Provide culturally competent care to women, children, and families.
6. Outline the various roles and functions assumed by the nurse working with women, children, and families.
7. Demonstrate the ability to use excellent therapeutic communication skills when interacting with women, children, and families.
8. Explain the process of health teaching as it relates to women, children, and families.
9. Examine the importance of discharge planning and case management in providing nursing care.
10. Explain the reasons for the increased emphasis on community-based care.
11. Differentiate community-based nursing from nursing in acute care settings.
12. Identify the variety of settings where community-based care can be provided to women, children, and families.

***Maria* was home a few days after giving birth to her first child. She had just changed her newborn son and placed him on his stomach for a nap when the community health nurse arrived for a postpartum visit. Because the nurse didn't speak Spanish and Maria didn't speak English, a great deal of gesturing followed. After examining Maria, the nurse then picked up her son and placed him on his back in the crib. How might the nurse have prepared for this home visit? What message did the nurse convey in changing the newborn's position?**

INTRODUCTION

Now more than ever, nurses contribute to nearly every health care experience. Historically, people were born at home, cared for when ill at home, and then died at home surrounded by loved ones. Today, these events from birth to death, and every health care emergency in between, will likely involve the presence of a nurse. Involvement of a knowledgeable, supportive, comforting nurse often leads to a positive health care experience. Skilled nursing practice depends on a solid base of knowledge and clinical expertise delivered in a caring, holistic manner. Nurses, using their knowledge and passion, help meet the health care needs of their clients throughout the life span, whether the client is a pregnant woman, a fetus, a partner, a child, or the parents or family members of a child. Nurses fill a variety of roles in helping clients to live healthier lives by providing direct care, emotional support, comfort, information, advice, advocacy, support, and counseling. Nurses are often "in the trenches" advocating on various issues, drawing attention to the importance

of health care for women and children, encouraging a focus on education and prevention, and assisting families who lack resources or access to health care.

Women, children, and families receive a majority of their health care, both well and ill care, in the community setting. During the past several years, the health care delivery system has changed dramatically. Medicare's prospective payment system (PPS) for hospitals, introduced in the United States in 1983, replaced cost reimbursement with a system of fixed rates which created incentives for hospitals to control costs. With a focus on cost containment, people are spending less time in the hospital. Clients are being discharged "sicker and quicker" from their hospital beds (Hansen, 2015). The health care system has moved from reactive treatment strategies in hospitals to a proactive approach in the community. This has resulted in an increasing emphasis on health promotion and illness prevention within the community.

Nurses play an important role in the health and wellness of a community. This is an exciting time for nurses delivering out-of-hospital care. The rising trend of delivering care in or near people's homes and away from acute care facilities will necessitate flexible ways of working and greater integration of community nursing roles (Massey, 2015). They not only meet the health care needs of the individual but also go beyond that to implement interventions that affect the community as a whole. Nurses practice in a variety of settings within a community, such as clinics and physician offices, schools, shelters, churches, health departments, community health centers, and homes. They promote the health of individuals, families, groups, communities, and populations and promote an environment that supports health.

This chapter describes the core concepts of maternal and child health nursing and community and community-based nursing. Nurses need to be knowledgeable about these concepts to ensure that they provide professional care.

CORE CONCEPTS OF MATERNAL AND CHILD HEALTH NURSING

Maternal and child health nursing focuses on providing evidence-based care to the client within the context of the family. This care involves the implementation of an interdisciplinary plan in a collaborative manner to ensure continuity of care that is cost-effective, quality-oriented, and outcome-focused. Nurses provide this care by focusing on the family, using evidence-based practice, working collaboratively, providing atraumatic therapeutic care, communicating effectively, providing education, providing discharge planning and case management, providing advocacy and resource management, providing preventative care, providing culturally competent nursing care, and being knowledgeable about complementary and alternative medicine (CAM).

Family-Centered Care

Family-centered care refers to the collaborative partnership among the individual, family, and caregivers to determine goals, share information, offer support, and formulate plans for health care. It is generally understood to be an approach in which clients and their families are considered integral components of the health care decision-making and delivery processes. It recognizes the client and the family as the source of control and a full partner in their care (Roberts, 2015). It is based

on mutual trust and collaboration between women, children, families, and the health care professional. It is a partnership approach of families and their caregivers that recognizes the strength and integrity of the family.

The philosophy of family-centered care recognizes the family as the constant. The health and functioning of the family affect the health of the client and other members of the family. Family members support one another well beyond the health care provider's brief time with them, such as during the childbearing process or during a child's illness.

Family-centered care requires sensitivity to the client's and family's beliefs and those supporting their culture. This involves listening to the family's needs and a shift of the nurse's authoritarian role to the family to empower them to make their own decisions within the context of a supportive environment.

With family-centered care, support and respect for the uniqueness and diversity of families are essential, along with encouragement and enhancement of the family's strengths and competencies. It is important to create opportunities for families to demonstrate their abilities and skills. Families also can acquire new abilities and skills to maintain a sense of control and empowerment in meeting the needs of the client. Family-centered care promotes greater family self-determination, decision-making abilities, control, and self-efficacy, thereby enhancing the client's and family's sense of empowerment. When implementing family-centered care, nurses seek caregiver input. These suggestions and advice are incorporated into the client's plan of care as the nurse counsels and teaches the family appropriate health care interventions. Today, as nurses partner with various experts to provide high-quality and cost-effective care, one expert partnership that nurses can make is with the client's family.

The impact of family-centered care can be seen in the models of care delivery for women and children. From the 1980s to the present, there has been increased access to care for all women (regardless of their ability to pay) and hospital redesigns (labor, delivery, and recovery [LDR] rooms; labor, delivery, recovery, and postpartum [LDRP] spaces) aimed at keeping families together during the childbirth experience and to minimize interruptions in breast-feeding dyads (Ayers, Grassley, & Koprowski, 2015). This impact also can be seen in the care of children. For example, rooming-in and liberal visiting policies allow parents and other family members to participate in the child's care (Fig. 2.1).

Family-centered care works well in all arenas of health care, from preventive care to long-term care. Using a family-centered approach is associated with positive outcomes such as decreased anxiety, improved pain management, shorter recovery times, and enhanced confidence and problem-solving skills. Communication between the health care team and the family is also improved, leading to greater satisfaction for both health care providers and health care consumers (families). It is important for nurses to remain neutral to all they hear and see in order to enhance trust and maintain open communication lines with all family members. Nurses need to remember that clients are an expert of their own health, thus nurses should work within the clients' framework when planning health promotion interventions.

FIGURE 2.1 Providing an opportunity for the parent to interact with the child is an important component of family-centered nursing care.

Evidence-Based Care

Evidence-based nursing practice involves the use of research or evidence in establishing a plan of care and then implementing that care. It is a clinical decision-making approach that involves the integration of the best scientific evidence, client values and preferences, clinical circumstances, and clinical expertise to promote best outcomes (Williamson et al, 2015). It is important that nurses develop the skills and knowledge necessary to ask pertinent clinical questions, search for current best evidence, analyze the evidence, integrate the evidence into practice when appropriate, and evaluate outcomes. Evidence-based practice may lead to a decrease in variations in care while at the same time increasing quality and improving health care.

Scientific research findings help nurses not only stay current in their clinical specialties, but also in their choice of the most effective interventions. Many of the professional organizations Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN, ANA, NLN, etc.) have developed evidence-based clinical practice guidelines for the safest and effective delivery of family-centered nursing care. Nurses should be diligent in seeking out these evidence-based guidelines to ensure excellence in their daily practice. When evidence-based practice (EBP) is delivered in a context of caring and in a supportive organizational culture, the highest quality of care and best client outcomes can be achieved (Bridges, 2015; Makic et al., 2015).

Collaborative Care

Nurses must embrace interprofessional collaborative care because health care reform has transformed health care delivery models that require team work. Nurses must transition from working in a silo to working with interprofessional teams. This transition is needed to provide high-quality, safe, and accountable care to achieve positive client outcomes (Lomax & White, 2015). Modern health care focuses on an interdisciplinary plan of care designed to meet a client's physical, developmental, educational, spiritual, and psychosocial needs. This interdisciplinary collaborative type of care is termed **case management**, a collaborative process involving assessment, planning, implementation, coordination, monitoring, and evaluation. It involves the following components:

• Advocacy, communication, and resource management
• Client-focused comprehensive care across a continuum
• Coordinated care with an interdisciplinary approach (Commission for Case Management Certification, n.d.)

When the nurse effectively functions in the role as a case manager, client and family satisfaction is increased, fragmentation of care is decreased, and outcome measurement for a homogenous group of clients is possible.

Atraumatic Pediatric Care

Children undergo a wide range of interventions, many of which can be traumatic, stressful, and painful. The various settings where the child receives care can be scary and overwhelming to the child and family. The child and family interact with various health care personnel, which leads to an increased potential for anxiety. A major component of the child health nursing philosophy is the importance of providing atraumatic care. **Atraumatic care** refers to the delivery of care that minimizes or eliminates the psychological and physical distress experienced by children and their families in the health care system (Wong, n.d.). The key principles of atraumatic care include the following:
• Preventing or minimizing physical stressors
• Preventing or minimizing separation of the child from the family
• Promoting a sense of control

Nurses must be alert for any situation that has the potential for causing distress and should be able to identify potential stressors. Pediatric nurses should minimize separation of the child from the family, should decrease the child's exposure to stressful situations, and should strive to prevent or minimize pain and injury. The importance of providing atraumatic care to children is integrated throughout this text and discussed in detail in Chapter 30.

Communication

Communication is a way of conveying messages to various people using a common system of symbols, signs, or behaviors. Infants start their first communication soon after birth when they cry to convey the message of discomfort or hunger. Effective therapeutic communication with women, children, and families is essential to the provision of quality nursing care. Client- and family-centered communication increases satisfaction with nursing care and aids in improving knowledge and health care skills (Arnold & Boggs, 2016). The significance of communication revolves around its effectiveness and the climate in which communication occurs. Trust, respect, and empathy are three factors needed to create and foster effective therapeutic communication between people. (See Chapter 30 for specifics on effective communication when working with children.)

Verbal Communication

Communicating through the use of words, either written or spoken, is termed **verbal communication**. Nurses use verbal communication throughout the day when interacting with clients. Good verbal communication skills are necessary when performing nursing assessments and providing child/family teaching. General

guidelines for appropriate verbal communication include the following:
• Use open-ended questions that do not restrict the child's or parents' answers.
• Redirect the conversation to maintain focus.
• Use reflection to clarify the parents' feelings.
• Paraphrase the child's or parents' feelings to demonstrate empathy.
• Acknowledge emotions.
• Demonstrate active listening by using the child's or family's own words.

Remember that most parents are laypersons, so avoid using medical jargon. The abbreviations and shortened terms that health care providers use almost without thinking may sound scary or foreign to children and parents. When medical terminology is necessary, provide a definition using developmentally appropriate language (*Healthy People 2020*).

Nonverbal Communication

Nonverbal communication, or body language, includes attending to others and active listening. The nurse should listen to the other person's verbal communication from the beginning of the interaction. When women, children, and parents feel they are being heard, trust and rapport are established. Guidelines for appropriate nonverbal communication include the following:
• Relax; maintain an open posture, with the arms uncrossed.
• Sit opposite the family and lean forward slightly.
• Maintain eye contact.
• Nod your head to demonstrate interest.
• Note the child's or parent's posture, eye contact, and facial expressions.

HEALTHY PEOPLE 2020

Objective	Significance
Increase the proportion of persons who report that their health care providers have satisfactory communication skills. (Developmental) Improve the health literacy of the population.	• Assess health learning needs of children and their families. • Plan health care education in collaboration with children and their families. • Provide health education at each client encounter. • Assess for poor health literacy skills

Healthy People Objectives retrieved from http://www.healthypeople.gov.

Take Note!

People of all ages desire to be listened to without interruption (Gupta, Mehta, & Sagar, 2015).

Active listening is critical to the communication process. Listening may uncover

fears or concerns that the nurse may not have discovered through questioning.

Paying attention while children and parents talk is a powerful communication tool. By not listening, the nurse may miss critical information and the family may be reluctant to share further. When interacting with the child and family, determine whether the messages sent by the child's or parents' verbal and nonverbal communication are congruent.

Recall Maria, who recently was discharged from the hospital with her newborn son. How did the nurse communicate with Maria? Did the nurse's actions during the visit promote the development of trust between Maria and the nurse? What might have been done differently to foster trust?

Communicating Across Cultures

Understanding and respecting the client's and family's culture helps foster good communication and improves child and family education about health care. Culture, religion, and spirituality are intertwined concepts that affect the client's and family's communication styles, health status, and health beliefs. It is important to be aware of the family's background, lifestyle, and health care practices to meet their information needs.

Learning about the practices of various cultures is just the beginning; the nurse must assess each family's individual beliefs and practices, not generalize. The best way to assess the family's cultural practices is to ask and then listen. Determine the language spoken at home and observe the use of eye contact and other physical contact. Demonstrate a caring, nonjudgmental attitude and sensitivity to the client's and family's cultural diversity.

Working with an Interpreter

Attempting to communicate with a family who does not speak English can be one of the most frustrating situations in which health care providers find themselves. In this situation, trained interpreters are an invaluable aid and an essential component of client and family education. Whether working with an interpreter in person or over the phone, it is important to coordinate efforts so that both the family and the interpreter understand the information to be communicated. Working as a team, the nurse questions or informs and the interpreter conveys the information completely and accurately (see Healthy People, 2020). Well-trained translators can also help prevent cultural missteps and can help guide the health care provider to provide information in a more culturally accepted manner (Levetown and the Committee on Bioethics, 2011). Box 2.1 presents tips for working with an interpreter to maximize teaching efforts.

HEALTHY PEOPLE 2020

Objective	Significance
Increase the proportion of local health departments that have established culturally appropriate and linguistically competent community health promotion and disease prevention programs.	• Work with professionals and individuals from various cultures to develop materials and programs for health promotion that are culturally competent. • Ensure teaching materials are provided in the appropriate language.

Healthy People Objectives retrieved from http://www.healthypeople.gov.

Several helpful resources and websites are listed on thePoint, including Language Line, which offers telephone interpreters who speak 150 languages, and The Center for Applied Linguistics, Northwest Translators and Interpreters Society, among others.

On the second visit to Maria's home, the nurse brought a Spanish-speaking interpreter who explained the reason for the "back to sleep" position and demonstrated to Maria several other useful positions for feeding and holding. Maria was smiling when the nurse left and asking when she would be back. What made the difference in their relationship the second visit? What interventions demonstrate culturally competent care?

Communicating With Deaf or Hearing-Impaired Clients and Families

Nearly one in five Americans has hearing loss, and for those over the age of 65, the ratio climbs to one in three (Berg & Serpanos, 2016). Health care providers are under a duty to provide auxiliary aids and services to establish effective communication with their clients. Providing assistance to the hearing impaired in health care settings is critically important because, without assistance through auxiliary aids and services, health service providers run the risk of not understanding the client's symptoms, misdiagnosing the client's health problem, and prescribing inadequate or even harmful treatment (Smith, 2015).

BOX 2.1

TIPS FOR WORKING WITH AN INTERPRETER

- **Help the interpreter prepare and understand what needs to be done ahead of time.** A few minutes of preparation may save a lot of time and help communication flow more smoothly in the long run.
- **Introduce yourself to both parties.** It is the key to easy communication across the language barrier.
- **Physically place yourselves so that you are facing your client, and your**

client is facing you. Place the interpreter physically close to both of you, but not in a position that breaks the line of sight between you and your client.

- **Begin with a minute or two of light conversation to establish a rhythm before getting into the business at hand.** This establishes the quantity of speech in the conversation.
- **Remember, the interpreter is the "communication bridge" and not the "content expert."** The nurse's presence at teaching sessions is vital.
- **Establish a rapport with the interpreter.**
- **Be patient. The interpreter's timing may not match that of others involved.** It often takes longer to say in some languages what has already been said in English; therefore, plan for more time than you normally would.
- **Speak slowly and clearly.** Avoid jargon. Use short sentences and be concise. Avoid interrupting the interpreter.
- **Pause every few sentences so the interpreter can translate your information.** After 30 seconds of speaking, stop and let the interpreter express the information. Talk directly to the family, not the interpreter.
- **Give the family and the interpreter a break.** Sessions that last longer than 20 or 30 minutes are too much for anyone's attention span and concentration.
- **Express the information in two or three different ways if needed.** There may be cultural barriers as well as language and dialect differences that interfere with understanding. Interpreters may often know the correct communication protocols for the family.
- **Use an interpreter to help ensure the family can read and understand translated written materials.** The interpreter can also help answer questions and evaluate learning.
- **Avoid side conversations during sessions.** These can be uncomfortable for the family and jeopardize client–provider relationships and trust.
- **Remember, just because someone speaks another language doesn't mean that he or she will make a good interpreter.** An interpreter who has no medical background may not understand or interpret correctly, no matter how good his or her language skills are.
- **Do not use children as interpreters.** Doing so can affect family relationships, proper understanding, and compliance with health care issues.

(2015). ***Tips for working with an interpreter.*** **Retrieved from http://www.asha.org/practice/multicultural/issues/interpret.htm; and Refugee Health Technical Assistance Center. (2011).** ***Best practices for communicating through an interpreter.*** **Retrieved from http://refugeehealthta.org/access-to-care/language-access/best-practices-communicating-through-an-interpreter/**

Hearing-impaired pregnant women are often neglected mostly due to a lack of understanding of how best to care for women with different communication needs. Nurses have a key role in exchanging information and taking the time to understand their needs in order to act as an advocate and help them to overcome the barriers that can be created by deafness. In order to fulfill this role, nurses need to have an understanding of the problems faced by women with hearing impairment and their partners when accessing maternity services (Jackson, 2011).

For the hearing-impaired, determine the method of communication used: lip

reading, American Sign Language (ASL), another method, or some combination. If the nurse is not proficient in ASL and the client or family uses it, then an ASL interpreter must be available if another adult family member is not present for translation. According to federal law (Americans With Disabilities Act), deaf clients and deaf family members must be given the ability to communicate effectively with health care providers (Burkey, 2015).

Education

Due to shortened hospital stays and decreased admissions, providing client and family education is a key role for nurses. Many times teaching begins in the primary care setting and then continues in the community setting, especially the home. In the community-based setting, client teaching is often focused on assisting the client and family to achieve independence.

Regardless of the type of setting, nurses are in a unique position to help clients and families manage their own health care needs. Clients and families need to be knowledgeable about areas such as their condition, the health care management plan, and when and how to contact health care providers. With the limited time available in all health care arenas, nurses must focus on teaching goals and begin teaching at the earliest opportunity. Education and planning care are essential components of quality client care (Peter et al., 2015).

Client education occurs when nurses share information, knowledge, and skills with clients and families, thus empowering them to take responsibility for their health care. Through client education, clients and families can overcome feelings of powerlessness and helplessness and gain the confidence and capability to be active members in their plan of care.

HEALTHY PEOPLE 2020

Objective	Significance
Increase the proportion of persons appropriately counseled about health behaviors. (Developmental) Increase the proportion of health care organizations that provide client and family education; increase the proportion of clients who report that they are satisfied with the client education they receive from their health care organization.	• Assess health learning needs of women, children, and their families. • Plan health care education in collaboration with clients and their families. • Provide health education at each client encounter.

Healthy People Objectives retrieved from http://www.healthypeople.gov.

Overall, client and family education allows clients and families to make informed

decisions, ensures the presence of basic health care skills, promotes recognition of problem situations, promotes appropriate responses to problems, and allows for questions to be answered. When thorough and structured education begins in the hospital setting, it can carry over into the home setting, which can decrease hospital readmissions. Verification sheets can play an important role in aiding bedside nurses to provide early formal education for clients and families being discharged home with a new device so that safe care can be achieved in the home setting (Hamilton, 2011). Client and family education is a priority and is addressed in *Healthy People 2020*.

Take Note!

To cope effectively with illness, understand and participate in decisions about treatment plans, and maintain and improve health after treatment, clients and their families must have access to the specific knowledge and skills relevant to their conditions (Patient Education Institute, 2013).

Steps of Client and Family Education

The steps of client and family education are similar to the steps of the nursing process. The nurse must assess the client, develop a plan, implement services needed, perform follow-up evaluation, and finally document education. Once the nurse achieves a level of comfort and experience with each of these steps, they all blend together into one harmonious whole that becomes an everyday part of nursing practice. Client education begins with the first client encounter and proceeds through discharge and beyond. Reassessment after each step or change in the process is critical to ensuring success.

ASSESSING TEACHING AND LEARNING NEEDS

Excellent nursing care begins with a thorough assessment of the client. In the same way, client and family education begins with a learning needs assessment that includes the client's and family's learning needs, learning styles and preferences, and potential barriers to learning. Based on the results of the assessment, an individualized plan can be developed to reduce the time and effort required for teaching while maximizing learning for the client and family. Although actual nursing care in pediatrics is given to the child, the educational process is targeted at both the child, when developmentally appropriate, and the adult members of the family. Therefore, it is advisable to conduct a learning needs assessment on both the adult caregivers and the child, when appropriate. Box 2.2 describes the components of a learning needs assessment. This is also a good time to establish rapport with the family, demonstrating your interest in them and your confidence in their ability to learn.

Share the assessment with all members of the interdisciplinary team so that the entire team can support the client's and family's learning. Although assessment generally takes place during the first or second meeting with the client and family, it should also occur with each encounter to check for any changes that may occur.

Malcolm Knowles outlined core learning principles to consider when teaching adults (Knowles, Holton III, & Swanson, 2011). He found that instruction for adults needs to focus more on the process than on the content. Box 2.3 lists adult learner-centered principles.

BOX 2.2

COMPONENTS OF LEARNING NEEDS ASSESSMENT

Assess

- Learner characteristics: Find out more about the child and family's life and how the child's illness has affected it. Learn more about the child and family's social, cultural, and spiritual values.
- Learner needs and readiness: Including what they want and need to know and what they know already; readiness and willingness to learn; motivation to learn and emotional concerns; capacity to learn such as physical or cognitive abilities including ability to read and developmental level.
- Learning style: How does the child and family learn best; preferred learning methods.
- Learning barriers: Cultural or language barriers; cognitive or physical disabilities; presence of pain; lack of support network.

BOX 2.3

SPECIFIC LEARNING PRINCIPLES RELATED TO PARENTS

- **Adults are self-directed.** Adults value independence and want to learn on their own terms. Teaching strategies that include such concepts as role playing, demonstration, and self-evaluation are most helpful. Using this model, nurses can partner with families to ensure that education is interactive and adopt the role of facilitator rather than lecturer.
- **Adults are problem-focused and task-oriented.** Adults learn best when they perceive there is a gap in their knowledge base and want information and skills to fill the gap. Providing a reason to learn can often motivate families that appear slow to comply with their child's care and education.
- **Adults are goal oriented.** Adults learn best at a time when learning meets an immediate need. Presenting information in an organized, sequential, and timely fashion can often help families understand the importance of learning a particular piece of information or task.
- **Adults value past experiences and beliefs.** Adults bring an accumulated wealth of experiences to each health care encounter; this provides a rich base for new learning. Education should take into account a wide range of backgrounds. Appreciating and using individual differences during teaching encounters can help improve compliance and reduce resistance to educational goals.

Knowles, M. S., Holton III, E. F., & Swanson, R. A. (2011). *The adult learner* (7th ed.). Burlington, MA: Elsevier.

CULTURAL IMPACT ON ASSESSMENT OF LEARNING NEEDS

In addition to determining the language spoken in the home and use of eye and physical contact, investigate the following during the assessment:

- Who is the person caring for the child at home?
- Who is the authority figure in the family?
- What is the social support structure?
- Are there any special dietary needs and concerns?
- Are any traditional health practices used (e.g., healers, shamans, talismans, folk remedies, and herbs)?
- Are any special clothes or other items used to help maintain health?
- What religious beliefs, ceremonies, and spiritual practices are important?

Learning needs can then be negotiated with the family and met based on the assessment. Issues encountered when teaching immigrant or refugee families might include confusion regarding the use of the English versus the metric scale; preparing formulas and medicines using a "handful" or "pinch" of ingredients rather than specific measurements such as a measuring cup or syringe; access to refrigeration for liquid antibiotics; and breast-feeding practices.

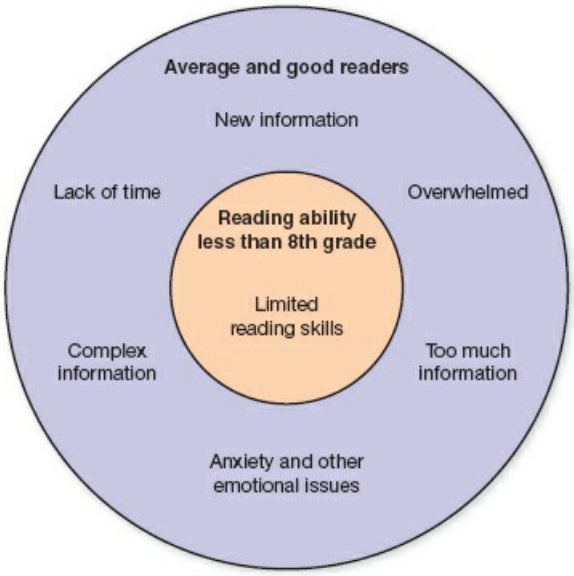

FIGURE 2.2 **Factors contributing to poor health literacy.**

LITERACY ISSUES

Adequate literacy skills are essential for client and family education, yet many people in America today have marginal reading capabilities. In the United States, 36 million adults cannot read better than the average third grader (ProLiteracy, 2014).

Even people with adequate literacy skills may have difficulty reading, understanding, and applying information to health care situations (Fig. 2.2). **Health literacy** is the ability to read, understand, and use health care information to make appropriate health care decisions and successfully navigate the health care system (Hersh, Salzman, & Snyderman, 2015). It is not simply having the ability to read the health care information, but also includes listening; displaying oral, analytic, and decision-making skills; using electronic technology; and applying these skills to health care situations. The inability to read and comprehend health care

information is an enormous problem for many Americans today. Low health literacy affects people of all ages, races, and educational and income levels.

Take Note!

The American Medical Association reports that poor health literacy skills are a stronger predictor of health status than age, income, employment status, education level, or racial or ethnic group (NNLM, 2015). Poor health literacy leads to increased complications and increased mortality (Boodman, 2011). The cost of low health literacy to the U. S. economy is between $106 and $238 billion annually (NNLM, 2015). Other health literacy studies have suggested that people with inadequate health literacy have higher rates of hospitalization and longer hospital stays, higher usage of expensive emergency services, increased medication errors, and generally a higher level of illness (Centers for Disease Control and Prevention [CDC], 2015d).

Medical information is becoming increasingly complex, while the amount of time nurses have to spend with clients is decreasing. Also, when unfamiliar information is introduced or when emotional distress is present, reading ability and understanding are further reduced. As a result, many studies have shown that persons with limited literacy skills cannot understand basic medical words and health concepts, verbal or written. For example, in one study it was noted that:

- One in four did not understand when their next appointment was scheduled.
- Almost half did not understand the instructions, "Take medication on an empty stomach."
- Three quarters misunderstood warnings on medication labels or the rights and responsibilities section of a Medicaid application (Duell et al., 2015).

Take Note!

Recent Federal programs, such as the Affordable Care Act of 2010, the Department of Health and Human Services' National Action Plan to Improve Health Literacy, and the Plain Writing Act of 2010 have been developed to improve health literacy (Koh et al., 2012).

RECOGNIZING POOR HEALTH LITERACY SKILLS

Poor health literacy skills are difficult to recognize: appearance, verbal ability, employment status, and educational level cannot reliably detect persons who do not read well. Also, many people who do not read well go to great lengths to hide their disability; 68% of people with limited literacy skills have never told their spouse and 75% have never told their health care provider (Brega et al., 2015). Poor health literacy affects all segments of the population but certain groups such as the elderly, the poor, members of minority groups, recent immigrants to the United States who do not speak English, and those who are born in the United States but English is a second language are at higher risk (Zambrana et al., 2015).

Red flags that might indicate poor literacy skills include the following:

- Difficulty filling out registration forms, questionnaires, and consent forms; forms are incomplete, incorrect, or inaccurate
- Frequently missed appointments
- Noncompliance and lack of follow-up with treatment regimens
- History of medication errors
- Responses such as, "I forgot my glasses" or "I'll read this when I get home"
- Inability to answer common questions about their treatment or medicines

• Avoiding asking questions for fear of looking “stupid” (Brega et al., 2015)

Nurses need to provide understandable and accessible information to all clients, regardless of their literacy or education levels. This would include avoiding medical jargon, breaking down information or instructions into small concrete steps, limiting the focus of a visit to three key points or tasks, and assessing for comprehension. In addition, printed information should be written at or below a 5th to 6th grade reading level with plenty of visual aids or pictures (Hersh et al., 2015).

PLANNING EDUCATION

Once the assessment is completed, plan mutually agreed-upon, achievable learning goals and objectives. It is important that both the teacher and learner believe the goals can be accomplished. Finding common ground and building a bridge between the client’s and family’s concerns and what the health care team believes they need to know is a critical part of an education plan. This also is an excellent time to consider which client education materials and resources can be used to maximize learning and retention. No single teaching method will suit every client and family. Individualize educational methods to meet the learning needs and abilities of the audience that is being taught. Ensuring instructional methods are chosen based on educational outcomes is a key to success (Su, Herron, & Osisek, 2011).

A review of recent research on patient education found effective teaching strategies that include computer technology, audiotapes, videos, written materials prepared at an appropriate reading level for the general population, and demonstration (Friedman et al., 2011). Verbal instruction was found to be least effective and should be used along with another teaching method (Friedman et al., 2011). Using multiple teaching strategies, such as using videos, dolls, play therapy, or computer-based instruction along with written material for future reference, are beneficial. Almost 67% of patients had better outcomes when multiple teaching methods were used (Friedman et al., 2011). Visual aids such as pictures and illustrations are very helpful and can assist those with low literacy. Education that is culturally appropriate, presented in a structured manner and specific to the individual has been found to be more effective (Friedman et al., 2011).

Planning client and family education should involve input from the entire interdisciplinary team when appropriate. Through good communication and collaboration, team members can work together to empower the child and family to become knowledgeable and skillful caregivers. Leaving behind the traditional path of teacher-centered education and providing family-centered education instead requires thought and skill.

TABLE 2.1 SIX TECHNIQUES TO IMPROVE LEARNING

Technique	Explanation
Slow down and repeat information often.	Since most of the education in a health care setting is done verbally, repeat important information at least four or five times.
Speak in conversational style using plain, nonmedical language.	When writing directions, write only several words, bullet points, or phrases. Use common, "living-room-type" language containing one or two syllables whenever possible.
Group information and teach it in small amounts using logical steps.	This is especially important when there are large amounts of complex information for the family to learn. Teach for 10 to 15 minutes, give the learner a break, and return later to teach again.
Prioritize information and teach "survival skills" first.	Due to time constraints and multiple demands on the part of staff, coupled with the rapid turnaround times of health care encounters for clients, there never seems to be enough time to teach. Nurses must provide the client and family with the necessary information to meet their immediate needs. This may include information about the following: • The child's medical condition • Treatment information • Why the information is important • Possible problems, adverse effects, or concerns • What to do if problems arise • Who to contact for further help, information, or supplies
Use visuals, such as pictures, videos, and models.	Use visual resources to enhance and reinforce learning when available. Drawing simple pictures and charts or using alternative methods such as color-coding often allows learning to occur for families who are having difficulty grasping information or concepts.
Teach using an interactive, "hands-on" approach.	When the learner uses hands-on practice or participates in care, learning occurs more quickly and easily. Learning first on a doll or model can ease anxiety and bolster self-confidence before actually doing care or procedures on the child.

PRACTICAL INTERVENTIONS TO ENHANCE LEARNING

The assessed needs and planned learning objectives lead to good teaching interventions. Evaluate these interventions frequently to ensure that the child and family are learning and meeting agreed-upon goals. Table 2.1 presents six techniques that can help improve learning.

HELPING CHILDREN AND FAMILIES WITH POOR HEALTH LITERACY SKILLS

Nurses are in an excellent position to create a "blame-free" environment and offer help. It is entirely appropriate to say to the child or family member, "Many people have a problem reading and remembering the information on this teaching sheet (booklet, manual). Is this ever a problem for you?" For children or family members with low health literacy, the nurse can adjust oral communication techniques and written materials to assist with learning, and should communicate this need to the entire interdisciplinary health care team.

If literacy problems are known or suspected, the nurse can take the following steps to enhance learning:

- Draw pictures or use medical illustrations.
- Use videos.
- Color-code medications or the steps of a procedure.
- Record an audiotape.
- Repeat verbal information often and organize it into small groups.
- Teach a "back-up" family member.

EVALUATING LEARNING

Teaching, even when done well, does not necessarily mean that learning has occurred. Evaluation of learning is critical to ensure that the client and family have actually learned what was taught. In a health care setting, perform an evaluation with each educational encounter and adjust goals and interventions accordingly. The nurse, along with the rest of the interdisciplinary team, is responsible for client and family learning. Help ensure understanding by asking for feedback and offering an opportunity for questions. Also, assessing for signs of confusion, such as increased anxiety, can help evaluate learning. If they have not learned, the health care team ensures that teaching strategies are adjusted so that the client or family does learn.

Take Note!

The ultimate goal of education is a change in behavior on the part of the child and family; this change can occur in their level of knowledge, skill, or both.

Evaluation can occur in several different ways, depending on the topic and the method of teaching. The child or family may:

- Demonstrate a skill, often referred to as return demonstration. Learning can quickly and easily be identified using this method.
- Repeat back or teach back the information using their own words.
- Answer open-ended questions. Open-ended questions provide an opportunity to assess for missing or incorrect information. Open-ended questions are those that cannot be answered with a simple "yes" or "no."

Another option to evaluate learning is to provide a "pretend" scenario for the family, mentally placing them in their own home. Have them verbalize all the steps needed to care for their child, from routine care to handling an emergency situation. They will need to convey information accurately and completely as they walk through the steps necessary to provide care for their child independently at home.

DOCUMENTING EDUCATION FOR THE CHILD AND FAMILY

Documenting child care and education on the medical record is part of every nurse's professional practice and serves four main purposes. First and foremost, the child's medical record serves as a communication tool that the entire interdisciplinary team can use to keep track of what the child and family has learned already and what learning still needs to occur. Next, it serves to testify to the education the family has received if and when legal matters arise. Thirdly, it verifies standards set by The Joint Commission, Centers for Medicare and Medicaid Services (CMS), and other accrediting bodies that hold health care providers accountable for child and family education activities. Finally, it informs third-party payers of goods and services provided for reimbursement purposes.

Documentation of child and family education is imperative. It is the only way to ensure that the family's educational plan and objectives have been completed and that the family is ready for discharge. Documentation of child and family education should include such topics as the following:

- The learning needs assessment
- Information on the client's medical condition and plan of care
- Goals of client education; the date goal is met

- Teaching method used and how it was received by client and family
- Medications, including drug–drug and drug–food interactions
- Modified diets and nutritional needs
- Safe use of medical equipment
- Follow-up care and community resources discussed

Client and family education plays an essential role in promoting safe self-management practice. To ensure that clients and their families attain the required abilities, client and family education needs to be competency based. When developing and applying a competency-based education lesson/program, each nurse must identify essential competencies to be taught, optimal teaching methods, best method to evaluate achievement, and documentation of evidence of learning taken place (King, 2015).

Discharge Planner and Case Manager

Discharge planning involves the development and implementation of a comprehensive plan for the safe discharge of a client from a health care facility and for continuing safe and effective care in the community and at home. Case management focuses on coordinating health care services while balancing quality and cost outcomes. Due to the short length of stays in acute settings and the shift to community settings for clients with complex health needs, discharge planning and case management have become an especially important nursing role in the community (Stanhope & Lancaster, 2015). Often clients requiring community-based care, especially home care, have complex medical needs that require an interdisciplinary team to meet their physical, psychosocial, medical, nursing, developmental, and education needs. The nurse plays an important role in initiating and maintaining the link between team members and the client to ensure that the client and family are receiving comprehensive, coordinated care. (See Chapter 33 for more information on discharge planning and case management for the pediatric population.)

Client Advocate and Resource Manager

Client advocate is another important role of the maternity and pediatric nurse to ensure that the client's and family's needs are being met. Advocacy also helps ensure that the client and family have available resources and appropriate health care services. For example, the pregnant woman on bed rest at home may need help in caring for her other children, maintaining the household, or getting to her appointments. Children with complex medical needs may require financial assistance through Medicaid or Medicaid waivers (state-run programs that use federal and state money to pay for the health care of individuals with certain medical conditions). They may also need assistance in obtaining needed equipment, additional services, and transportation. Nurses need a basic understanding of community, state, and federal resources to ensure that clients and their families have access to those necessary for them. (See Chapter 33 for more information on advocacy and resource management in the pediatric population.)

Preventative Care

The concept of prevention is a key part of maternal and pediatric nursing. The emphasis on health care delivery has moved beyond primary preventive health care (e.g., well-child checkups, routine physical examinations, prenatal care, and treatment of common acute illnesses) and now encompasses secondary and tertiary care.

Primary Prevention

It is the responsibility of all nurses to incorporate health promotion and disease prevention activities into their professional roles. The concept of primary prevention involves preventing the disease or condition before it occurs through health promotion activities, environmental protection, and specific protection against disease or injury. Its focus is on health promotion to reduce the person's vulnerability to any illness by strengthening the person's capacity to withstand physical, emotional, and environmental stressors (Clark, 2014). It encompasses a vast array of areas, including nutrition, good hygiene, sanitation, immunizations, protection from ultraviolet rays, genetic counseling, bicycle helmets, handrails on bathtubs, drug education for school children, adequate shelter, smoking cessation, family planning, and the use of seat belts (Stanhope & Lancaster, 2015). See Figure 2.3 for examples.

Approximately 3,000 children each year in the United States are born with defects of the neural tube – the part of a growing fetus that will become the brain and spinal cord—which can cause severe mental and physical disability or death (CDC, 2015b). Prevention of neural tube defects (NTDs), such as anencephaly and spina bifida, is an example of primary prevention. The use of folic acid supplementation daily for 3 months before and 3 months after conception reduces the risk of first occurrence of an NTD. Women who get enough folic acid have a 50% to 70% reduced risk of having a baby with such a defect (CDC, 2015b). All women of childbearing age should take 0.4-mg folic acid daily as soon as they plan to become pregnant and should continue taking it throughout the pregnancy to prevent this devastating condition. Giving anticipatory guidance to parents about poison prevention and safety during play is another example of primary prevention.

FIGURE 2.3 **Levels of prevention. A. At the primary prevention level, the nurse provides anticipatory guidance and family teaching. B. At the secondary level of prevention, a woman undergoes a mammography screening for early detection of breast problems. C. At the tertiary level of prevention, a child with a developmental disability participates in a rehabilitation program.**

Secondary Prevention

Secondary prevention is the early detection and treatment of adverse health conditions. This level of prevention is aimed at halting the disease, thus shortening its duration and severity to get the person back to a normal state of functioning. Health screenings are the mainstay of secondary prevention. Pregnancy testing,

blood pressure evaluations, cholesterol monitoring, fecal occult blood testing, breast examinations, mammography screening, hearing and vision examinations, and Papanicolaou (Pap) smears are examples of this level of prevention. Such interventions do not prevent the health problem but are intended for early detection and prompt treatment to prevent complications (Smith, 2015). If the health condition cannot be cured and further complications and disability moves in, then the tertiary level of prevention is needed.

Tertiary Prevention

Tertiary prevention is designed to reduce or limit the progression of a permanent, irreversible disease or disability. The purpose of tertiary prevention is to restore individuals to their maximum potential (Klemp, 2015). Tertiary intervention takes place only if the condition results in a permanent disability. Tertiary prevention measures are supportive and restorative. For example, tertiary prevention efforts would focus on minimizing and managing the effects of a chronic illness such as cerebrovascular disease or the chronic effects of sexually transmitted infections (e.g., herpes, human immunodeficiency virus [HIV], and untreated syphilis). Another example would involve working with women who have suffered long-term consequences of violence. Client education is the cornerstone of all disease management programs. The focus of the nurse would be to maximize the woman's strengths through education, to help her recover from the trauma and loss, and to build support systems.

The Nurse's Role in Preventive Care

All health professionals have a special role in health promotion, health protection, and disease prevention. Much of nursing involves prevention, early identification, and prompt treatment of health problems and monitoring for emerging threats that might lead to health problems. Nurses provide health care for women and children at all three levels of prevention. This care often involves advocacy for services to meet their needs.

Culturally Competent Nursing Care

The United States contains an ever-changing mix of cultural groups. The Migration Policy Institute (2015) reports that immigrants accounted for 13% of the total 316 million U.S. residents; adding the U.S.-born children (of all ages) of immigrants means that approximately 80 million people, or one-quarter of the overall U.S. population, is either of the first or second generation. This population is made up of numerous diverse cultural backgrounds arriving from every corner of the world into our country daily.

Take Note!

One million immigrants come to the United States each year, and more than half are of childbearing age. Latin America accounts for more than 50% of immigrants to the United States. By the year 2050, people of African, Asian, and Latino backgrounds will make up one half of our population (Colby & Ortman, 2015).

This growing diversity has significant implications for the health care system. For years nurses have struggled with the issues of providing optimal health care that

meets the needs of women, children, and their families from varied cultures and ethnic groups. In addition to displaying competence in technical skills, nurses must also become competent in caring for clients from varied ethnic and racial backgrounds. Adapting to different cultural beliefs and practices requires flexibility and acceptance of others' viewpoints. Nurses must listen to clients and learn about their beliefs about health and wellness. To provide culturally appropriate care to diverse populations, nurses need to know, understand, and respect culturally influenced health behaviors. Chapter 1 provides a more detailed discussion of culture and its impact on the health of women, children, and families.

Nurses must research and understand the cultural characteristics, values, and beliefs of the various people to whom they deliver care so that false assumptions and stereotyping do not lead to insensitive care. Time orientation, personal space, family orientation (patriarchal, matriarchal, or egalitarian), and language are important cultural concepts. Although the location might be different in community-based care, these principles apply to both inpatient and outpatient settings.

Nurses should possess an understanding of the perspectives, traditions, values, practices, and family systems of culturally diverse individuals, families, communities, and populations for whom they provide care, as well as knowledge of the complex variables that affect the achievement of health and well-being (USDHHS Office of Minority Health, n.d.). **Cultural competence** is a dynamic process during which nurses obtain and then apply cultural information. Nurses must look at clients through their own eyes and the eyes of clients and family members. Nurses must develop nonjudgmental acceptance of cultural differences in clients, using diversity as a strength that empowers them to achieve mutually acceptable health care goals. Nurses must integrate their client's cultural beliefs and practices into health prescriptions to eliminate or mitigate health disparities and provide client satisfaction. Cultural competence is a dynamic, lifelong learning process. Understanding the process for assessing cultural patterns and factors that influence individual and group differences is critical in preventing overgeneralization and stereotyping (Harkess & Kaddoura, 2015). This cultural awareness allows nurses to see the entire picture and improves the quality of care and health outcomes (Box 2.4). Cultural competence does not appear suddenly; it must be developed through a series of steps.

BOX 2.4

STEPS TO DEVELOPING CULTURAL COMPETENCE

1. Cultural Self-Awareness
   - Become aware of, appreciate, and become sensitive to the values, beliefs, customs, and behaviors that have shaped one's own culture.
   - Engage in self-exploration beyond one's own culture and "see" clients from different cultures.
   - Health care has a multicultural environment.
   - Cultural diversity is awareness of the presence of differences among clients.
   - Examine personal biases and prejudices toward other cultures.
   - Become aware of differences in personal and clients' backgrounds.
2. Cultural Knowledge

- Obtain knowledge about various worldviews of different cultures, such as through reading about different cultures, attending continuing education courses on different cultures, accessing websites, and attending cultural diversity conferences.
- Become familiar with culturally/ethnically diverse groups, worldviews, beliefs, practices, lifestyles, and problem-solving strategies.

3. Cultural Skills
   - Learn how to perform a competent cultural assessment.
   - Assess each client's unique cultural values, beliefs, and practices without depending solely on written facts about specific cultural groups.
   - Embracing ethics empowers mutual respect, equality, and trust.
4. Cultural Encounter
   - Engage in cross-cultural interactions with people from culturally diverse backgrounds, such as attending religious services or ceremonies and participating in important family events.
   - Participate in as many cultural encounters as possible to avoid cultural stereotyping.

Adapted from Burnard, P., & Gill, P. (2015). *Culture, communication and nursing* (2nd ed.). New York, NY: Taylor & Francis Publishers; Harkess, L., & Kaddoura, M. (2015). Culture and cultural competence in nursing education and practice: The state of the art. *Nursing Forum*. doi: 10.1111/nuf.12140; and Darnell, L. K., & Hickson, S. V. (2015). Cultural competent patient-centered nursing care. *Nursing Clinics*, *50*(1), 99–108.

Consider This

Our medical mission took a team of nurse practitioners into the rural mountains of Guatemala to offer medical services to people who had never had any. One day, a distraught mother brought her 10-year-old daughter to the mission clinic, asking me if there was anything I could do about her daughter's right wrist. She had sustained a fracture a year ago and it had not healed properly. As I looked at the girl's malformed wrist, I asked if it had been splinted to help with alignment, knowing what the answer was going to be. The interpreter enlightened me by saying that this young girl would never marry and have children because of this injury. I appeared puzzled at the interpreter's prediction of this girl's future. It was later explained to me that if the girl couldn't make tortes from corn meal for her husband because of her wrist disability, she would not be worthy of becoming someone's wife and thus would probably live with her parents the rest of her life.

I reminded myself during the week of the medical mission not to impose my cultural values on the women for whom I was caring and to accept their cultural mores without judgment. These silent self-reminders served me well throughout the week, for I was open to learning about their lifestyles and customs.

Thoughts: What must the young girl be feeling at the age of 10, being rejected for a disability that wasn't her fault? What might have happened if I had imposed my value system on this client? How effective would I have been in helping her if she didn't feel accepted? This incident ripped my heart out, for this young girl will be deprived of a fulfilling family life based on a wrist disability. This is just another example of female suppression that happens all over the world—such a tragedy—and yet a part of their culture, on which nurses should not pass judgment.

Barriers to Cultural Competence

Illness is culturally shaped in the sense that how we perceive, experience, and cope with disease is based upon our explanations of sickness. Awareness of how this

might be of influence—instead of mere knowledge about the cultural practices or beliefs of specific ethnic groups—and an appreciation of this factor helps nurses deal effectively with cultural issues (Burnard & Gill, 2015). When a health care provider lacks knowledge of a client's cultural practices and beliefs or when the provider's beliefs differ from those of the client, the provider may be unprepared to respond when the client makes unexpected health care decisions. System-related barriers can occur if agencies that have not been designed for cultural diversity want all clients to conform to the established rules and regulations and attempt to fit everyone into the same mold.

Cultural competence does not mean replacing one's own cultural identity with another, ignoring the variability within cultural groups, or even appreciating the cultures being served. Instead, nurses skilled at cultural competence show a respect for difference, an eagerness to learn, and a willingness to accept multiple views of the world. Much of the process of developing cultural competence involves a reexamination of our values and the influence of these values on our beliefs, which affect our attitudes and actions. At the core of both client centeredness and cultural competence is the importance of seeing the client as a unique person (Dauvrin & Lorant, 2015). It is important for all nurses to incorporate the client's traditional healing and health practices with conventional medicine by asking such questions as, Do you have treatment preferences you would like me to include in your care plan? Some clients may prefer certain foods or drinks when they are ill. In addition, during fasting and religious seasons, diets may be different and need to be considered during the process of determining the appropriate course of treatment. Some may have a different idea of what caused the illness. Spirituality, culture, and experience may have a significant role in the client's understanding and treatment of the illness.

Complementary and Alternative Medicine

The federal government formed the National Center for Complementary and Integrative Health (NCCIH) to conduct and support research and education and to provide information on complementary and alternative medicine (CAM) to health care providers and the public. The use of CAM is not unique to a specific ethnic or cultural group: interest in CAM therapies continues to grow nationwide and will affect care of many clients. People from all walks of life and in all areas of the community use CAM. Overall, CAM use is seen more in women than men, and in people with higher educational levels. In the United States, approximately 36% of adults (about 4 in 10) and approximately 12% of children (about 1 in 9) are using some form of CAM. Prayer specifically for health reasons is the most commonly used CAM therapy (NCCIH, 2015a). It is well known that CAM, including homeopathy, acupuncture, phytotherapy, and hydrotherapy, is also being used increasingly by midwives for childbirth (Hall, Griffiths, & McKenna, 2015).

CAM includes diverse practices, products, and health care systems that are not currently considered to be part of conventional medicine (NCCIH, 2015a). *Complementary* medicine is used together with conventional medicine, such as using aromatherapy to reduce discomfort after surgery or to reduce pain during a procedure or during early labor. *Alternative* medicine is used in place of conventional medicine, such as eating a special natural diet to control nausea and

vomiting or to treat cancer instead of undergoing surgery, chemotherapy, or radiation that has been recommended by a conventional doctor. *Integrative* medicine combines mainstream medical therapies and CAM therapies for which there is some scientific evidence of safety and effectiveness (NCCIH, 2015a). These include acupuncture, reflexology, therapeutic touch, meditation, yoga, herbal therapies, nutritional supplements, homeopathy, naturopathic medicine, and many more used for the promotion of health and well-being (Holden et al., 2015).

The philosophy of integrative medicine focuses on treating the whole person, not just the disease. The goal is to treat the mind, body, and spirit all at the same time. History has taught us that in science application of the results is never determined by a single study, but by the weight of the evidence. It is right that medicine rests upon a foundation that begins with good clinical observations, case reports, and careful interpretations. Replication across scientists, which is the true hallmark of valid science, establishes whether those clinical observations are important and perhaps applicable. While some of the therapies used are nonconventional, a guiding principle within integrative medicine is to use therapies that have some high-quality evidence to support them (George, 2015). Integrative medicine combines conventional Western medicine with complementary treatments—all in the effort to treat the whole person. The nurse should avoid judgment and encourage the family to research all approaches that are evidence based that support healthy outcomes. Table 2.2 describes selected CAM therapies and treatments.

The theoretic underpinnings of complementary and alternative health practices propose that health and illness are complex interactions of the mind, body, and spirit. It is then surmised that many aspects of clients' health experiences are not subject to traditional scientific methods. This field does not lend itself readily to scientific study or to investigation and therefore is not easily embraced by many hard-core scientists (Ernst, 2015). Much of what is considered to be alternative medicine comes from the Eastern world, folk medicine, and religious and spiritual practices. There is no unifying basic theory for the numerous treatments or modalities, except (as noted previously) that health and illness are considered to be complex interactions among the body, mind, and spirit.

Because of heightened interest in complementary treatments and their widening use, anecdotal efficacy, and growing supporting research evidence, nurses need to be sensitive to and knowledgeable enough to answer many of the questions clients ask and to guide them in a safe, objective way (Ernst, 2015). Nurses have a unique opportunity to provide services that facilitate wholeness. They need to understand all aspects of CAM, including costs, client knowledge, and drug interactions, if they are to promote holistic strategies for clients and families. With all of the enthusiasm in favor of CAM therapies, nurses must not forget their obligation to embrace the principles of evidence-based practice and critical evaluation before being misled into therapies that have no scientific basis to justify their use.

TABLE 2.2 SELECTED COMPLEMENTARY AND ALTERNATIVE THERAPIES

Therapy	Description
Aromatherapy	Use of essential oils to stimulate the sense of smell for balancing mind, body, and spirit
Homeopathy	Based on the theory of "like treats like"; helps restore the body's natural balance
Acupressure	Restoration of balance by pressing an appropriate point so self-healing capacities can take over
Feng shui (pronounced *fung shway*)	The Chinese art of placement. Objects are positioned in the environment to induce harmony with chi.
Guided imagery	Use of consciously chosen positive and healing images along with deep relaxation to reduce stress and to help people cope
Reflexology	Use of deep massage on identified points of the foot or hand to scan and rebalance body parts that correspond with each point
Therapeutic touch	Balancing of energy by centering, invoking an intention to heal, and moving the hands from the head to the feet several inches from the skin
Herbal medicine	The therapeutic use of plants for healing and treating diseases and conditions
Spiritual healing	Praying, chanting, presence, laying on of hands, rituals, and meditation to assist in healing
Chiropractic therapy	Aimed at removing irritants to the nervous system to restore proper function—spinal manipulation done for musculoskeletal complaints
Massage therapy	Therapeutic stroking or kneading of the body to decrease pain, produce relaxation, and/or to improve circulation to that body part

Adapted from Hall, H. G., Griffiths, D., & McKenna, L. G. (2015). Complementary and alternative medicine: Interaction and communication between midwives and women. *Women and Birth, 28*(2), 137–142; and National Center for Complementary and Integrative Health. (2015a). *Complementary, alternative, or Integrative health: What's in a name?* Retrieved from https://nccih.nih.gov/health/integrative-health

The growing use of complementary and alternative therapies during pregnancy and childbirth could be interpreted as a response by women regarding a need for autonomy and active participation in their health care during this time. Studies show that massage, acupuncture, vitamins, and herbs are the most frequently applied methods during pregnancy. In a recent study, only half of the pregnant women revealed their use of CAM to their health care provider during their prenatal visits (Holden et al., 2015).

Many clients who use complementary or alternative therapies do not reveal this fact to their health care provider. Therefore, one of the nurse's most important roles during the assessment phase of the nursing process is to encourage clients to communicate their use of these therapies to eliminate the possibility of harmful interactions and contraindications with current medical therapies. When assessing clients, ask specific questions about any nonprescription medications they may be taking, including vitamins, minerals, or herbs. Clients should also be asked about any therapies they are taking that have not been ordered by their primary health care provider.

When caring for clients and their families who practice CAM, nurses need to:

- Be culturally sensitive to nontraditional treatments
- Acknowledge and respect different beliefs, attitudes, and lifestyles
- Keep an open mind, remembering that standard medical treatments do not work for all clients
- Accept CAM and integrate it if it brings comfort without harm
- Provide accurate information, not unsubstantiated opinions
- Advise clients how they can best monitor their condition using CAM
- Discourage practices only if they are harmful to the client's health

• Instruct the client to weigh the risks and benefits of CAM use
• Avoid confrontation when asking clients about CAM
• Be reflective, nonjudgmental, and open-minded about CAM.

The use of complementary therapies is widespread, especially by women desiring to alleviate the nausea and vomiting of early pregnancy. Ginger powder or tea, Sea-Bands (acupressure), hypnosis, and vitamin B6 are typically used to treat morning sickness (Tyler & Nagtalon-Ramos, 2015). Although these may not cause any ill effects during the pregnancy, most substances ingested cross the placenta and have the potential to reach the fetus, so nurses should stress to all pregnant women that it is better to be cautious when using CAM.

Women at risk for osteoporosis are seeking alternatives to menopausal hormone therapy since the Women's Health Initiative (WHI) study raised doubts about the benefit of estrogen. Some of the alternative therapies for osteoporosis include soy isoflavones, progesterone cream, magnet therapy, tai chi, and hip protectors (NCCIH, 2015b). In addition, menopausal women may seek CAM therapies for hot flashes. Once again, despite many claims, most of these therapies have not undergone scientific testing and thus could place the woman at risk.

If clients are considering the use of or using CAM therapies, suggest they check with their health care provider before taking any "natural" substance. Offer clients the following instructions:

• Do not take for granted that because a substance is a natural herb or plant product, it is beneficial or harmless.
• Seek medical care when ill.
• Always inform the provider if you are taking herbs or other therapies.
• Be sure that any product package contains a list of all ingredients and amounts of each.
• Be aware that frequent or continual use of large doses of a CAM preparation is not advisable, and harm may result if therapies are mixed (e.g., vitamin E, garlic, and aspirin all have anticoagulant properties).
• Research CAM through resources such as books, websites, and articles (Chang & Chang, 2015).

All nurses, especially nurses working in the community, must educate themselves about the pros and cons of CAM and be prepared to discuss and help their clients make sense of it all. Expanding our consciousness by understanding and respecting diverse cultures and CAM will enable nurses to provide the best treatment for clients and their families receiving community-based care.

COMMUNITY-BASED CARE

Community may be defined as a specific group of people, often living in a defined geographical area, who share common interests, who interact with each other, and who function collectively within a defined social structure to address common concerns (Stanhope & Lancaster, 2015). The common features of a community may be common rights and privileges as members of a certain city or common ties of identity, values, norms, culture, language, or social support. Women are caregivers to children, parents, spouses, and neighbors and provide important social support in these roles. The child's community consists of the family, school, neighborhood, youth organizations, and other peer groups.

A person can be a part of many communities during the course of daily life. Examples might include area of residence (home, apartment, shelter), gender, place of employment (organization or home), language spoken (Spanish, Chinese, English), educational background or student status, culture (Italian, African American, Indian), career (nurse, businesswoman, housewife), place of worship (church or synagogue), and community memberships (garden club, YMCA, support group, school PTA, youth organizations, athletic teams).

A **population** is a group of people who share personal or environmental characteristics. Typically the most common characteristic is geographic location. Populations are made up of human beings within complex social and physical environments. The betterment of human populations remains the goal of community-based nursing care.

In community-based care, the community is the unit of service. The providers of care are concerned not only with the clients who present for service but also with the larger population of potential or at-risk clients.

Community Health Nursing

Community health nursing focuses on preventing illness and improving the health of populations and communities. Population is defined as a group of people who may or may not interact with each other within a defined geographic location (McMurray & Clendon, 2015). Community health nurses work in geographically and culturally diverse settings. They address current and potential health needs of the population or community. They promote and preserve the health of a population and are not limited to particular age groups or diagnoses. Public health nursing is a specialized area of community health nursing.

Epidemiology, the study of the causes, distribution, and control of disease in populations, can help determine the health and health needs of a population and assist in planning health services. Community health nurses perform epidemiologic investigations to help analyze and develop health policy and community health initiatives. Community health initiatives can be focused on the community as a whole or a specific target population with specific needs. *Healthy People 2020: Improving the Health of Americans* (HP 2020) is an example of national health initiatives developed using the epidemiologic process. HP 2020 ensures that health care professionals evaluate the individual as well as the community. It emphasizes the ever-present link between the individual's health and the health of the community (Thomas et al., 2015). HP 2020 identifies two major goals: to increase the quality of life and the life expectancy of individuals of all ages and to decrease health disparities among different populations (U.S. Department of Health and Human Services [USDHHS], 2015a). Relevant HP 2020 objectives are highlighted throughout this text.

The focus of health care initiatives today is on people and their needs, strengthening their abilities to shape their own lives. The emphasis has shifted away from dependence on health professionals toward personal involvement and personal responsibility, and this gives nurses the opportunity to interact with individuals in a variety of self-help roles. Nurses in the community can be the primary force in identifying the challenges and implementing changes in women's and children's health for the future.

Community-Based Nursing

In the past, the only community-based roles for nurses were community health nurses or public health nurses. This is now a subset of what is considered community-based nursing. The health needs of the society and consumer demand brought about community-based and community-focused services. The movement from an illness-oriented "cure" perspective in hospitals to a focus on health promotion and primary health care in community-based settings has dramatically changed employment opportunities for today's nurses.

This shift in emphasis to primary care and outpatient treatment and management will likely continue. As a result, employment growth in a variety of community-based settings can be expected for properly educated nurses.

With the worldwide strategic shift of health care delivery from secondary to primary care settings, more newly qualified nurses are working in primary care, making exposure to the variety of roles available to nurses essential for future workforce development. The idea of nurses being change agents and thriving amidst change may seem overwhelming, but all nurses need to be open to change. The time is now for nurses to be lifelong learners prepared for change in any health care setting (Orr & Davenport, 2015).

The Bureau of Labor Statistics, U.S. Department of Labor, Occupational Employment Statistics (2014) found the following trends in registered nurse (RN) employment settings:

- 61% of RNs work in the hospital setting.
- 26% work outside the hospital setting in community-based settings.
- The number of RNs employed in community-based settings has continued to grow largely due to an increase in nurses working in home health care and managed care organizations.

Shift in Responsibilities from Hospital-Based to Community-Based Nursing

Many nurses find the shift from acute care nursing to a community setting challenging. Community care, especially home care, is a rapidly growing service in the United States. Nurses play an important role in the treatment and care of clients in the community and need to collaborate with acute care nurses to integrate appropriate community interventions along the continuum of care (Lemetti et al., 2015). Community-based care has been shown to be a cost-effective method for providing care. An increase in disposable income and the increased longevity of people with chronic and debilitating health conditions have also contributed to the continued shift of health care to the community and home setting. Technology has advanced, allowing for improved monitoring of clients in community settings and at home as well as allowing complicated procedures to be done at home, such as intravenous administration of antibiotics, telehealth surveillance, and renal dialysis (Farrar, 2015).

Caring for children at home not only improves their physical health but also allows for adequate growth and development within their family. They are in a familiar environment with the comfort and support of family, which leads to improved care and quality of life.

Community-based nursing settings include ambulatory care, home health care, occupational health, school health, and hospice settings (Table 2.3). Clinical

practice within the community may also include case management, research, quality improvement, and discharge planning. Nurses with advanced practice and experience may be employed in areas of staff development, program development, and community education.

Community-Based Nursing Interventions

Nursing interventions involve any treatment that the nurse performs to enhance the client's outcome. Nursing practice in the community uses the nursing process and is similar to that in the acute care setting, because assessing, performing procedures, administering medications, coordinating services and equipment, counseling clients and their families, and teaching about care are all part of the care administered by nurses in the community. See Evidence-Based Practice 2.1. Box 2.5 highlights the most common nursing interventions used in community-based nursing practice.

TABLE 2.3 COMMUNITY-BASED PRACTICE SETTINGS

Setting	Description
Ambulatory care	Doctor's offices settings Health maintenance organizations (HMOs) Day surgery centers Freestanding urgent care centers Family planning clinics Mobile mammography centers
Home health care services	High-risk pregnancy/neonate care Maternal/child newborn care Skilled nursing care Hospice care
Health Department services	Maternal/child health clinics Family planning clinics Sexually transmitted infection programs Immunization clinics Substance abuse programs Jails and prisons
Long-term care	Skilled nursing facilities Nursing homes Hospices Assisted living
Other community-based settings	Parish nursing programs Summer camps Childbirth education programs School health programs Occupational health programs

EVIDENCE-BASED PRACTICE 2.1

COMMUNITY-BASED INTERVENTION PACKAGES FOR REDUCING MATERNAL–NEONATAL MORBIDITY AND MORTALITY AND IMPROVING NEONATAL OUTCOMES

Maternal, infant, and under-five child mortality rates have declined significantly in the past decades, but newborn mortality rates have reduced more slowly. About half of all newborn deaths are preventable by using evidence-based interventions such as tetanus toxoid immunizations to mothers, clean and skilled care at birth, newborn resuscitation, exclusive breast-feeding, clean umbilical cord care, and management of newborn infections. A large portion of these maternal and newborn deaths and diseases can be addressed through community-based packaged interventions.

STUDY

The purpose of this study was to assess the effectiveness of community-based intervention packages in reducing maternal and neonatal morbidity and mortality to improve neonatal outcomes. The authors found 26 randomized and quasi-randomized controlled studies evaluating the impact of community-based intervention packages for the prevention of maternal illnesses and death and in improving newborn health outcomes.

Findings

A statistically significant reduction was observed in maternal morbidity, neonatal mortality, and perinatal mortality as a consequence of implemented community-based interventional care packages. It is found that the value of integrating maternal and newborn care in community settings through a range of interventions impacts the health of this vulnerable population positively.

Nursing Implications

This review highlights the importance of integrating maternal and newborn care in community settings through a range of interventions which can be delivered by community health nurses and health promotion groups. There is sufficient evidence to scale up community-based care. As this study pointed out-–maternal–child care can't stop upon discharge from the hospital, it must continue in community health care settings and homes to impact maternal–neonatal outcomes positively. Community health nurses can take a lead role in facilitating this care to improve maternal–child outcomes.

Adapted from Lassi, Z. S., & Bhutta, Z. A. (2015). Community-based intervention packages for reducing maternal and neonatal morbidity and mortality and improving neonatal outcomes. *Cochrane Database of Systematic Reviews*, *3*:CD007754. doi: 10.1002/14651858.CD007754.pub3.

BOX 2.5

COMMUNITY-BASED NURSING INTERVENTIONS

- Health screening—detecting unrecognized or preclinical illness among individuals so they can be referred for definitive diagnosis and treatment (e.g., mammogram or Pap smear, well-child vision and hearing checks)
- Health education programs—assisting clients in making health-related decisions about self-care, use of health resources, and social health issues such as smoking bans and motorcycle helmet laws (e.g., childbirth education or breast self-examination, child safety programs, poisoning prevention, youth drug awareness programs)

- Medication administration—preparing, giving, and evaluating the effectiveness of prescription and over-the-counter drugs (e.g., hormone replacement therapy in menopausal women, childhood immunizations)
- Telephone consultation—identifying the problem to be addressed; listening and providing support, information, or instruction; documenting advice/instructions given to concerns raised by caller (e.g., consultation for a mother with a newborn with colic, interaction with a parent whose child has a fever or is vomiting)
- Health system referral—passing along information about the location, services offered, and ways to contact agencies (e.g., referring a woman for a breast prosthesis after a mastectomy, arranging for home tutoring for a child with a long-term illness)
- Instructional—teaching an individual or a group about a medication, disease process, lifestyle changes, community resources, or research findings concerning their environment (e.g., childbirth education class, basic life support classes for parents, child safety education classes)
- Nutritional counseling—demonstrating the direct relationship between nutrition and illness while focusing on the need for diet modification to promote wellness (e.g., Women, Infants, and Children [WIC] program; counselor interviewing a pregnant woman or a child and parents who have anemia; eating disorders program)
- Risk identification—recognizing personal or group characteristics that predispose people to develop a specific health problem, and modifying or eliminating them (e.g., genetic counseling of an older pregnant woman at risk for a Down syndrome infant; genetic screening of family members for cystic fibrosis or Huntington disease)

Adapted from Wright, L. M., & Leahey, M. (2013). *Nurses and families: A guide to family assessment and intervention* (6th ed.). Philadelphia, PA: F.A. Davis Company.

Community-Based Nursing Challenges

Despite the benefits achieved by caring for families in their own homes and communities, challenges also exist. Clients are being discharged from acute care facilities very early in their recovery course and present with more health care needs than in the past. As a result, nursing care and procedures in the home and community are becoming more complex and time-consuming. Consider the example of a woman who developed a systemic infection, a pelvic abscess, and deep vein thrombosis in her leg after a cesarean birth who is being discharged from the hospital. The nurse's primary focus of care in this situation would be to administer heparin and antibiotics intravenously rather than educating her about child care and follow-up appointments. In the past, this woman would have remained hospitalized for treatment, but home infusion therapy is now less costly and allows the client to be discharged sooner.

This demand on the nurse's time may limit the amount of time spent on prevention measures, education, and the family's psychosocial issues. More time may be needed to help families deal with these issues and concerns. With large client caseloads, nurses may find it difficult to spend the time needed while meeting

the time restrictions dictated by their health care agencies. Nurses need to plan the tasks to be accomplished (Box 2.6).

Nurses working in the community have fewer resources available to them compared with the acute care setting. Decisions often have to be made in isolation. The nurse must possess excellent assessment skills and the ability to communicate effectively with the family to be successful in carrying out the appropriate plan of care.

Nurses interested in working in community-based settings must be able to apply the nursing process in an environment that is less structured or controlled than that associated with acute care facilities. Nurses must be able to assimilate information well beyond the immediate physical and psychosocial needs of the client in a controlled acute care setting and deal with environmental threats, lifestyle choices, family issues, different cultural patterns, financial burdens, transportation problems, employment hazards, communication barriers, limited resources, and client acceptance and compliance.

Although opportunities for employment in community-based settings are plentiful, many positions require a baccalaureate degree. Previous medical–surgical experience in an acute care setting is typically required by home health agencies because these nurses must function fairly independently within the home environment.

The nurse must also be familiar with and respectful of many different cultures and socioeconomic levels, remaining objective in dealing with such diversity and demonstrating an understanding of and appreciation for cultural differences. Nurses are increasingly working with clients from diverse cultural backgrounds with different cultural values pertaining to their health. Interventions must be individualized to address the cultural, social, and economic diversity among clients in their own environment (Darawsheh & Chard, 2015).

BOX 2.6

HOME CARE VISITATION PLANNING

- Review previous interventions to eliminate unsuccessful ones.
  - Check previous home visit narrative to validate interventions.
  - Communicate with previous nurse to ask questions and clarify.
  - Formulate plan of interventions based on data received (e.g., client preference of IV placement or order of fluids).
- Prioritize client needs based on their potential to threaten the client's health status.
  - Use Maslow's hierarchy of needs to set forth a plan of care.
  - Address life-threatening physiologic issues first (e.g., an infectious process would take precedence over anorexia).
- Develop goals that reflect primary, secondary, and tertiary prevention levels.
  - *Primary prevention*—Have the client consume adequate fluid intake to prevent dehydration.
  - *Secondary prevention*—Administer drug therapy as prescribed to contain and treat an existing infectious process.
  - *Tertiary prevention*—Instruct the stroke client how to exercise to minimize

disability.
- Bear in mind the client's readiness to accept intervention and education.
  - Ascertain the client's focus and how she sees her needs.
  - Address client issues that might interfere with intervention (e.g., if the client is in pain, attempting to teach her about her care will be lost; her pain must be addressed first before she is ready to learn).
- Consider the timing of the visit to prevent interfering with other client activities.
  - Schedule all visits at convenient times per client if possible (e.g., if the client has a favorite television show to watch, attempt to schedule around that event if at all possible).
  - Reschedule a home visit if a client event comes up suddenly.
- Outline nursing activities to be completed during the scheduled visit.
  - Know the health care agency's policy and procedures for home visits.
  - Consider the time line and other visits scheduled that day.
  - Research evidence-based best practices to use in the home to validate your intervention decisions.
- Obtain necessary materials/supplies before making the visit.
  - Assemble all equipment needed for any procedure in advance.
  - Secure any equipment that might be needed if a problem occurs (e.g., bring additional IV tubing and a catheter to make sure the procedure can be carried out without delay).
- Determine criteria to be used to evaluate the effectiveness of the home visit.
  - Revisit outcome goals to determine the effectiveness of the intervention.
  - Assess the client's health status to validate improvement.
  - Monitor changes in the client's behavior toward health promotion activities and disease prevention (e.g., verify/observe that the client demonstrates correct hand-washing technique after instruction and reinforcement during the home care visit).

Community-Based Nursing Care Settings for Women and Children

Community-based nursing takes place in a variety of settings, including physician's offices, clinics, health departments, urgent care centers, hospital outpatient centers, schools, camps, churches, shelters, and clients' homes. Nurses provide well care, episodic ill care, and chronic care. They work to promote, preserve, and improve the health of the women, children, and families in these settings.

Due to technologic advances, cost containment, and shortened hospital stays, the home is a common care setting for women, children, and families today. Home care is geared toward the needs of the client and family. Private-duty nursing care is used when more extensive care is needed; it may be delivered hourly (several hours per day) or on a full-time, live-in basis. Periodic nursing visits may be used for

intermittent interventions, such as IV antibiotic administration, follow-up with client teaching, and monitoring. The goals of nursing care in the home setting include promoting, restoring, and maintaining the health of the client.

Home care focuses on minimizing the effects of the illness or disability along with providing the client with the means to care for the illness or disability at home. Nurses in the home care setting are direct care providers, educators, advocates, and case managers.

Prenatal Care

Early, adequate prenatal care has long been associated with improved pregnancy outcomes (March of Dimes, 2015). Adequate prenatal care is a comprehensive process in which any problems associated with pregnancy are identified and treated. Basic components of prenatal care are early and continuing risk assessment, health promotion, medical and psychosocial interventions, and follow-up. Within the community setting, several services are available to provide health care for pregnant women (Box 2.7).

Not all women are aware of the community resources available to them. Most public health services are available for consultation, local hospitals have "hotlines" for questions, and public libraries have pregnancy-related resources as well as Internet access. Nurses can be a very helpful link to resources for all women regardless of their economic status.

Technologically advanced care has been shown to improve maternal and child outcomes. Regionalized high-risk care, recommended by the American Academy of Pediatrics in the late 1970s, aimed to promote uniformity nationwide, covering the prenatal care of high-risk pregnancies and high-risk newborns. The advanced technology found in perinatal regional centers and community-based prenatal surveillance programs have resulted in better risk-adjusted mortality rates. Regionalized systems of perinatal care are recommended to ensure that each mother and newborn achieve optimal outcomes. A recent proposed classification system for multiple levels of maternal care pertains to birth centers, basic care (level I), specialty care (level II), subspecialty care (level III), and regional perinatal health care centers (level IV). The goal of regionalized maternal care is for high-risk pregnant women to receive care in facilities that are prepared to provide the required level of specialized care, thereby reducing maternal morbidity and mortality rates (American College of Obstetricians and Gynecologists [ACOG], 2015). For example, fetal monitoring and ultrasound technology have traditionally been used in acute care settings to monitor the progress of many high-risk pregnancies. However, with the increased cost of hospital stays, many services were moved to outpatient facilities and into the home. The intent was to reduce health care costs and to monitor women with complications of pregnancy in the home rather than in the hospital. Examples of services offered in the home setting might include the following:

- Infusion therapy to treat infections or combat dehydration
- Hypertension monitoring for women with gestational hypertension
- Uterine monitoring for mothers who are at high risk for preterm labor
- Fetal monitoring to evaluate fetal well-being
- Portable ultrasound to perform a biophysical profile to assess fetal well-being

BOX 2.7

MATERNAL–CHILD COMMUNITY HEALTH CARE SERVICES

- State public health prenatal clinics provide access to care based on a sliding scale payment schedule or have services paid for by Medicaid.
- Federally funded community clinics typically offer a variety of services, which may include prenatal, pediatric, adult health, and dental services. A sliding scale payment schedule or Medicaid may cover costs.
- Hospital outpatient health care services offer maternal–child health services. Frequently they are associated with a teaching hospital in which medical school students, interns, and OB/GYN residents rotate through the clinic services to care for clients during their education process.
- Private OB/GYN offices are available for women with health insurance seeking care during their pregnancies. Some physicians in private practice will accept Medicaid clients as well as private clients.
- Community free clinics offer maternal–child services in some communities for women with limited economic resources (homeless, unemployed).
- Freestanding birth centers offer prenatal care for low-risk mothers as well as childbirth classes to educate couples regarding the birthing process. Most centers accept private insurance and Medicaid for reimbursement services.
- Midwifery services are available in many communities where midwives provide women's health services. They usually accept a multitude of payment plans from private pay to health insurance to Medicaid for reimbursement purposes.
- WIC provides food, nutrition counseling, and access to health services for low-income women, infants, and children. WIC is a federally funded program and is administered by each state. All people receiving Aid to Families with Dependent Children (AFDC), food stamps, or Medicaid are automatically eligible for WIC. WIC serves 53% of all infants born in the United States up to their fifth birthday (USDA Food and Nutrition Service, 2015).
- Childbirth classes offer pregnant women and their partners a series of educational classes on childbirth preparation. Women attend them during their last trimester of pregnancy. Some classes are free and some have a fee.
- Local La Leche League groups provide mother-to-mother support for breast-feeding, nutrition, and infant care problem-solving strategies. All women who have an interest in breast-feeding are welcome to participate in the meetings, which are typically held in the home of a La Leche member.

As a result, home care has the potential to produce cost savings compared to inpatient care.

Labor and Birth Care

Pregnancy involves numerous choices: cloth or disposable diapers, breast-feeding or bottle feeding, doctor or midwife, and where to give birth—at a birthing center, at

home, or at a hospital. Deciding where to give birth depends on the woman's pregnancy risk status. For the pregnant woman who is at high risk as a result of medical or social factors, the hospital is considered the safest place for birth. Potential complications can be addressed because medical technology, skilled professionals, and neonatal services are available. For low-risk women, a freestanding birthing center or a home birth is an option.

The choice between a birthing center, home birth, or hospital depends on the woman's preferences, her risk status, and her distance from a hospital. Some women choose an all-natural birth with no medications and no medical intervention, whereas others would feel more comfortable in a setting in which medications and trained staff are available if needed. Presenting the facts to women and allowing them to choose in collaboration with their health care provider is the nurse's role. Client safety is paramount, but at the same time nurses must protect the woman's right to select birth options and should promote family-centered care in all maternity settings.

BIRTHING CENTER

A birthing center is a cross between a home birth and a hospital. Birthing centers offer a home-like setting but with close proximity to a hospital in case of complications. Midwives often are the sole care providers typically in freestanding birthing centers, with obstetricians as backups in case of emergencies. Birthing centers usually have fewer restrictions and guidelines for families to follow and allow for more freedom in making decisions about labor. The rates of cesarean birth and the costs are much lower than those of a hospital (Childbirth Connection, 2015). Midwife-led comprehensive care in a birthing center using the same medical guidelines as in standard care in hospitals reduced medical interventions without jeopardizing maternal and infant health. Birthing centers advertise themselves as a natural alternative to a hospital, as well as a place of female empowerment and control (American Association of Birth Centers [AABC], 2015). The normal discharge time after birth is usually measured in hours (4 to 24 hours), not days.

Birthing centers aim to provide a relaxing home environment and promote a culture of normalcy. Currently, we are seeing a rise in the number of birth centers being established, which is essential in the promotion of normality. It is in these birth centers that midwives will learn about normalcy, building the skills needed to support women through labor, rather than managing labor. The current economic climate may result in more efficient use of resources, possibly normalizing birth (AABC, 2015). Birth is considered a normal physiologic process, and most centers use a noninterventional view of labor and birth. The range of services for the expectant family often includes prenatal care, childbirth education, intrapartum care, and postpartum care, including home follow-up and family planning (Fig. 2.4). One of the hallmarks of the freestanding birthing center is that it can provide truly family-centered care by approaching pregnancy and birth as a normal family event and encouraging all family members to participate. Education is often provided by such centers, encouraging families to become informed and self-reliant in the care of themselves and their families (Steinberg & Sackmary, 2015).

Birthing centers provide an alternative for women who are uncomfortable with a home birth but who do not want to give birth in a hospital. Advantages of birthing centers include a noninterventional approach to obstetric care, freedom to eat and

move around during labor, ability to give birth in any position, and the right to have any number of family and friends attend the birth. Disadvantages are that some centers have rigid screening criteria, which may eliminate healthy mothers from using birth centers; many have rigid rules concerning transporting the mother to the hospital (e.g., prolonged labor, ruptured membranes); and many have no pediatrician on staff if the newborn has special needs after birth (Childbirth Connection, 2015).

HOME BIRTH

For centuries women have been giving birth to babies in their home. Many feel more comfortable and relaxed when giving birth in their own environment. Women who want no medical interventions and a very family-centered birth often choose to have a home birth. Home births are recommended for pregnant women who are considered to be at low risk for complications during labor and birth (Zielinski, Ackerson, & Low, 2015). Home birth is advantageous because it:

- Is the least expensive
- Allows the woman to experience labor and birth in the privacy, comfort, and familiarity of home while surrounded by loved ones
- Permits the woman to maintain control over every aspect affecting her labor (e.g., positions, attire, support people)
- Minimizes interference and unnecessary interventions, allowing labor to progress normally
- Provides continuous one-on-one care by the midwife throughout the childbirth process
- Promotes the development of a trusting relationship with the nurse midwife (American Pregnancy Association, 2015).

FIGURE 2.4 **Birthing centers aim to provide a relaxing home environment and promote a culture of normality while offering a full range of health care services to the expectant family. (Photos by Gus Freedman.)**

A home birth has certain disadvantages, however, including the limited availability of pain medication and danger to the mother and baby if an emergency arises (e.g., placenta abruptio, uterine rupture, cord prolapse, or a distressed fetus). Delay in getting to the hospital could jeopardize the life of the child or the mother. A backup plan for a health care provider and nearby hospital on standby must be established should an emergency occur. The available evidence suggests that planned home birth is safe for women who are at low risk of complications and are cared for by appropriately qualified and licensed midwives with access to timely transfer to a hospital if required (Zielinski et al., 2015).

Postpartum and Newborn Care

Recent reforms in health care financing have reduced hospital stays significantly for new mothers. As a result, community-based nurses play a major role in extending care beyond the hospital setting. When new mothers are discharged from the hospital, most are still experiencing perineal discomfort and uterine cramping. They may still have pain from an episiotomy. They are fatigued and may be constipated. They may feel uncertain about feeding and caring for their newborn. These new mothers need to be made aware of community resources such as telephone

consultation by nurses, outpatient clinics, home visits, neighborhood mothers' support groups, and online new parent forums.

TELEPHONE CONSULTATION

Many hospitals offer telephone consultation services by their maternity nurses. The discharged mother is given the phone number of the nursing unit on the day of discharge and is instructed to call if she has any questions or concerns. Because the nurses on the unit are familiar with her birth history and the newborn, they are in a good position to assist her in adjusting to her new role. Although this service is usually free, not all families recognize a problem early or use this valuable informational resource.

OUTPATIENT CLINICS

Outpatient clinics offer another community-based site where the childbearing family can obtain services. Usually the mother has received prenatal care before giving birth and thus has established some rapport with the nursing staff there. The clinic staff is usually willing to answer any questions she may have about her health or that of her newborn. Appointments usually include an examination of the mother and newborn and instructions about umbilical cord care, postpartum and infant care, and nutrition for both mother and infant.

POSTPARTUM HOME VISITS

Home visits offer services similar to those offered at a scheduled clinic visit, but they also give the nurse an opportunity to assess the family's adaptation and dynamics and the home environment. During the past decade, hospital stays have averaged 24 to 48 hours or less for vaginal births and 72 to 96 hours for cesarean births (CDC, 2015c). Federal legislation went into effect in 1998 that prohibited insurers from restricting hospital stays for mothers and newborns to less than 2 days for vaginal births or 4 days for cesarean births (CDC, 2015c). These shortened stays have reduced the time available for educating mothers about caring for themselves and their newborns. Home visiting programs in general seek to promote child health/development, prevent child abuse/neglect, improve maternal well-being, and improve the parental capacity of mothers.

Postpartum care in the home environment usually includes the following:

- Monitoring the physical and emotional well-being of the family members (Fig. 2.5)
- Identifying potential or developing complications for the mother and newborn
- Breast care during breast-feeding and engorgement
- Instruction on pelvic floor exercises, nutrition, and self-hygiene care
- Linking the family, as needed, to community social services, housing, and governmental programs
- Bridging the gap between discharge and ambulatory follow-up for mothers and their newborns (King et al., 2015)

SUPPORT GROUPS FOR NEW MOTHERS

Typically these groups are locally led by a facilitator with previous experience in motherhood, breast-feeding, and infant care. Usually they are composed of 6 to 12 mothers who share information on breast-feeding techniques, infant sleeping patterns, child care issues, body image issues, and how to integrate the new baby

into the family unit. The support group usually meets weekly and provides an avenue of support for new mothers on the same journey.

FIGURE 2.5 The nurse makes a postpartum home visit to assess the woman and her newborn. During the visit, the nurse assists the mother with breast-feeding.

ONLINE MOTHERHOOD FORUMS/BLOGS

Support groups in online communities provide an anonymous place to exchange information and advice. Previous research has suggested that these groups offer a safe, nonjudgmental forum for new mothers to share experiences and interact anonymously. They serve as a safe, supportive space in which new mothers can better understand their new role of parenting. They offer a viable form of education for new parents, but caution must be used on advice provided on some websites to new mothers (Makinen & Tuominen, 2015).

HIGH-RISK NEWBORN HOME CARE

With the reduced lengths of stay, high-risk newborns are also being cared for in community settings. High-technology care once was provided only in the hospital. Now, however, the increasing cost of complex care and the influences of managed care have led to the provision of such care at home. Families have become "health care systems" by providing physical, emotional, social, and developmental home care for their technology-dependent infants. Suitable candidates for home care may include preterm infants who continue to need oxygen, low-birthweight infants needing nutritional or hypercaloric formulas or adjunct feeding methods (e.g., tube feedings), or infants with hydrocephalus or cerebral palsy. Home care with prepared caregivers might contribute to earlier detection of significant residual/recurrent problems amenable to therapy (Stewart, 2015). A wide range of equipment may be used, including mechanical ventilation, electronic apnea monitors, home oxygen equipment, intravenous infusions, respiratory nebulizers, phototherapy, and suction equipment.

All family members must work together to provide 24-hour care. The parents must negotiate with insurers for reimbursement for durable medical equipment, must be able to troubleshoot equipment problems, and must be able to manage

inventories of supplies and equipment. In addition, they must be able to assess the infant for problems; determine the problem; decide when to call the nurse, pharmacist, or physical therapist; and interpret and implement prescriptions. Technology in the home requires nurses to focus on the family "home care system" to provide total care to the infant.

Nurses can play a key role in assisting families by preparing them for and increasing their confidence in caring for their infants at home. This adaptation begins before discharge from the hospital. Family members are active participants in the transition-to-home plan. Recognition of parental needs and addressing each area in the discharge plan will ease the transition home.

Assessment of the family's preparedness is essential. The following areas should be explored:

- *Parenting education*—assess the family's knowledge of positioning and handling of their infant, nutrition, hygiene, elimination, growth and development, immunizations needed, and recognition of illnesses. Asking questions in a sensitive manner will assist the nurse in identifying knowledge deficiencies, so they can be reinforced in the nurse's teaching plan.
- *Postpartum care*—determine the mother's concerns in areas of body image, weight loss, sleep/rest needs, discomfort, fatigue, and adjustment to her new role. Asking open-ended questions concerning these areas will help the nurse extract more information to include in the teaching plan. Targeting the mother's areas of concern will help the nurse focus on needed education to facilitate the mother's transition into her new role as a parent.
- *Support systems*—assess physical and emotional support for the new mother by asking questions about the availability of her immediate family, other relatives, and significant others to help out. If lacking, referrals may need to be made to community parenting programs, cooperative daycare, or other community resources needed to assist this family. Exploring these vital areas through sensitive questioning hopefully will convey the nurse's concern for the infant and family while obtaining a thorough assessment of the family's learning needs.

Once preparedness has been assessed, the nurse can intervene as necessary. For example, if the caretakers do not think they are prepared to maintain machinery, technology, medication, or developmental therapy, then the nurse can demonstrate the care to the family. The nurse provides instructions and hands-on experience within a supportive environment until the family's confidence increases. The nurse can also assist the family to anticipate the common problems that might occur (e.g., advising them to avoid running out of supplies, to have enough medication or special formula mixture to last throughout the weekend, and to keep backup batteries for powering machines or portable oxygen). The outcome of the preparedness assessment and intervention is that the safety of the infant is established and maintained.

Nursing for families who are using complex home care equipment requires caring for the infant and family members' physical and emotional well-being as well as providing effective solutions to problems they may encounter. Home health nurses need to identify, mobilize, and adapt a myriad of community resources to support the family in giving the best possible care in the home setting. Preparing families for high-tech care before hospital discharge, with home health nurses continuing and

reinforcing that focus, will help ease the burden of managing high-tech equipment in the home.

Women's Health Care

A woman's reproductive years span half her lifetime, on average. This is not a static period, but rather one that encompasses several significant stages. As her reproductive goals change, so do a woman's health care needs. Because of these changing needs, comprehensive community-centered care is critical.

Community-based women's health services have received increased emphasis during the past few decades simply because of economics. Women use more health care services than men, they make as many as 90% of health care decisions, and they represent the majority of the population (CDC, 2015a). Women spend 66 cents of every health care dollar, and 7 of the 10 most frequently performed surgeries in the United States are specific to women (Alexander et al., 2014). Examples of community-based women's health care services that can be freestanding or hospital-based include the following:

- Screening centers that offer mammograms, Pap smears, bone density assessments, genetic counseling, ultrasound, breast examinations, complete health risk appraisals, laboratory studies (complete blood count, cholesterol testing, thyroid testing, glucose testing for diabetes, follicle-stimulating hormone [FSH] levels), and electrocardiograms
- Educational centers that provide women's health lectures, instruction on breast self-examinations and Pap smears, and computers for research
- Counseling centers that offer various support groups: genetics, psychotherapy, substance abuse, sexual assault, and domestic violence
- Wellness centers that offer stress reduction techniques, massage therapy, guided imagery, hypnosis, smoking cessation, weight reduction, tai chi, yoga, and women's fitness/exercise classes
- Alternative/wholeness healing centers that provide acupuncture, aromatherapy, biofeedback, therapeutic touch, facials, reflexology, and herbal remedies
- Retail centers that offer specialty equipment for rental and purchase, such as breast prostheses

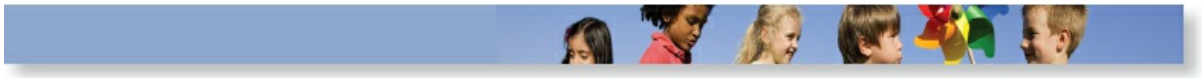
Women have multiple choices regarding services, settings, and health care providers. In the past most women received health care services from physicians such as obstetricians, gynecologists, and family physicians, but today nurse midwives and nurse practitioners are becoming more prevalent in providing well-women care.

Nurses who work in community-based settings need to be familiar with the many health issues commonly encountered by women within their communities. All nurses who work with women of any age in community-based settings, including the workplace, schools, practitioner offices, and clinics, should possess a thorough understanding of the scope of women's health care and should be prepared to intervene appropriately to prevent problems and to promote health.

Child Health Care

The majority of care for a child occurs in the community setting. The numerous settings may be broad or highly specialized. For example, one setting may provide

well-child care as well as illness-related care. Another setting may be limited to providing well-child care; a third setting may be limited to diagnostic evaluation, emergency care, or surgical intervention. Other settings may focus on caring for children with specific conditions or diagnosis, such as diabetes or cancer. See Chapter 33 for specific community-based child health care settings.



KEY CONCEPTS

- Core concepts of maternal and pediatric nursing include family-centered care, evidence-based practice, collaborative care, atraumatic therapeutic care, communication, education, discharge planning and case management, advocacy and resource management, preventative care, culturally competent care, and being knowledgeable about CAM.
- Family-centered care recognizes the concept of the family as the constant. The health and functioning ability of the family influences and impacts the health of the client and other members of the family. Family-centered care recognizes and respects family strengths and individuality, encourages referrals for family support, and facilitates collaboration. It ensures flexible, accessible, and responsive health care delivery while incorporating developmental needs and implementing policies to provide emotional and financial support to women, children, and their families.
- Open, honest lines of communication are essential for nurses. The use of an interpreter may be necessary to ensure effective communication with women, children, and their families in the community setting. Maintaining confidentiality and privacy are key.
- A family's knowledge related to the client's health or illness is vitally important. Nurses play a major role in educating women, children, and their families. For children, teaching is provided based on the child's developmental level.
- Discharge planning provides a comprehensive plan for the safe discharge of a client from a health care facility and for continuing safe and effective care in the community. Case management focuses on coordinating health care services while balancing quality and cost outcomes. Both contribute to improved transition from the hospital to the community for women, children, their families, and the health care team.
- Advocacy and resource management help ensure that the client and family have the necessary resources and appropriate health care services available to them.
- Health care delivery has moved from acute care settings out into the community, with an emphasis on health promotion and illness prevention (Clark, 2011). Community health nursing focuses on prevention and improvement of the health of populations and communities, addressing current and potential health needs of the population or community, promoting and preserving the health of a population regardless of a particular age group or diagnosis. Community health nurses perform epidemiologic investigations to help analyze and develop health policy and community health initiatives.

- Community-based nurses focus on providing personal care to individuals and families in the community. They focus on promoting and preserving health as well as preventing disease or injury. They help women, children, and their families cope with illness and disease. Community-based nurses are direct care providers as well as advocators and educators. They focus on minimizing and removing barriers to allow the client to develop to his or her full potential.
- Settings for community-based nursing include physicians' offices, clinics, health departments, urgent care centers, clients' homes, schools, camps, churches, and shelters such as abuse, homeless, and disaster shelters. Nurses provide both well, episodic ill care, and chronic care to women, children, and their families.
- There has been a rise in home health care due to shorter hospital stays and cost containment along with an increase in income and longevity of people with chronic and debilitating health conditions. Technology also has improved, which allows clients to be monitored and to undergo complicated procedures at home.

CHAPTER WORKSHEET

MULTIPLE-CHOICE QUESTIONS

1. When caring for children, how should the nurse best incorporate the concept of family-centered care?
   a. Encourage the family to allow the physician to make health care decisions for the child.
   b. Use the concepts of respect, family strengths, diversity, and collaboration with family.
   c. Advise the family to choose a pediatric provider who is on the covered child's health care plan.
   d. Recognize that families undergoing stress related to the child's illness cannot make good decisions.
2. A community-based nurse is involved in secondary prevention activities. Which activities might be included? Select all that apply.
   a. Fecal occult blood testing
   b. Hearing screening
   c. Smoking cessation program
   d. Cholesterol testing
   e. Hygiene program
   f. Pregnancy testing
3. A woman is to undergo a colonoscopy at a freestanding outpatient surgery center. Which would the nurse identify as a major disadvantage associated with this community-based setting?
   a. Increased risk for infection
   b. Increased health care costs
   c. Need to be transferred if overnight stay is required
   d. Increased disruption of family functioning
4. When developing a teaching plan for a child and his parents, which action would the nurse do first?
   a. Decide which procedures and medications the child will be discharged on.
   b. Determine the child's and family's learning needs and styles.
   c. Ask the family if they have ever performed this type of procedure.
   d. Tell the child and family what the goals of the teaching session are.
5. The clinic nurse is concerned about the client's ability to understand the instructions given and the health literacy level of her client. Which of the following can the nurse employ to increase the client's understanding of the instructions?
   a. Draw pictures of the procedure and write down the steps to it.
   b. Instruct the client to call the nurse if they have questions.

c. Discuss the instructions with an elderly family member in addition to the client.
d. Question the client about their reading level and educational level.

CRITICAL THINKING EXERCISES

1. A 3-year-old girl from Saudi Arabia has become seriously ill while on a visit to the United States. It is projected that she will require a lengthy hospitalization. Describe the steps the nurse should take to communicate with and provide extensive health care teaching to this child's family.
2. A pregnant woman is discharged home from the hospital after admission due to preterm labor. The woman is to be on complete bed rest and will receive home health care through a local agency to assist her and her family and to monitor her health status. As the home health nurse assigned to this woman, what should your nursing assessment include?

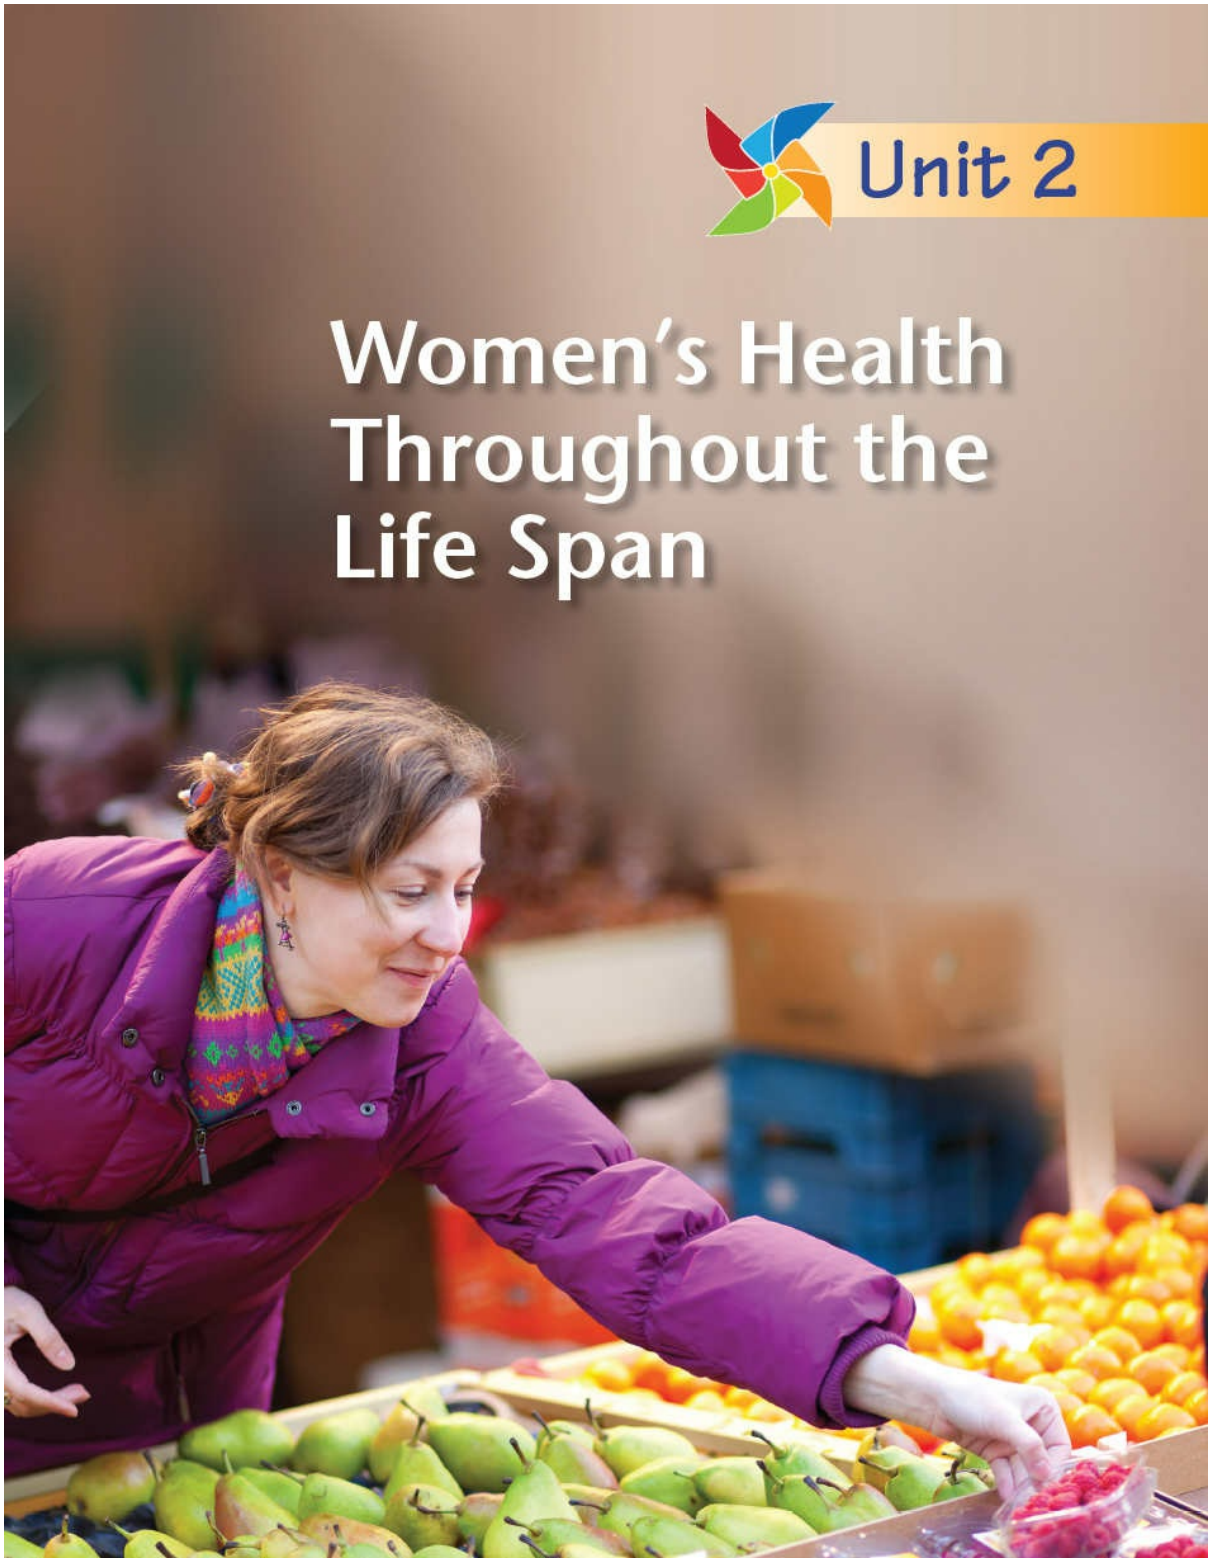
STUDY ACTIVITIES

1. Shadow a nurse working in a community setting, such as a women's health clinic, birthing center, camp, home care, or health department. Identify the role the nurse plays in the health of women, children, and families in the setting and in the community.
2. Arrange for a visit to a community health center that offers services to various cultural groups. Interview the staff about the strategies used to overcome communication barriers and different health care practices for the women and children in these groups.
3. Select one of the websites listed on thePoint and explore the information provided. How could a community-based nurse use this information?

BRINGING IT ALL TOGETHER: A CASE STUDY

Bianca, a 23-year-old Hispanic, is about to give birth to her first child, a daughter that will be named Amelia. Her partner, Alejandro, has been supportive of Bianca during her labor and plans to be present during the delivery but seems uneasy about the prospect of caring for his daughter claiming, "I'm not use to being around little babies." The birthing center focuses on family-centered care and the nurse will plan the care of Bianca and Amelia as well as the support of Alejandro based on that model.

Go to thePoint to find questions to consider about this case.



Unit 2
Women's Health Throughout the Life Span

3

Anatomy and Physiology of the Reproductive System

WOW

Words of Wisdom

All nurses should take care of and respect the human body, for it is a wondrous precision machine.

KEY TERMS

breasts
cervix
endometrium
estrogen
fallopian tubes
follicle-stimulating hormone (FSH)
luteinizing hormone (LH)
menarche
menstruation
ovaries

ovulation
penis
progesterone
testes
uterus
vagina
vulva

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Contrast the structure and function of the major external and internal female genital organs.
2. Outline the phases of the menstrual cycle, the dominant hormones involved, and the changes taking place in each phase.
3. Classify external and internal male reproductive structures and the function of each in hormonal regulation.

***Linda*, 49, started menstruating when she was 12 years old. Her menstrual periods have always been regular, but now she is experiencing irregular, heavier, and longer ones. She wonders if there is something wrong or if this is normal.**

The reproductive system is a collection of organs that function in the production of offspring. Scientists argue that the reproductive system is among the most important systems in the entire body. Without the ability to reproduce, a species dies. The female reproductive system produces the female reproductive cells (the eggs, or ova) and contains an organ (**uterus**) in which development of the fetus takes place; the male reproductive system produces the male reproductive cells (the sperm) and contains an organ (**penis**) that deposits the sperm within the female. Nurses need to have a thorough understanding of the anatomy and physiology of the male and female reproductive systems to be able to assess the health of these systems, to promote reproductive system health, to care for conditions that might affect the reproductive organs, and to provide client teaching concerning the reproductive system. This chapter reviews the female and male reproductive systems and the menstrual cycle as it relates to reproduction.

FEMALE REPRODUCTIVE ANATOMY AND PHYSIOLOGY

The female reproductive system is composed of both external and internal reproductive organs. It consists of the paired ovaries and oviducts, the uterus, the vagina, the external genitalia, and the mammary glands. All of these structures have evolved for the important functions of **ovulation**, fertilization of an ovum by a sperm, support of the developing embryo and fetus, and the birth and care of a newborn.

External Female Reproductive Organs

The external female reproductive organs collectively are called the **vulva** (which means "covering" in Latin). The vulva serves to protect the urethral and vaginal openings and is highly sensitive to touch to increase the female's pleasure during sexual arousal (Patton & Thibodeau, 2016). The structures that make up the vulva include the mons pubis, the labia majora and minora, the clitoris and prepuce, the structures within the vestibule, and the perineum (Fig. 3.1).

Mons Pubis

The mons pubis is the elevated, rounded, fleshy prominence made up of fatty tissue that overlays the symphysis pubis. The skin of this fatty tissue is covered with coarse, curly public hair after puberty. The mons pubis protects the symphysis pubis during sexual intercourse.

Labia

The labia majora (large lips), which are relatively large and fleshy, are comparable to the scrotum in males. The labia majora contain sweat and sebaceous (oil-secreting) glands; after puberty, they are covered with hair. Their function is to protect the vaginal opening and provide cushioning during sexual activity. The labia minora (small lips) are the delicate hairless inner folds of skin; they can be very small or up to 2 in wide. They lie just inside the labia majora and surround the openings to the vagina and urethra. The labia minora grow down from the anterior inner part of the labia majora on each side. These lips surround the vaginal opening and extend upward to form protection around both the clitoris and urethra. They are highly vascular and abundant in nerve supply. They lubricate the vulva, swell in response to stimulation, and are highly sensitive.

FIGURE 3.1 A. The external female reproductive organs. B. Normal appearance of external structures. (Photo by B. Proud.)

Clitoris and Prepuce

The clitoris is a small, cylindrical mass of erectile tissue and nerves. It is highly sensitive and is analogous to the head of the male's penis. Unlike the penis, however, the function of the clitoris is purely erogenous. Most of the components of the clitoris are buried under the skin and connective tissue of the vulva. It is located at the anterior junction of the labia minora. There are folds above and below the clitoris. The joining of the folds above the clitoris forms the prepuce, a hood-like covering over the clitoris; the junction below the clitoris forms the frenulum.

Take Note!

The hood-like covering over the clitoris is the site for female genital mutilation or cutting, which is a cultural ritual still practiced in some countries, including in the United States. It is internationally recognized as a human rights violation against women.

A rich supply of blood vessels gives the clitoris a pink color. Like the penis, the clitoris is very sensitive to touch, stimulation, and temperature and can become erect. For its small size, 9 to 11 cm, it has a generous blood and nerve supply. There are more free nerve endings of sensory reception located on the clitoris than on any other part of the body, and it is, unsurprisingly, the most erotically sensitive part of the genitalia for most females. Its function is sexual stimulation (Pauls, 2015).

Take Note!

The word clitoris is from the Greek word for "key"; in ancient times the clitoris was thought to be the key to a woman's sexuality.

Vestibule

The vestibule is an oval area enclosed by the labia minora laterally. It is inside the labia minora and outside of the hymen and is perforated by six openings. Opening into the vestibule are the urethra from the urinary bladder, the vagina, and two sets of glands. The opening to the vagina is called the introitus, and the half-moon–shaped area behind the opening is called the fourchette. Through tiny ducts beside the introitus, Bartholin glands, when stimulated, secrete mucus that supplies lubrication for intercourse. Skene glands are located on either side of the opening to the urethra. They secrete a small amount of mucus to keep the opening moist and lubricated for the passage of urine (Velkey, Hall, & Robboy, 2015).

The vaginal opening is surrounded by the hymen (maidenhead). The hymen is a tough, elastic, perforated, mucosa-covered tissue across the vaginal introitus. In a virgin, the hymen may completely cover the opening, but it usually encircles the opening like a tight ring. Because the degree of tightness varies among women, the hymen may tear at the first attempt at intercourse, or it may be so soft and pliable that no tearing occurs. In a woman who is not a virgin, the hymen usually appears as small tags of tissue surrounding the vaginal opening, but the presence or absence of the hymen can neither confirm nor rule out sexual experience (Acien & Acien, 2015).

Take Note!

Heavy physical exertion, use of tampons, or injury to the area can alter the appearance of the hymen in girls and women who have not been sexually active.

Perineum

The perineum is the most posterior part of the external female reproductive organs. This external region is located between the vulva and the anus. It is made up of skin, muscle, and fascia. The perineum can become lacerated or incised during childbirth and may need to be repaired with sutures. Incising the perineum area to provide more space for the presenting part is called an episiotomy. Although still a common obstetric procedure, the use of episiotomy has decreased during the past 25 years. The procedure should be applied selectively rather than routinely. An episiotomy can add to postpartum discomfort and perineal trauma and can lead to fecal incontinence (King, et al., 2015).

Internal Female Reproductive Organs

The internal female reproductive organs consist of the vagina, uterus, fallopian tubes, and ovaries (Fig. 3.2). These structures develop and function according to specific hormonal influences that affect fertility and childbearing.

Vagina

The **vagina** is a highly distensible canal situated in front of the rectum and behind the bladder. It is a tubular, fibromuscular organ lined with mucous membrane that

lies in a series of transverse folds called rugae. The rugae allow for extreme dilation of the canal during labor and birth. The vagina is a canal that connects the external genitals (vulva) to the cervix. It receives the penis and the sperm ejaculated during sexual intercourse, and it serves as an exit passageway for menstrual blood and for the fetus during childbirth. The front and back walls normally touch each other so that there is no space in the vagina except when it is opened (e.g., during a pelvic examination or intercourse). In the adult, the vaginal cavity is 3 to 4 in long. Muscles that control its diameter surround the lower third of the vagina. The upper two thirds of the vagina lies above these muscles and can be stretched easily. During a woman's reproductive years, the mucosal lining of the vagina has a corrugated appearance and is resistant to bacterial colonization. Before puberty and after menopause (if the woman is not taking estrogen), the mucosa is smooth due to lower levels of estrogen (Farage, Miller, & Maibach, 2015).

The vagina has an acidic environment, which protects it against ascending infections. Antibiotic therapy, douching, perineal hygiene sprays, and deodorants upset the acid balance within the vaginal environment and can predispose women to infections.

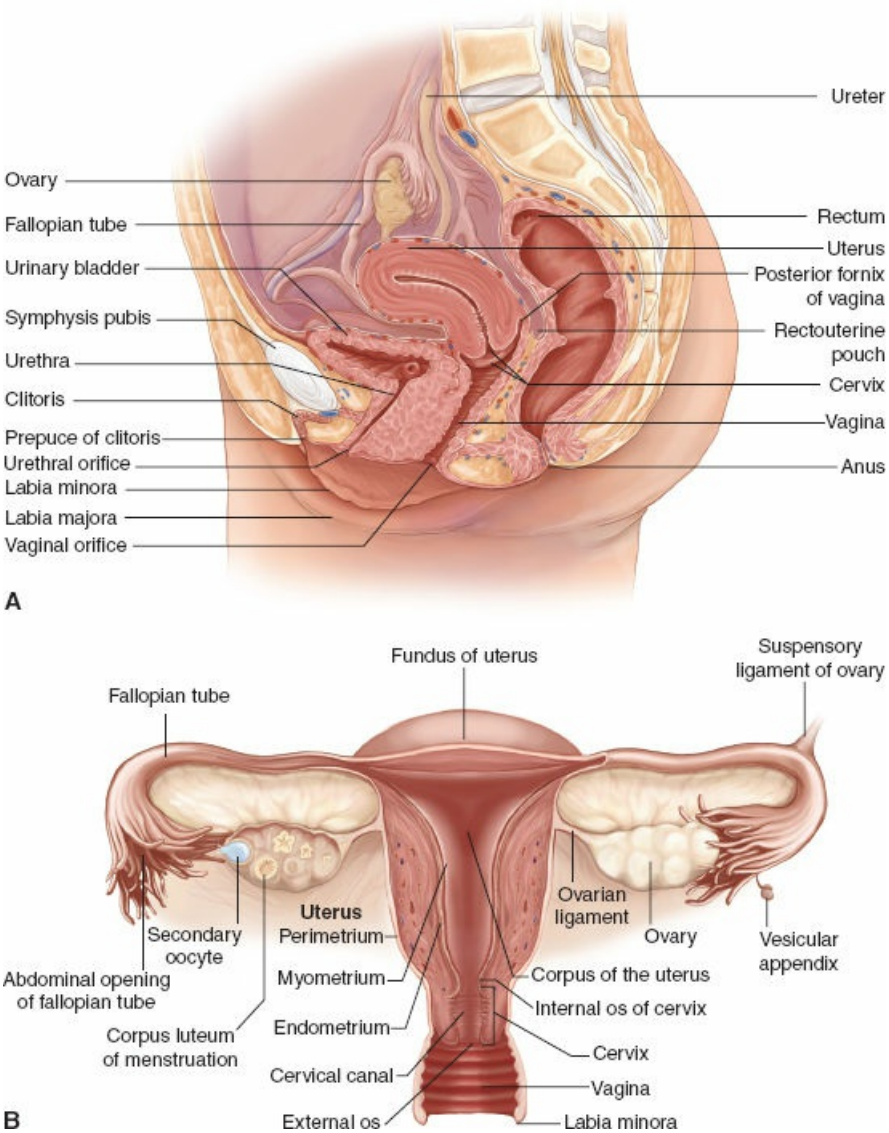


FIGURE 3.2 The internal female reproductive organs. A. Lateral view. B. Anterior view. (Adapted from Anatomical Chart Company. (2001). *Atlas of human anatomy*. Springhouse, PA: Springhouse.)

Uterus

The uterus is an inverted, pear-shaped muscular organ at the top of the vagina. It lies behind the bladder and in front of the rectum and is anchored in position by eight ligaments, although it is not firmly attached or adherent to any part of the skeleton. A full bladder tilts the uterus backward; a distended rectum tilts it forward. The uterus alters its position by gravity or with change of posture, and is the size and shape of an inverted pear. It is the site of menstruation, receiving a fertilized ovum, development of the fetus during pregnancy, and contracting to help in the expulsion of the fetus and placenta. Before the first pregnancy, it measures approximately 3 in long, 2 in wide, and 1 in thick. After a pregnancy, the uterus remains larger than before the pregnancy. After menopause, it becomes smaller and atrophies.

The uterine wall is relatively thick and composed of three layers: the **endometrium** (innermost layer), the myometrium (muscular middle layer), and the perimetrium (outer serosal layer that covers the body of the uterus). The endometrium is the mucosal layer that lines the uterine cavity in nonpregnant women. It varies in thickness from 0.5 to 5 mm and has an abundant supply of glands and blood vessels (Tambouret & Wilbur, 2015). The myometrium makes up the major portion of the uterus and is composed of smooth muscle linked by connective tissue with numerous elastic fibers. During pregnancy, the upper myometrium undergoes marked hypertrophy, but there is limited change in the cervical muscle content.

Anatomic subdivisions of the uterus include the convex portion above the uterine tubes (the fundus), the central portion (the corpus or body) between the fundus and the cervix, and the cervix, or neck, which opens into the vagina.

CERVIX

The **cervix**, the lower part of the uterus, is sometimes called the neck of the uterus. It opens into the vagina and has a channel that allows sperm to enter the uterus and menstrual discharge to exit. It is composed of fibrous connective tissue. During a pelvic examination, the part of the cervix that protrudes into the upper end of the vagina can be visualized. Like the vagina, this part of the cervix is covered by mucosa, which is smooth, firm, and doughnut shaped, with a visible central opening called the external os (Fig. 3.3). Before childbirth, the external cervical os is a small, regular, oval opening. After childbirth, the opening is converted into a transverse slit that resembles lips (Fig. 3.4). Except during menstruation or ovulation, the cervix is usually a good barrier against bacteria. The cervix has an alkaline environment, which protects the sperm from the acidic environment in the vagina.

The canal or channel of the cervix is lined with mucus-secreting glands. This mucus is thick and impenetrable to sperm until just before the ovaries release an egg (ovulation). At ovulation, the consistency of the mucus changes so that sperm can swim through it, allowing fertilization. At the same time, the mucus-secreting glands of the cervix actually become able to store live sperm for 2 or 3 days. These sperm can later move up through the corpus and into the fallopian tubes to fertilize the egg; thus, intercourse 1 or 2 days before ovulation can lead to pregnancy.

Because some women do not ovulate consistently, pregnancy can occur at varying times after the last menstrual period. During pregnancy the cervix is the vital mechanical barrier which resists compressive and tensile loads generated from a growing fetus. The channel in the cervix is too narrow for the fetus to pass through during pregnancy, but during labor it stretches to let the newborn through.

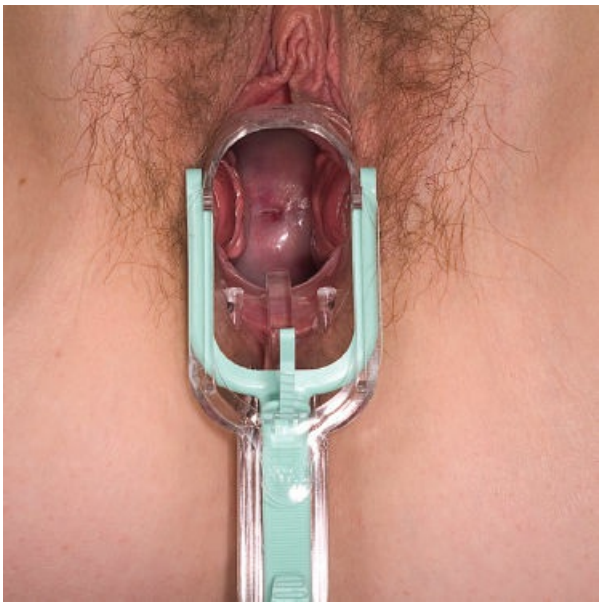

FIGURE 3.3 **Appearance of normal cervix. *Note:* This is the cervix of a multipara female. (Photo by B. Proud.)**

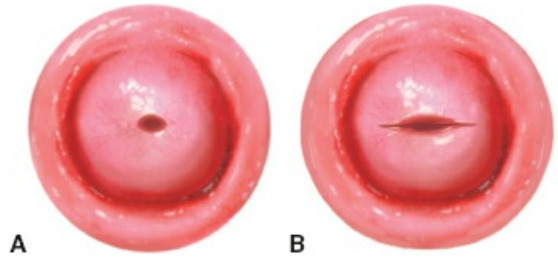

FIGURE 3.4 **A. Nulliparous cervical os. B. Parous cervical os.**

CORPUS

The corpus, or the main body of the uterus, is a highly muscular organ that enlarges to hold the fetus during pregnancy. The inner lining of the corpus (endometrium) undergoes cyclic changes as a result of the changing levels of hormones secreted by the ovaries: it is thickest during the part of the menstrual cycle in which a fertilized egg would be expected to enter the uterus and is thinnest just after menstruation. If fertilization does not take place during this cycle, most of the endometrium is shed and bleeding occurs, resulting in the monthly period. If fertilization does take place, the embryo attaches to the wall of the uterus, where it becomes embedded in the endometrium (about 1 week after fertilization); this process is called implantation (Patton & Thibodeau, 2015). Menstruation then ceases during the 40 weeks (280 days) of pregnancy. During labor, the muscular walls of the corpus contract to push the baby through the cervix and into the vagina.

Fallopian Tubes

The **fallopian tubes**, also known as oviducts, are hollow, cylindrical structures that extend 2 to 3 in from the upper edges of the uterus toward the ovaries. Each tube is about 7 to 10 cm long (4 in) and approximately 0.7 cm in diameter. The end of each tube flares into a funnel shape, providing a large opening for the egg to fall into when it is released from the ovary. Cilia (beating, hair-like extensions on cells) line the fallopian tube and the muscles in the tube's wall. The fallopian tubes convey the ovum from the ovary to the uterus and sperm from the uterus toward the ovary. This movement is accomplished via ciliary action and peristaltic contraction. If sperm are present in the fallopian tube as a result of sexual intercourse or artificial insemination, fertilization of the ovum can occur in the distal portion of the tube. If the egg is fertilized, it will divide over a period of 4 days while it moves slowly down the fallopian tube and into the uterus, where it implants into the uterine lining.

Ovaries

The **ovaries** are a set of paired glands resembling unshelled almonds that are the organs of gamete production in the female. They are set in the pelvic cavity below and to either side of the umbilicus. They are usually pearl colored, oblong, and have a lumpy surface. They are homologous to the testes. Each mature ovary weighs from 2 to 5 g and is about 4 cm long, 2 cm wide, and 1 cm thick (Jones & Lopez, 2014). The ovaries are not attached to the fallopian tubes but are suspended nearby from several ligaments, which help hold them in position. The development and the release of the ovum and the secretion of the hormones **estrogen** and **progesterone** are the two primary functions of the ovary. The ovaries link the reproductive system to the body's system of endocrine glands, as they produce the ova (eggs) and secrete, in cyclic fashion, the female sex hormones estrogen and progesterone. After an ovum matures, it passes into the fallopian tubes.

Breasts

The two mammary glands, or **breasts**, are accessory organs of the female reproductive system that are specialized to secrete milk following pregnancy. They overlie the pectoralis major muscles and extend from the second to the sixth ribs and from the sternum to the axilla. Each breast has a nipple located near the tip, which is surrounded by a circular area of pigmented skin called the areola. Each breast is composed of approximately nine lobes (the number can range between 4 and 18), which contain glands (alveolar) and a duct (lactiferous) that leads to the nipple and opens to the outside (Fig. 3.5). The lobes are separated by dense connective and adipose tissues, which also help support the weight of the breasts (Kandeel, 2014).

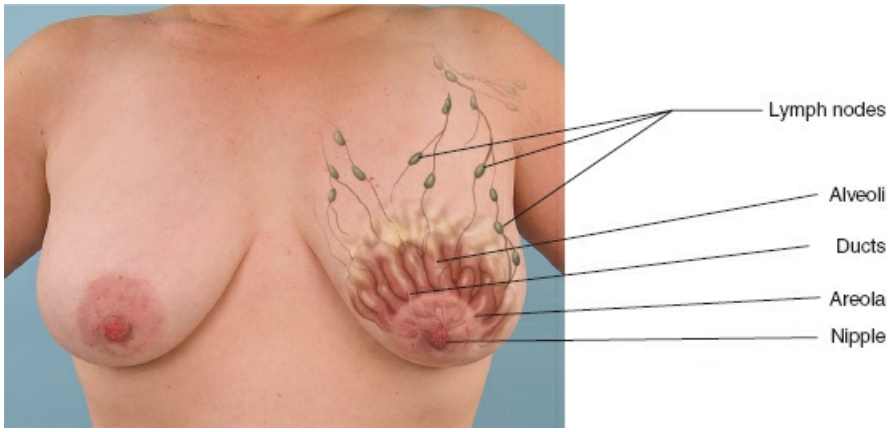

FIGURE 3.5 Anatomy of the breasts. (Photo by B. Proud.)

During pregnancy, placental estrogen and progesterone stimulate the development of the mammary glands. Because of this hormonal activity, the breasts may double in size during pregnancy. At the same time, glandular tissue replaces the adipose tissue of the breasts.

Following childbirth and the expulsion of the placenta, levels of placental hormones (progesterone and lactogen) fall rapidly, and the action of prolactin (milk-producing hormone) is no longer inhibited. Prolactin stimulates the production of milk within a few days after childbirth, but in the interim, dark yellow fluid called colostrum is secreted. Colostrum contains more minerals and protein, but less sugar and fat, than mature breast milk. Colostrum secretion may continue for approximately a week after childbirth, with gradual conversion to mature milk. Colostrum is rich in maternal antibodies, especially immunoglobulin A (IgA), which offers protection for the newborn against enteric pathogens.

Female Sexual Response

The sexual response in both females and males is governed primarily by the nervous system rather than by hormones. The sexual response starts in a state of sexual neutrality, and the person's sexual desire is more of a reciprocal response than a spontaneous one (Housman & Odum, 2016). The sexual cycle is usually thought of as having five phases: desire, excitement, plateau, orgasm, and resolution:

1. *Desire:* starts with a desire for sexual intimacy, also known as *libido*
2. *Excitement:* both men and women have a heightened sexual awareness. When a female is sexually aroused, her brain coordinates a patterned sexual response cycle consisting of increased heart rate, respiratory rate, blood pressure, and general level of excitement (Sherwood, 2016). With sexual stimulation, tissues in the clitoris and breasts and around the vaginal orifice fill with blood and the erectile tissues swell. At the same time, the vagina begins to expand and elongate to accommodate the penis. As part of the whole vasocongestive reaction, the labia majora and minor swell and darken. As sexual stimulation intensifies, the vestibular glands secrete mucus to moisten and lubricate the tissues to facilitate insertion of the penis. Hormones play an integral role in the female sexual response as well. Adequate estrogen and testosterone must be available for the brain to sense incoming arousal stimuli. Research indicates that estrogen preserves the vascular function of female sex organs and affects genital sensation.

It also is believed to promote blood flow to these areas during stimulation. Testosterone is needed to stimulate sexual desire in women. Recent research findings also suggest that testosterone therapy improves sexual desire, arousal, orgasm frequency, and satisfaction in women (Davis, 2013).

3. *Plateau:* The heart rate, blood pressure, level of muscle tension, and respiration rate all increase. During this phase, the penile erection intensifies and the vagina constricts around the penis. Continued stimulation of the clitoris and penis with movement leads to the next phase of the sexual response—*orgasmic phase.*
4. *Orgasm:* women experience rhythmic contractions of the pelvic muscles and vaginal walls. In men, ejaculation occurs during the *orgasmic phase* and both sexes experience a peak of sexual pleasure at orgasm. Typically the woman feels warm and relaxed after an orgasm. Within a short time after orgasm, the two physiologic mechanisms that created the sexual response, vasocongestion and muscle contraction, rapidly dissipate. The orgasmic experience varies from person to person and from time to time in the same person. Orgasm is an intense sensation of pleasure achieved by stimulation of erogenous zones. Women do not have a refractory period after each orgasm and can, therefore, experience multiple orgasms. Clitoral sexual response and the female orgasm are not affected by aging (Minkin, 2016). Some orgasms are intense, some are quiet, and some are gentle (Wheatley & Puts, 2015). At the completion of the sexual episode, the brain and body return to an unaroused state, which is termed *sexual resolution.* During this phase, the heart rate, blood pressure, and respirations slow; the muscles relax. Frequently, fatigue sets in for both people.

THE FEMALE REPRODUCTIVE CYCLE

The female reproductive cycle is a complex process that encompasses an intricate series of chemical secretions and reactions to produce the ultimate potential for fertility and birth. The female reproductive cycle is a general term that includes the ovarian cycle, the endometrial (uterine) cycle, the hormonal changes that regulate them, and the cyclical changes in the breasts. The endometrium, ovaries, pituitary gland, and hypothalamus are all involved in the cyclic changes that help to prepare the body for fertilization. Absence of fertilization results in menstruation, the monthly shedding of the uterine lining. **Menstruation** (shedding of the endometrium) marks the beginning and end of the monthly cycle. Menopause is the naturally occurring cessation of menstrual cycles.

The menstrual cycle results from a functional hypothalamic–pituitary–ovarian axis and a precise sequencing of hormones that lead to ovulation. The ovarian cycle, during which ovulation occurs, and the endometrial cycle, during which menstruation occurs, are divided at midcycle by ovulation. Ovulation occurs when the ovum is released from its follicle; after leaving the ovary, the ovum enters the fallopian tube and journeys toward the uterus. If sperm fertilize the ovum during its journey, pregnancy occurs (Fig. 3.6).

Ovarian Cycle

The ovarian cycle is the series of events associated with a developing oocyte (ovum or egg) within the ovaries. Whereas men manufacture sperm daily, often into

advanced age, women are born with a single lifetime supply of ova that are released from the ovaries gradually throughout the childbearing years. In the female ovary, 1 million oocytes are present at birth, and about 200,000 to 400,000 follicles are still present at puberty. Typically, a woman ovulates one oocyte per month over an approximately 40-year reproductive life span. This accounts for the loss of 400 to 500 follicles. By age 35 she will have fewer than 100,000 follicles, and, by menopause, her follicular supply will be nearly depleted (Jones & Lopez, 2014). The ovarian cycle begins when the follicular cells (ovum and surrounding cells) swell and the maturation process starts. The maturing follicle at this stage is called a graafian follicle. The ovary raises many follicles monthly, but usually only one follicle matures to reach ovulation. The ovarian cycle consists of three phases: the follicular phase, ovulation, and the luteal phase.

Follicular Phase

This phase is so named because it is when the follicles in the ovary grow and form a mature egg. The goal of this phase is to produce an ovum for fertilization. This phase starts on day 1 of the menstrual cycle and continues until ovulation, approximately 10 to 14 days later. The follicular phase is not consistent in duration because of the time variations in follicular development. These variations account for the differences in menstrual cycle lengths (Sherwood, 2016). The hypothalamus is the initiator of this phase. Increasing levels of estrogen secreted from the maturing follicular cells and the continued growth of the dominant follicle cell induce proliferation of the endometrium and myometrium. This thickening of the uterine lining supports an implanted ovum if pregnancy occurs.

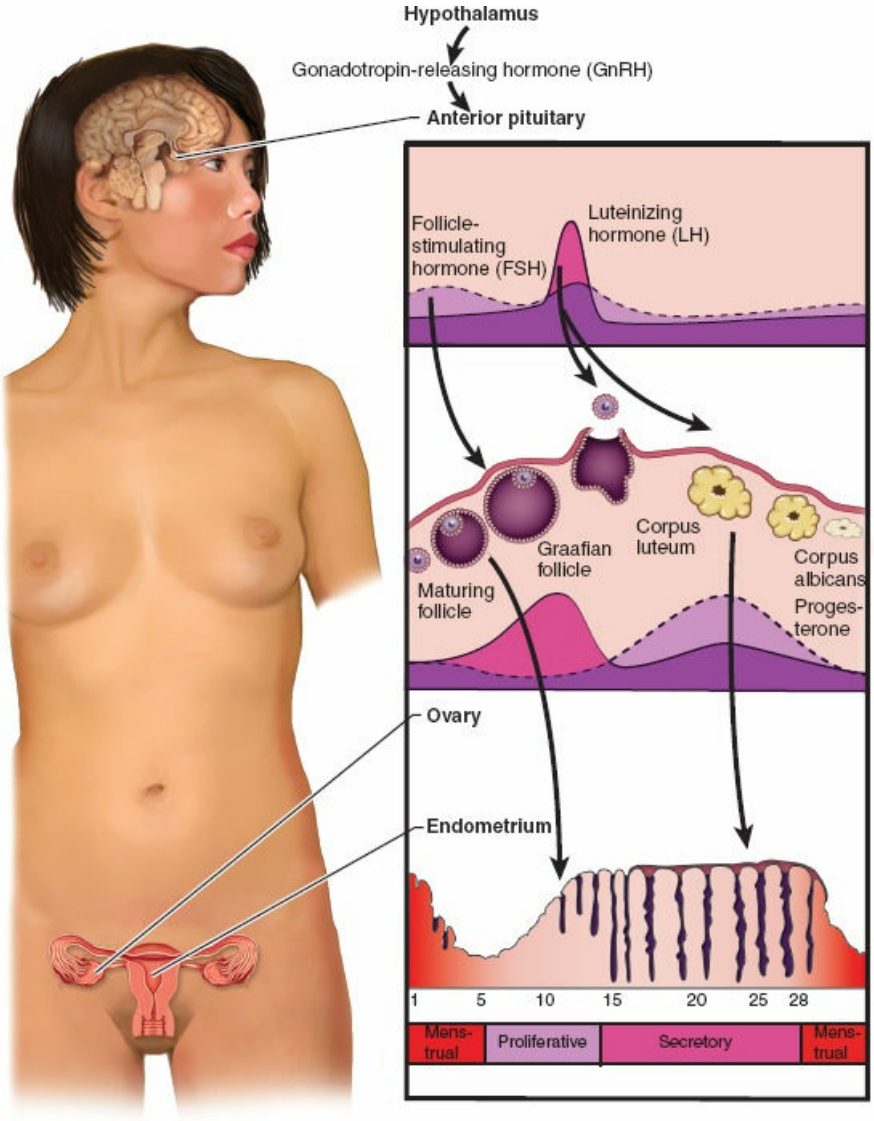

FIGURE 3.6 **Menstrual cycle summary based on a 28-day (average) menstrual cycle.**

Prompted by the hypothalamus, the pituitary gland releases **follicle-stimulating hormone (FSH)**, which stimulates the ovary to produce 5 to 20 immature follicles. Each follicle houses an immature oocyte or egg. The follicle that is targeted to mature fully will soon rupture and expel a mature oocyte in the process of ovulation. A surge in **luteinizing hormone (LH)** from the anterior pituitary gland is actually responsible for affecting the final development and subsequent rupture of the mature follicle.

Ovulation

At ovulation, a mature follicle ruptures in response to a surge of LH, releasing a mature oocyte (ovum). No one single event causes ovulation. This usually occurs on day 14 in a 28-day cycle. When ovulation occurs, there is a drop in estrogen. Typically ovulation takes place approximately 10 to 12 hours after the LH peak and 24 to 36 hours after estrogen levels peak (King et al., 2015). The distal ends of the fallopian tubes become active near the time of ovulation and create currents that help carry the ovum into the uterus. The life span of the ovum is only about 24 hours; unless it meets a sperm on its journey within that time, it will die.

During ovulation, the cervix produces thin, clear, stretchy, slippery mucus that is designed to capture the man's sperm, nourish it, and help the sperm travel up through the cervix to meet the ovum for fertilization. Ovulation symptoms also include vaginal spotting, an increase in vaginal discharge giving the woman a "feeling of wetness," an increased libido leading to more desire to be intimate, a slight rise in basal body temperature, and lower abdominal cramping.

The one constant, whether a women's cycle is 28 days or 120 days, is that ovulation takes place 14 days before menstruation (Housman & Odum, 2016).

Take Note!

About one in five women can feel a pain on one side of the abdomen around the time the egg is released. This midcycle pain is called mittelschmerz.

Luteal Phase

The luteal phase begins at ovulation and lasts until the menstrual phase of the next cycle. It typically occurs on days 15 through 28 of a 28-day cycle. After the follicle ruptures as it releases the egg, it closes and forms a corpus luteum. The corpus luteum secretes increasing amounts of the hormone progesterone, which interacts with the endometrium to prepare it for implantation. At the beginning of the luteal phase, progesterone induces the endometrial glands to secrete glycogen, mucus, and other substances. These glands become tortuous and have large lumens due to increased secretory activity. The progesterone secreted by the corpus luteum causes the temperature of the body to rise slightly until the start of the next period. A significant increase in temperature, usually 0.5° to 1°F, is generally seen within a day or two after ovulation has occurred; the temperature remains elevated until 3 days before the onset on the next menstruation (Housman & Odum, 2016). This rise in temperature can be plotted on a graph and gives an indication of when ovulation has occurred. In the absence of fertilization, the corpus luteum begins to degenerate and consequently ovarian hormone levels decrease. As estrogen and progesterone levels decrease, the endometrium undergoes involution. In a 28-day cycle, menstruation then begins approximately 14 days after ovulation in the absence of pregnancy. FSH and LH are generally at their lowest levels during the luteal phase and highest during the follicular phase.

Endometrial (Uterine) Cycle

The endometrial (uterine) cycle occurs in response to cyclic hormonal changes. The four phases of the endometrial cycle are the proliferative phase, secretory phase, ischemic phase, and menstrual phase.

Proliferative Phase

The proliferative phase of the endometrial cycle corresponds to the follicular phase of the ovarian cycle. It starts with enlargement of the endometrial glands in response to increasing amounts of estrogen. The blood vessels become dilated and the endometrium increases in thickness dramatically from 0.5 to 5 mm in height and increases eightfold in thickness in preparation for implantation of the fertilized ovum (Oyelowo & Johnson, 2016). Cervical mucus becomes thin, clear, stretchy, and more alkaline, making it more favorable to sperm to enhance the opportunity

for fertilization. The proliferative phase starts on about day 5 of the menstrual cycle and lasts to the time of ovulation. This phase depends on estrogen stimulation resulting from ovarian follicles, and this phase coincides with the follicular phase of the ovarian cycle.

Secretory Phase

The secretory phase begins at ovulation to about 3 days before the next menstrual period. Under the influence of progesterone released by the corpus luteum after ovulation, the endometrium becomes thickened and more vascular (growth of the spiral arteries) and glandular (secretion of more glycogen and lipids). These dramatic changes are all in preparation for implantation, if it were to occur. This phase typically lasts from day 15 (after ovulation) to day 28 and coincides with the luteal phase of the ovarian cycle. In the absence of fertilization by day 23 of the menstrual cycle, the corpus luteum begins to degenerate and consequently ovarian hormone levels decrease. As estrogen and progesterone levels decrease, the endometrium undergoes involution.

Concept Mastery Alert

Proliferative Versus Secretory Phases of the Uterine Cycle

During the proliferative phase, the ovarian follicles are producing increased amounts of estrogen, and the endometrium prepares for possible fertilization with pronounced growth. The secretory phase begins at time of ovulation. If the ovum is not fertilized, then the corpus luteum degenerates and hormone levels fall, ultimately resulting in menstruation.

Ischemic Phase

If fertilization does not occur, the ischemic phase begins. Estrogen and progesterone levels drop sharply during this phase as the corpus luteum starts to degenerate. Changes in the endometrium occur with spasm of the arterioles, resulting in ischemia of the basal layer. The ischemia leads to shedding of the endometrium down to the basal layer, and menstrual flow begins.

Menstrual Phase

The menstrual phase begins as the spiral arteries rupture secondary to ischemia, releasing blood into the uterus, and the sloughing of the endometrial lining begins. If fertilization does not take place, the corpus luteum degenerates. As a result, both estrogen and progesterone levels fall and the thickened endometrial lining sloughs away from the uterine wall and passes out via the vagina. The beginning of the menstrual flow marks the end of one menstrual cycle and the start of a new one. Most women report menstrual bleeding for an average of 3 to 7 days. The amount of menstrual flow varies, but averages 1 ounce or a range of approximately $^{2}/_{3}$ to $2^{2}/_{3}$ ounces in volume per cycle (Thornhill & Gangestad, 2015).

Menstruation

Menstruation is a term derived from the Latin word *mensis,* meaning “month.” It is

the normal, predictable physiologic process whereby the inner lining of the uterus (endometrium) is expelled by the body. Typically, this occurs monthly. Menstruation has many effects on girls and women, including emotional and self-image issues. In the United States, the average age at **menarche** (the start of menstruation in females) is 12.8 years, with a range between 8 and 18. Genetics is the most important factor in determining the age at which menarche starts, but geographic location, nutrition, weight, general health, nutrition, cultural and social practices, the girl's educational level, attitude, family environment, and beliefs are also important (Krieger et al., 2015).

Pubertal events preceding the first menses have an orderly progression: thelarche, the development of breast buds; adrenarche, the appearance of pubic and then axillary hair, followed by a growth spurt; and menarche (occurring about 2 years after the start of breast development). In healthy pubertal girls, the menstrual period varies in flow heaviness and may remain irregular in occurrence for up to 2 years following menarche. After that time, the regular menstrual cycle should be established. Most women will experience 300 to 400 menstrual cycles within their lifetime (King et al., 2015). Normal, regular menstrual cycles vary in frequency and blood loss (Kandeel, 2014). Irregular menses can be associated with irregular ovulation, polycystic ovary syndrome, type 2 diabetes, weather conditions, stress, disease, and hormonal imbalances (Senie, 2014).

Think back to Linda, who was introduced at the beginning of the chapter. What questions might need to be asked to assess her condition? What laboratory work might be anticipated to validate her heavier flow?

Although menstruation is a normal process, various world cultures have taken a wide variety of attitudes toward it, seeing it as everything from a sacred time to an unclean time. Folk culture surrounding menstrual-related matters has considerable implications for symptom expression and treatment-seeking behavior. Recent research findings imply the need for education to help adolescent girls manage menstrual symptoms and increase awareness of the benefit of treating them. Given that menstrual-related information comes from mothers, family, and social culture, negative attitudes toward their monthly cycles can be formed in young impressionable girls. Nurses, through formal instruction, can help young girls in shaping good menstrual attitudes and a more positive image of this natural physiologic process (Clark & Paraska, 2014).

Take Note!

Knowledge about menstruation has increased significantly and attitudes have changed. What was once discussed only behind closed doors is discussed openly today.

Consider This

We had been married 2 years when my husband and I decided to start a family. I began thinking back to my high school biology class and tried to remember about ovulation and what to look for. I also used the Internet to find the

answers I was seeking. As I was reading, it all started to come into place. During ovulation, a woman's cervical mucus increases and she experiences a wet sensation for several days midcycle. The mucus also becomes stretchable during this time. In addition, body temperature rises slightly and then falls if no conception takes place. Armed with this knowledge, I began to check my temperature daily before arising and began to monitor the consistency of my cervical mucus. I figured that monitoring these two signs of ovulation could help me discover the best time to conceive. After 6 months of trying without results, I wondered what I was doing wrong. Did I really understand my body's reproductive activity?

Thoughts: What additional suggestions might the nurse offer this woman in her journey to conception? What community resources might be available to assist this couple? How does knowledge of the reproductive system help nurses take care of couples who are trying to become pregnant?

BOX 3.1

SUMMARY OF MENSTRUAL CYCLE HORMONES

- Luteinizing hormone (LH) rises and stimulates the follicle to produce estrogen.
- As estrogen is produced by the follicle, estrogen levels rise, inhibiting the output of LH.
- Ovulation occurs after an LH surge damages the estrogen-producing cells, resulting in a decline in estrogen.
- The LH surge results in establishment of the corpus luteum, which produces estrogen and progesterone.
- Estrogen and progesterone levels rise, suppressing LH output.
- Lack of LH promotes degeneration of the corpus luteum.
- Cessation of the corpus luteum means a decline in estrogen and progesterone output.
- The decline of the ovarian hormones ends their negative effect on the secretion of LH.
- LH is secreted, and the menstrual cycle begins again.

Menstrual Cycle Hormones

The menstrual cycle involves a complex interaction of hormones. The predominant hormones include gonadotropin-releasing hormone (GnRH), FSH, LH, estrogen, progesterone, and prostaglandins. Box 3.1 summarizes menstrual cycle hormones.

Gonadotropin-Releasing Hormone

GnRH is secreted from the hypothalamus in a pulsatile manner throughout the reproductive cycle. It pulsates slowly during the follicular phase and increases during the luteal phase. GnRH induces the release of FSH and LH to assist with ovulation.

Follicle-Stimulating Hormone

FSH is secreted by the anterior pituitary gland and is primarily responsible for the maturation of the ovarian follicle. FSH secretion is highest and most important during the first week of the follicular phase of the reproductive cycle.

Luteinizing Hormone

LH is secreted by the anterior pituitary gland and is required for both the final maturation of preovulatory follicles and luteinization of the ruptured follicle. As a result, estrogen production declines and progesterone secretion continues. Thus, estrogen levels fall a day before ovulation, and progesterone levels begin to rise.

Estrogen

Estrogen is secreted by the ovaries and is crucial for the development and maturation of the follicle. Estrogen is predominant at the end of the proliferative phase, directly preceding ovulation. After ovulation, estrogen levels drop sharply as progesterone dominates. In the endometrial cycle, estrogen induces proliferation of the endometrial glands. Estrogen also causes the uterus to increase in size and weight because of increased glycogen, amino acids, electrolytes, and water. Blood supply is expanded as well.

Progesterone

Progesterone is secreted by the corpus luteum. Progesterone levels increase just before ovulation and peak 5 to 7 days after ovulation. During the luteal phase, progesterone induces swelling and increased secretion of the endometrium. This hormone is often called the hormone of pregnancy because of its calming effect (reduces uterine contractions) on the uterus, allowing pregnancy to be maintained.

Prostaglandins

Prostaglandins are primary mediators of the body's inflammatory processes and are essential for the normal physiologic function of the female reproductive system. They are a closely related group of oxygenated fatty acids that are produced by the endometrium, with a variety of effects throughout the body. Although they have regulatory effects and are sometimes called hormones, prostaglandins are not technically hormones because they are produced by all tissues rather than by special glands (Jones & Lopez, 2014). Prostaglandins increase during follicular maturation and play a key role in ovulation by freeing the ovum inside the graafian follicle. Large amounts of prostaglandins are found in menstrual blood. Current research suggests that the pathogenesis of menstrual cramps/pain is due to prostaglandin F2a (PGF2a), a potent myometrial stimulant and vasoconstrictor, in the secretory endometrium. Elevated prostaglandin levels are found in the endometrial fluid of women with dysmenorrhea (painful menses) and correlates well with their degree of pain. Nonsteroidal anti-inflammatory drugs have been introduced as the primary choice of treatment for menstrual cramps (Nguyen, et al., 2015).

Perimenopause

Perimenopause or menopausal transition and menopause are biologic markers of the transition from young adulthood to middle age. Neither of these is a symptom or disease, but rather a natural maturing of the reproductive system.

During the perimenopausal years (2 to 8 years prior to menopause), women may experience physical changes associated with decreasing estrogen levels, which may include vasomotor symptoms of hot flashes, irregular menstrual cycles, sleep disruptions, forgetfulness, irritability, mood disturbances, weight gain and bloating,

irregular menses, headaches, decreased vaginal lubrication, night sweats, fatigue, vaginal atrophy, and depression (McNamara, Batur, & DeSapri, 2015). Vasomotor symptoms (hot flashes and night sweats) are the most common complaints for which women seek treatment. Several therapies can be considered to help manage these complaints. Choosing an appropriate treatment approach for the management of these symptoms requires careful assessment of the risk/benefit ratio of each alternative, as well as individual client preference (Schuiling & Likis, 2016).

Menopause

Menopause is a universal and irreversible part of the overall aging process involving a woman's reproductive system, after which she no longer menstruates. This naturally occurring phase of every woman's life marks the end of her childbearing capacity. The average age of natural menopause—defined as 1 year without a menstrual period—is 50 to 51 years old (Alexander et al., 2014). This period is frequently termed the *climacteric* or *perimenopause,* but mostly recently the *menopausal transition* has been used (Hoyt & Falconi, 2015). As the average life expectancy for women increases, the number of women reaching and living in menopause has escalated. Most women can expect to spend more than one third of their lives beyond menopause. It is usually marked by atrophy of the breasts, uterus, fallopian tubes, and ovaries (Crawford, 2015).

Many women pass through menopause without untoward symptoms. These women remain active and in good health with little interruption of their daily routines. Other women experience vasomotor symptoms, which give rise to sensations of heat, cold, sweating, headache, insomnia, and irritability. A recent study found that women experiencing menopausal symptoms reported significantly lower health-related quality of life and significantly high work impairment when compared to women without menopausal symptoms (Coney, 2015).

Until recently, hormone therapy was the mainstay of menopause pharmacotherapy, but with the recent results of the Women's Health Initiative trial and the Heart and Estrogen Replacement Study (HERS), the use of hormone therapy has become controversial. Many women have turned to nontraditional remedies to manage their menopausal symptoms. Common complementary and alternative medicine (CAM) remedies used for the treatment of menopausal symptoms include black cohosh, dong quai, St John wort, hops, wild yam, ginseng, evening primrose oil, exercise, and acupuncture. Evidence supporting the efficacy and safety of most CAM for relief of menopausal symptoms is limited and most of the reports of efficacy don't support use of them (Wicks & Mahady, 2015). Nurses can play a major role in assisting menopausal women by educating and counseling them about the multitude of options available for disease prevention and treatments for menopausal symptoms during this time of change in their lives. Menopause should be an opportunity for women to strive for a healthy, long life, and nurses can help to make this opportunity a reality. (See Chapter 4 for more information about menopause.)

Recall Linda, who was experiencing changes in her menstrual patterns. Which hormones might be changing, and which systems might they affect?

What approach should the nurse take to enlighten Linda about what is happening to her?

MALE REPRODUCTIVE ANATOMY AND PHYSIOLOGY

The male reproductive system, like that of the female, consists of those organs that facilitate reproduction. The male organs are specialized to produce and maintain the male sex cells, or sperm; to transport them, along with supporting fluids, to the female reproductive system; and to secrete the male hormone testosterone. The organs of the male reproductive system include the penis, scrotum, two **testes** (where sperm cells and testosterone are made), and accessory organs (epididymis, vas deferens, seminal vesicles, ejaculatory duct, urethra, bulbourethral glands, and prostate gland).

External Male Reproductive Organs

The penis and the scrotum form the external genitalia in the male (Fig. 3.7).

Penis

The penis is the organ for copulation and serves as the outlet for both sperm and urine. The penis becomes engorged with blood during sexual arousal and is inserted into the female vagina during intercourse. The skin of the penis is thin, with no hairs. The prepuce (foreskin) is a circular fold of skin that extends over the glans unless it is removed by circumcision shortly after birth. The urinary meatus, located at the tip of the penis, serves as the external opening to the urethra (Fig. 3.8). The penis is composed mostly of erectile tissue. Most of the body of the penis consists of three cylindrical spaces (sinuses) of erectile tissue. The two larger ones, the corpora cavernosa, are side by side. The third sinus, the corpus spongiosum, surrounds the urethra. Erection results when nerve impulses from the autonomic nervous system dilate the arteries of the penis, allowing arterial blood to flow into the erectile tissues of the organ.

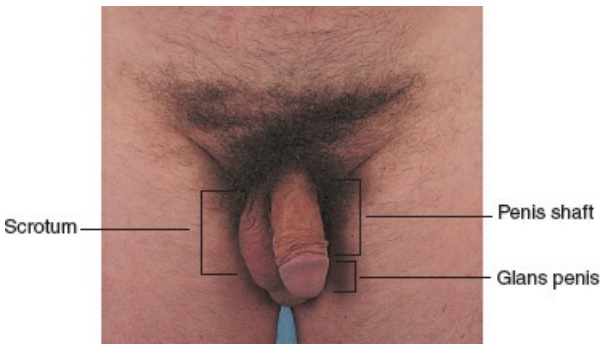

FIGURE 3.7 **The external male reproductive organs. (Photo by B. Proud.)**

FIGURE 3.8 **The urinary meatus. (Photo by B. Proud.)**

Scrotum

The scrotum is the thin-skinned sac that surrounds and protects the testes. The scrotum also acts as a climate-control system for the testes, because they need to be slightly cooler than body temperature to allow normal sperm development. The scrotum is covered with hair starting in puberty. The cremaster muscles in the scrotal wall relax or contract to allow the testes to hang farther from the body to cool or to be pulled closer to the body for warmth or protection (Patton & Thibodeau, 2015). A medial septum divides the scrotum into two chambers, each of which encloses a testis.

Internal Male Reproductive Organs

The internal structures include the testes, the ductal system, and accessory glands (Fig. 3.9).

Testes

The testes are oval bodies in the size of large olives that lie in the scrotum; usually the left testis hangs a little lower than the right one. These two nut-like structures are analogous to ovaries in the female and two testes are present in males. The testes have two functions: producing sperm and synthesizing testosterone (the primary male sex hormone). Sperm is produced in the seminiferous tubules of the testes. Similar to the female reproductive system, the anterior pituitary releases the gonadotropins, FSH and LH. These hormones stimulate the testes to produce testosterone, which assists in maintaining spermatogenesis, increases sperm production by the seminiferous tubules, and stimulates production of seminal fluid (Jones & Lopez, 2014). The epididymis, which lies against the testes, is a coiled tube almost 20 ft long. It collects sperm from the testes and provides the space and environment for sperm to mature (Fig. 3.10).

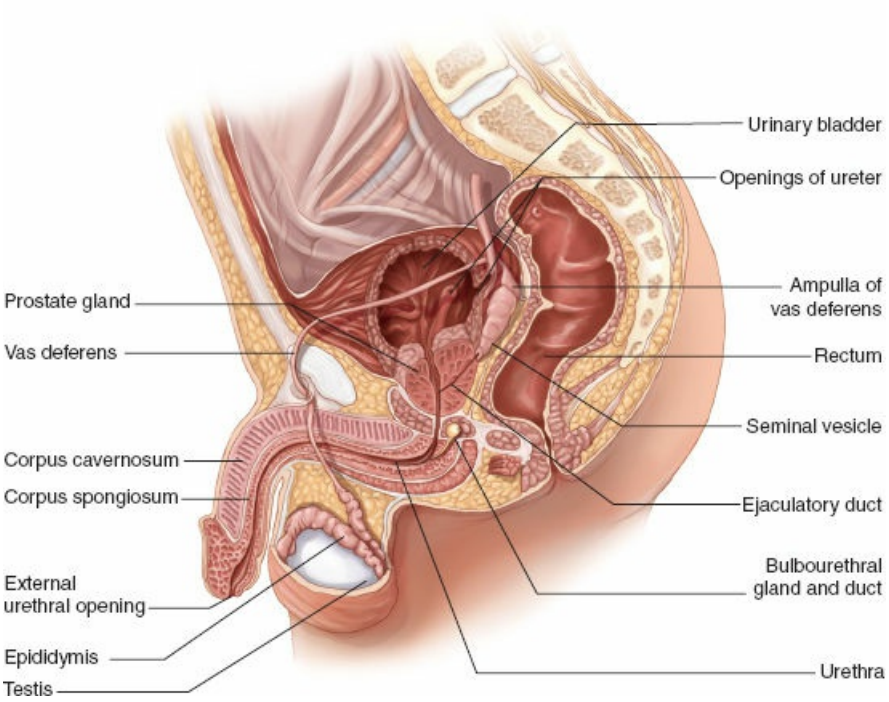

FIGURE 3.9 **Lateral view of the internal male reproductive organs. (Adapted from Anatomical Chart Company. (2001). *Atlas of human anatomy*. Springhouse, PA: Springhouse.)**

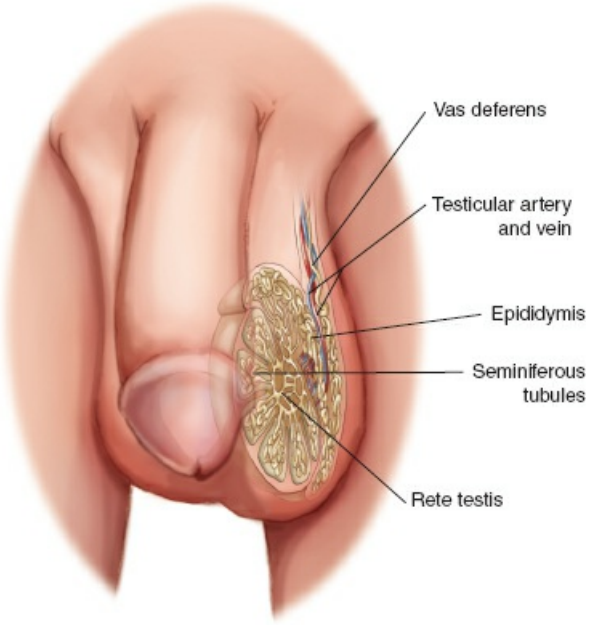

FIGURE 3.10 **Internal structures of a testis.**

The Ductal System

The vas deferens is a cord-like duct that transports sperm from the epididymis. One such duct travels from each testis up to the back of the prostate and enters the urethra to form the ejaculatory ducts. Other structures, such as blood vessels and nerves, also travel along with each vas deferens and together form the spermatic cord. The urethra is the terminal duct of the reproductive and urinary systems, serving as a passageway for semen (fluid containing sperm) and urine. It passes through the prostate gland and the penis and opens to the outside.

Accessory Glands

The seminal vesicles, which produce nutrient seminal fluid, and the prostate gland, which produces alkaline prostatic fluid, are both connected to the ejaculatory duct leading into the urethra. The paired seminal vesicles are convoluted pouch-like structures lying posterior to, and at the base of, the urinary bladder in front of the rectum. They secrete an alkaline fluid that contains fructose and prostaglandins. The fructose supplies energy to the sperm on its journey to meet the ovum, and the prostaglandins assist in sperm mobility.

The prostate gland lies just under the bladder in the pelvis and surrounds the middle portion of the urethra. Usually the size of a walnut, this gland enlarges with age. The prostate and the seminal vesicles above it produce fluid that nourishes the sperm. This fluid provides most of the volume of semen, the secretion in which sperm are expelled during ejaculation. Other fluid that makes up the semen comes from the vas deferens and from mucous glands in the head of the penis.

The bulbourethral glands (Cowper glands) are two small structures about the size of peas, located inferior to the prostate gland. They are composed of several tubes whose epithelial linings secrete a mucus-like fluid. It is released in response to sexual stimulation and lubricates the head of the penis in preparation for sexual intercourse, in addition, neutralizes the acidity of the urethra to protect sperm during their journey out of the body during ejaculation. Their existence is said to be constant, but they gradually diminish in size with advancing age.

Male Sexual Response

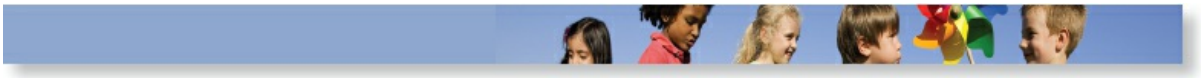
Regardless of the type of sexual stimulation, the physiologic response in both men and women is similar and usually follows a five-phase pattern, as described earlier:

1. *Desire:* Starts with a desire for sexual intimacy. This can also be termed libido.
2. *Excitement:* The man experiences sexual arousal with either thoughts or physical sexual stimuli which cause specific changes such as the heart beating faster, blood pressure rising, the testicles enlarging and more blood flowing into the penis, creating an erection.
3. *Plateau:* is the phase between excitement and orgasm in which the head of the penis enlarges and becomes more purplish in color; the glands secrete semen into the urethra; and it is challenging to stop from having an orgasm.
4. *Orgasm:* is a total body response. The tension that built up during the previous two phases is released. It triggers a series of muscle spasms in the legs, stomach, arms, back, and penis. The feelings are intense and pleasurable. Ejaculation of semen occurs at this time.
5. *Resolution:* The body returns to the physiologic nonstimulated state. The blood flows out of the penis and erection ceases; an overall feeling of relaxation ensues, and the testes and scrotum return to their normal size (Housman & Odum, 2016).

Sexual behavior involves the participation of autonomic and somatic nerves and the integration of numerous spinal sites in the central nervous system (CNS). The penile portion of the process that leads to erections represents only a single component. Penile erections are an integration of complex physiologic processes involving the CNS, peripheral nervous system, and hormonal and vascular systems

(Sherwood, 2016). With sexual stimulation, the arteries leading to the penis dilate and increase blood flow into erectile tissues. At the same time, the erectile tissue compresses the veins of the penis, reducing blood flow away from the penis. Blood accumulates, causing the penis to swell and elongate and producing an erection. As in women, the culmination of sexual stimulation is an orgasm, a pleasurable feeling of physiologic and psychological release.

Orgasm is accompanied by emission (movement of sperm from the testes and fluids from the accessory glands) into the urethra, where the sperm and fluids are mixed to form semen. As the urethra fills with semen, the base of the erect penis contracts, this increases pressure. This pressure forces the semen through the urethra to the outside (ejaculation). During ejaculation, the ducts of the testes, epididymis, and vas deferens contract and cause expulsion of sperm into the urethra, where the sperm mixes with the seminal and prostatic fluids. These substances, together with mucus secreted by accessory glands, form the semen, which is discharged from the urethra.



KEY CONCEPTS

- The female reproductive system produces the female reproductive cells (the eggs, or ova) and contains an organ (uterus) where the fetus develops. The male reproductive system produces the male reproductive cells (the sperm) and contains an organ (penis) that deposits the sperm within the female.
- The internal female reproductive organs consist of the vagina, the uterus, the fallopian tubes, and the ovaries. The external female reproductive organs make up the vulva. These include the mons pubis, the labia majora and minora, the clitoris and prepuce, structures within the vestibule, and the perineum.
- The breasts are accessory organs of the female reproductive system that are specialized to secrete milk following pregnancy.
- The main function of the reproductive cycle is to stimulate growth of a follicle to release an egg and prepare a site for implantation if fertilization occurs.
- Menstruation, the monthly shedding of the uterine lining, marks the beginning and end of the cycle if fertilization does not occur.
- The ovarian cycle is the series of events associated with a developing oocyte (ovum or egg) within the ovaries.
- At ovulation, a mature follicle ruptures in response to a surge of luteinizing hormone (LH), releasing a mature oocyte (ovum).
- The endometrial cycle is divided into four phases: the follicular or proliferative phase, the luteal or secretory phase, the ischemic phase, and the menstrual phase.
- The menstrual cycle involves a complex interaction of hormones. The predominant hormones are gonadotropin-releasing hormone (GnRH), follicle-stimulating hormone (FSH), LH, estrogen, progesterone, and prostaglandins.
- The organs of the male reproductive system include the penis, scrotum, two

testes (where sperm cells and testosterone are made), and accessory organs (epididymis, vas deferens, seminal vesicles, ejaculatory ducts, urethra, bulbourethral glands, and prostate gland).

CHAPTER WORKSHEET

MULTIPLE-CHOICE QUESTIONS

1. The predominant anterior pituitary hormones that orchestrate the menstrual cycle include:
   a. Thyroid-stimulating hormone (TSH)
   b. Follicle-stimulating hormone (FSH)
   c. Corticotropin-releasing hormone (CRH)
   d. Gonadotropin-releasing hormone (GnRH)
2. Which glands are located on either side of the female urethra and secrete mucus to keep the opening moist and lubricated for urination?
   a. Cowper's
   b. Bartholin's
   c. Skene's
   d. Seminal
3. What event occurs during the proliferative phase of the menstrual cycle?
   a. Menstrual flow starts
   b. Endometrium thickens
   c. Ovulation occurs
   d. Progesterone secretion peaks
4. Which hormone is produced in high levels to prepare the endometrium for implantation just after ovulation by the corpus luteum?
   a. Estrogen
   b. Prostaglandins
   c. Prolactin
   d. Progesterone
5. Sperm maturation and storage in the male reproductive system occur in the:
   a. Testes
   b. Vas deferens
   c. Epididymis
   d. Seminal vesicles
6. The nurse is preparing to teach a class to a group of middle-aged women regarding the most common vasomotor symptoms experienced during menopause and possible modalities of treatment available. Common vasomotor symptoms would include which of the following?
   a. Chronic fatigue and confusion
   b. Forgetfulness and irritability
   c. Night sweats and hot flashes
   d. Decrease in sexual response and appetite

CRITICAL THINKING EXERCISE

1. The school nurse was asked to speak to a 10th-grade biology class about menstruation. The teacher felt that the students did not understand this monthly event and wanted to dispel some myths about it. After the nurse explains the factors influencing the menses, one girl asks, “Could someone get pregnant if she had sex during her period?”
   a. How should the nurse respond to this question?
   b. What factor regarding the menstrual cycle was not clarified?
   c. What additional topics might this question lead to that might be discussed?

STUDY ACTIVITIES

1. Should sex education be taught in public schools, and if so, what topics should be addressed? Debate the pros and cons of teaching this and then outline which topics should be covered.
2. Respond to the following as a topic sentence: “When I was growing up, talking about sexual matters with my parents was _____ because _____ Now the situation is _____?
3. List the predominant hormones and their function in the menstrual cycle.
4. The ovarian cycle describes the series of events associated with the development of the _____ within the ovaries.
5. Sperm cells and the male hormone testosterone are made in which of the following structures? Select all that apply.

   a. Vas deferens
   b. Penis
   c. Scrotum
   d. Ejaculatory ducts
   e. Prostate gland
   f. Testes
   g. Seminiferous tubules
   h. Bulbourethral glands

BRINGING IT ALL TOGETHER: A CASE STUDY

A 53-year-old woman came to see her women’s health nurse practitioner for her annual examination. She had a hysterectomy 20 years ago for a prolapsed uterus and has been healthy up until now. She had a long list of symptoms that had been bothering her, but until recently just chalked them up to the aging process. She told the nurse practitioner that she was experiencing insomnia, weight gain around her middle despite not consuming additional calories, painful intercourse and hot flashes that were increasing in frequency throughout the day and night. She had been taking black cohosh for these distressing symptoms for the past several months, but was not getting any relief. She was concerned that something awful was wrong with her since this natural herb was not reducing her symptoms and they seemed to be getting worse.

1. What explanation should be offered to this woman regarding what is causing her distress?

2. What is the current thinking regarding natural herbs in the treatment of menopausal symptoms?
3. What treatment might be suggested for this woman?
4. What is the current principle concerning hormone therapy in the treatment of menopause?

Common Reproductive Issues

WOW

Words of Wisdom

When women bare their souls to us, we must respond without judgment.

KEY TERMS

abnormal uterine bleeding (AUB)
abortion
amenorrhea
basal body temperature (BBT)
cervical cap
cervical mucus ovulation method
coitus interruptus
condoms
contraception
contraceptive sponge
Depo-Provera
diaphragm
dysmenorrhea
dyspareunia

emergency contraception (EC)
endometriosis
fertility awareness
implant
infertility
intrauterine contraceptive (IUC)
lactational amenorrhea method (LAM)
menopausal transition
oral contraceptives (OCs)
osteoporosis
premenstrual syndrome (PMS)
sexual abstinence
Standard Days Method (SDM)
sterilization
symptothermal method
transdermal patch
tubal ligation
vaginal ring
vasectomy

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Examine common reproductive concerns in terms of symptoms, diagnostic tests, and appropriate interventions.
2. Identify risk factors and outline appropriate client education needed in common reproductive disorders.
3. Compare and contrast the various contraceptive methods available and their overall effectiveness.
4. Analyze the physiologic and psychological aspects of menopausal transition.
5. Delineate the nursing management needed for women experiencing common reproductive disorders.

***Izzy*, a 27-year-old, presents to her health care provider complaining of progressive severe pelvic pain associated with her monthly periods. She has to take off work and "dope up" with pills to endure the pain. In addition, she has been trying to conceive for over a year without any luck.**

INTRODUCTION

Good health throughout the life cycle begins with the individual. Women today can expect to live well into their 80s and need to be proactive in maintaining their own quality of life. Women need to take steps to reduce their risk of disease and need to become active partners with their health care professional to identify problems

early, when treatment may be most successful (Teaching Guidelines 4.1). Nurses can assist women in maintaining their quality of life by helping them to become more attuned to their body and its clues and can use the assessment period as an opportunity for teaching and counseling. Nurses are in a prime position to offer information that provides women with the tools needed to maintain a healthy lifestyle and assist in altering behaviors that may cause harm or illness.

Teaching Guidelines 4.1

TIPS FOR BEING AN ACTIVE PARTNER IN MANAGING YOUR HEALTH

- Become an informed consumer. Read, ask, and search.
- Know your family history and know factors that put you at high risk.
- Maintain a healthy lifestyle and let moderation be your guide.
- Schedule regular medical checkups and screenings for early detection.
- Ask your health care provider for a full explanation of any treatment.
- Seek a second medical opinion if you feel you need more information.
- Know when to seek medical care by being aware of disease symptoms.

Common reproductive issues addressed in this chapter that nurses might encounter in caring for women include menstrual disorders, infertility, contraception, abortion, and the menopausal transition.

MENSTRUAL DISORDERS

Many women sail through their monthly menstrual cycles with little or no concern. With few symptoms to worry about, their menses are like clockwork, starting and stopping at nearly the same times every month. For others, the menstrual cycle causes physical and emotional symptoms that initiate visits to their health care provider for consultation. The following menstruation-related conditions will be discussed in this section: amenorrhea, dysmenorrhea, abnormal uterine bleeding (AUB), premenstrual syndrome (PMS), premenstrual dysphoric disorder (PMDD), and endometriosis. To gain an understanding of menstrual disorders, nurses should know the terms used to describe them (Box 4.1).

BOX 4.1

MENSTRUAL DISORDER VOCABULARY

- *meno* = menstrual related
- *metro* = time
- *oligo* = few
- *a* = without, none or lack of
- *rhagia* = excess or abnormal
- *dys* = not or pain
- *rhea* = flow

Amenorrhea

Amenorrhea simply means absence of menses. Amenorrhea is normal in prepubertal, pregnant, postpartum, and postmenopausal females. The uterus, endometrial lining, ovaries, pituitary, and hypothalamus must function properly and in harmony for a menstrual cycle to occur. The two categories of amenorrhea are primary and secondary amenorrhea. Primary amenorrhea is defined as either the:

1. Absence of menses by age 14, with absence of growth and development of secondary sexual characteristics, or
2. Absence of menses by age 16, with normal development of secondary sexual characteristics (Schuiling & Likis, 2016).

Ninety-eight percent of girls living in the United States menstruate by age 15 (Krieger, Kiang, Kosheleva, et al., 2015). Findings of recent studies indicate that age at menarche has overall declined since the 20th century (King, Brucker, Kriebs, et al., 2015). Once menarche has occurred, cycles may take up to 2 years to become regular, ovulatory cycles. Secondary amenorrhea is the absence of regular menses for three cycles or irregular menses for 6 months in women who have previously menstruated regularly.

Nurses need to consider the causes of amenorrhea as occurring in one of four anatomical areas: outflow area of the uterus and vagina; the ovaries, the pituitary gland, or the central nervous system. Outflow area problems are obstructive in nature and can be found on physical examination, whereas ovarian, pituitary, and central nervous system problems involve disruptions in the hypothalamic–pituitary–ovarian axis that controls the neuroendocrine processes required for a normal menstrual cycle and are generally found through laboratory analysis (King et al., 2015).

Etiology

Primary amenorrhea has multiple causes:

- Extreme weight gain or loss
- Congenital abnormalities of the reproductive system
- Stress from a major life event
- Excessive exercise
- Eating disorders (anorexia nervosa or bulimia)
- Cushing disease
- Polycystic ovary syndrome
- Hypothyroidism
- Turner syndrome—defective development of the gonads (ovary or testes)
- Imperforate hymen
- Chronic illness—diabetes, thyroid disease, depression
- Pregnancy
- Cystic fibrosis
- Congenital heart disease (cyanotic)
- Ovarian or adrenal tumors

Causes of secondary amenorrhea can include:

- Pregnancy

• Breast-feeding
• Emotional stress
• Pituitary, ovarian, or adrenal tumors
• Depression
• Hyperthyroid or hypothyroid conditions
• Malnutrition
• Hyperprolactinemia
• Rapid weight gain or loss
• Chemotherapy or radiation therapy to the pelvic area
• Vigorous exercise, such as long-distance running
• Kidney failure
• Colitis
• Chemotherapy, irradiation
• Use of tranquilizers or antidepressants
• Postpartum pituitary necrosis (Sheehan syndrome)
• Early menopause (Kovanci & Schutt, 2015).

Therapeutic Management

Therapeutic intervention depends on the cause of the amenorrhea. The treatment of primary amenorrhea involves the correction of any underlying disorders and estrogen replacement therapy to stimulate the development of secondary sexual characteristics (Moses, 2015a). If a pituitary tumor is the cause, it might be treated with drug therapy, surgical resection, or radiation therapy. Surgery might be needed to correct any structural abnormalities of the genital tract. Dopamine agonists are effective in treating hyperprolactinemia. In most cases, this treatment restores normal ovarian endocrine function and ovulation (Goswami, 2015). Therapeutic interventions for secondary amenorrhea can include:
• Cyclic progesterone, when the cause is anovulation, or **oral contraceptives** (OCs)
• Bromocriptine to treat hyperprolactinemia
• Nutritional counseling to address anorexia, bulimia, or obesity
• Gonadotropin-releasing hormone (GnRH), when the cause is hypothalamic failure
• Thyroid hormone replacement, when the cause is hypothyroidism (Creatsas & Creatsa, 2015).

Nursing Assessment

Nursing assessment for a young girl or a woman experiencing amenorrhea includes a thorough health history, physical examination, and several laboratory and diagnostic tests of selected hormone levels to help to identify an underlying cause.

HEALTH HISTORY AND PHYSICAL EXAMINATION

A thorough history and physical examination are needed to determine the etiology. The history should include questions about the women's menstrual history; past illnesses; hospitalizations and surgeries; obstetric history; use of prescription and over-the-counter drugs; recent or past lifestyle changes; and history of present illness, with an assessment of anybody changes.

The physical examination should begin with an overall assessment of the woman's nutritional status and general health. A sensitive and gentle approach to the pelvic examination is critical in young women. Height, weight, and body mass index (BMI)

should be taken, along with vital signs. Hypothermia, bradycardia, hypotension, and reduced subcutaneous fat may be observed in women with anorexia nervosa. Facial hair and acne might be evidence of androgen excess secondary to a tumor. The presence or absence of axillary and pubic hair may indicate adrenal and ovarian hyposecretion or delayed puberty. A general physical examination may uncover unexpected findings that are indirectly related to amenorrhea. For example, hepatosplenomegaly, which may suggest a chronic systemic disease or an enlarged thyroid gland, might point to a thyroid disorder as well as a reason for amenorrhea (Tharpe, Farley, & Jordan, et al., 2016). Examination of the breasts also deserves careful attention because breast development is a reliable indicator of estrogen production. The Tanner stages of breast development should be noted also. The Tanner stages include:

- Stage I—Papilla elevation only
- Stage II—Breast buds palpable and areolae enlarge ~11 years old
- Stage III—Elevation of breast contour; areolae enlarge ~12 years old
- Stage IV—Areolae forms secondary mound on the breast ~13 years old
- Stage V—Adult breast contour; areola recesses to breast contour (Moses, 2015b)

Information gained from the history and physical examination clearly can exclude certain diagnostic possibilities, but first impressions also can be deceiving and lead to errors in judgment. A methodical, systematic approach to identify the etiology of amenorrhea is best.

LABORATORY AND DIAGNOSTIC TESTS

Common laboratory tests that might be ordered to determine the cause of amenorrhea include:

- Karyotype (might be positive for Turner syndrome)
- Ultrasound to detect ovarian cysts
- Quantitative human chorionic gonadotropin (hCG) test to rule out pregnancy
- Thyroid function studies to determine thyroid disorder
- Prolactin level (an elevated level might indicate a pituitary tumor)
- Follicle-stimulating hormone (FSH) level (an elevated level might indicate ovarian failure)
- Luteinizing hormone (LH) level (an elevated level might indicate gonadal dysfunction)
- 17-ketosteroids (an elevated level might indicate an adrenal tumor) (Pagana, Pagana, & Pagana, 2015).

Nursing Management

Counseling and education are primary interventions and appropriate nursing roles. Address the diverse causes of amenorrhea, the relationship to sexual identity, possible infertility, and the possibility of a tumor or a life-threatening disease. Evidence is mounting that loss of menstrual regularity is a risk factor for later development of osteoporosis and hip fractures, so treatment to restore regular menstrual cycles is essential (Carlson, 2015). In addition, inform the woman about the purpose of each diagnostic test, how it is performed, and when the results will be available to discuss with her. Listening sensitively, interviewing, and presenting treatment options are paramount to gain the woman's cooperation and

understanding.

Nutritional counseling is also vital in managing this disorder, especially if the woman has findings suggestive of an eating disorder. The relation between eating disorders and menstrual dysfunction has been identified in research studies. Careful evaluation of menstrual status is warranted for all women with eating disorders. Timely intervention is important because shorter duration of illness is associated with improved outcomes (Golden, Katzman, Sawyer, et al., 2015). Although not all causes can be addressed by making lifestyle changes, emphasize maintaining a healthy lifestyle (Teaching Guidelines 4.2).

Teaching Guidelines 4.2

TIPS FOR MAINTAINING A HEALTHY LIFESTYLE

- Balance energy expenditure with energy intake to maintain ideal weight range.
- Modify your diet to maintain ideal weight to avoid becoming over weight.
- Avoid excessive use of alcohol and mood-altering or sedative drugs.
- Avoid cigarette smoking to prevent cardiovascular disease and lung cancer.
- Identify areas of emotional stress and seek assistance to resolve them.
- Balance work, recreation, and rest to reduce anxiety and stress in life.
- Maintain a positive outlook regarding the diagnosis and prognosis.
- Participate in ongoing care to monitor any medical conditions.
- Maintain bone density through:
  - Calcium intake (1,200 to 1,600 mg daily)
  - Vitamin D (600 to 1,000 International Units/daily)
  - Weight-bearing exercise (30 min or more daily)
  - Hormone therapy for low risk women

Adapted from Centers for Disease Control and Prevention [CDC] (2015a) *Healthy eating for a healthy weight.* Retrieved from http://www.cdc.gov/healthyweight/healthy_eating/; Housman, J., & Odum, M. (2016) *Alters & Schiff's essential concepts for healthy living* (7th ed.). Burlington, MA: Jones & Bartlett Learning.

Dysmenorrhea

Dysmenorrhea refers to painful menstruation and is a common problem in adolescence. This condition has also been termed *cyclic perimenstrual pain.* Usually pain starts along with the start of bleeding and lasts for 48 to 72 hours (Creatsas & Creatsa, 2015). The term *dysmenorrhea* is derived from the Greek words *dys,* meaning "difficult, painful, or abnormal," and *rrhea,* meaning "flow." Based on results of large epidemiological studies, it is estimated that it may affect more than half of menstruating women. It is the leading cause of absenteeism of work and school and has adverse effects on the quality of life of young women (Joshi, Kural, Agrawal, et al., 2015). Another recent research study linked early smoking (<13 years old) to an increased risk for developing chronic dysmenorrhea (Weinberger, Smith, Allen, et al., 2015). Uterine contractions occur during all periods, but in some women these cramps can be frequent and very intense. It has a major impact on women's quality of life, work productivity, and health care utilization.

Dysmenorrhea is classified as primary (spasmodic) or secondary (congestive) (Calis, Popat, Dang, et al., 2015).

Etiology

Primary dysmenorrhea refers to painful menstrual bleedings in the absence of any detectable underlying pathology. It is caused by increased prostaglandin production by the endometrium in an ovulatory cycle. This hormone causes contraction of the uterus, and levels tend to be higher in women with severe menstrual pain than women who experience mild or no menstrual pain. Dysmenorrhea is caused by an excess of prostaglandin production. These levels are highest during the first 2 days of menses, when symptoms peak (Maurice & Rosenzweig, 2015). This results in increased rhythmic uterine contractions from vasoconstriction of the small vessels of the uterine wall. This condition usually begins within a few years of the onset of ovulatory cycles at menarche.

Secondary dysmenorrhea is painful menstruation due to pelvic or uterine pathology. It may be caused by endometriosis, adenomyosis, fibroids, pelvic infection, an intrauterine system (IUS), cervical stenosis, or congenital uterine or vaginal abnormalities. Adenomyosis involves the ingrowth of the endometrium into the uterine musculature. Endometriosis involves ectopic implantation of endometrial tissue in other parts of the pelvis. It occurs most commonly in the third or fourth decades of life and affects 10% of women of reproductive age. The pain tends to get worse, rather than better, over time (American College of Obstetricians & Gynecologists [ACOG], 2015a). **Endometriosis** is the most common cause of secondary dysmenorrhea and is associated with pain beyond menstruation, dyspareunia, low back pain, heavy or irregular bleeding, bloating, nausea, and vomiting, and infertility (ACOG, 2015a). Treatment is directed toward removing the underlying pathology.

Think back to Izzy from the chapter opener. Is her pelvic pain complaint a common one with women?

Therapeutic Management

The goal of treatment is to provide adequate pain relief to allow the woman to perform her usual activities. Current treatment is mainly based on surgery and ovarian suppressive agents (OCs, progestins, GnRh antagonist, levonorgestrel-releasing intrauterine system [LNG-IUS], and androgenic agents). Hormonal treatments are often associated with unwanted side effects and recurrence of symptoms when stopped. Severe dysmenorrhea can be distressing, adversely affecting social and occupational activities. Treatments vary from over-the-counter remedies to hormonal control. However, for some women satisfactory pain relief is difficult to achieve and increasingly, they seek alternative options. Complementary therapies such as acupuncture (needles are used to stimulate certain points of the body to balance the flow of energy within the body) and acupressure (the use of fingers and hands to stimulate acupoints and maintains the balance of energy) are gaining popularity and the evidence base for their use is growing (Wicks & Mahady, 2015).

Therapeutic intervention is directed toward pain relief and building coping strategies that will promote a productive lifestyle. General measures for management include client education and reassurance. Treatment is supportive and should be guided by individual needs. Treatment measures usually include treating infections if present; suppressing the endometrium if endometriosis is suspected by administering low-dose OCs; administering prostaglandin inhibitors to reduce the pain; administering Depo-Provera to suppress ovulation, which thins the endometrial lining of the uterus with subsequent reduction of fluid contents of the uterus during menses; and initiating lifestyle changes (Schuiling & Likis, 2016). Table 4.1 lists selected treatment options for dysmenorrhea.

Nursing Assessment

As with any gynecologic complaint, a thorough focused history and physical examination are needed to make the diagnosis of primary or secondary dysmenorrhea. In primary dysmenorrhea, the history usually reveals the typical cramping pain with menstruation, and the physical examination is completely normal. In secondary dysmenorrhea, the history discloses cramping pain starting after 25 years old with a pelvic abnormality, a history of infertility, heavy menstrual flow, irregular cycles, and little response to nonsteroidal anti-inflammatory drugs (NSAIDs), OCs, or both (Elnashar, 2015).

HEALTH HISTORY AND CLINICAL MANIFESTATIONS

Note past medical history, including any chronic illnesses and family history of gynecologic concerns. Determine medication and substance use, such as prescription medications, contraceptives, anabolic steroids, tobacco, and marijuana, cocaine, or other illegal drugs. A detailed sexual history is essential to assess for inflammation and scarring (adhesions) secondary to pelvic inflammatory disease (PID). Women with a previous history of PID, sexually transmitted infections (STIs), low consumption of fruits and vegetables, depression, high stress level, multiple sexual partners, or unprotected sex are at increased risk (Tharpe et al., 2016).

During the initial interview, the nurse might ask some of the following questions to assess the woman's history of dysmenorrhea:

- At what age did your menstrual cycles start?
- Have your cycles always been painful, or did the pain start recently?
- When in your cycle do you experience the pain?
- How would you describe the pain you feel?
- Are you sexually active?
- What impact does your cycle have on your physical and social activities?
- When was the first day of your last menstrual cycle?
- Was the flow of your last menstrual cycle a normal amount for you?
- Do your cycles tend to be heavy or last longer than 5 days?
- Are your cycles generally regular and predictable?
- What have you done to relieve your discomfort? Is it effective?
- Has there been a progression of symptom severity?
- Do you have any other symptoms?

TABLE 4.1 TREATMENT OPTIONS FOR DYSMENORRHEA

Therapy Options	Dosage	Comments
Nonsteroidal anti-inflammatory drugs (NSAIDs)		NSAIDS prevent prostaglandin synthesis by inhibiting COX-1 and COX-2 conversion, reducing cramping
Ibuprofen (Advil, Motrin, Midol)	400–800 mg TID	Take with meals Do not take with aspirin
Naproxen (Anaprox, Naprelan, Naprosyn, Aleve)	250–500 mg TID	Avoid alcohol Watch for signs of GI bleeding Same as above
Hormonal contraceptives		Decrease prostaglandin synthesis; second-line treatment
Low-dose oral contraceptives	Taken daily—extended cycle formulas (84 days on, 7 days off)	Take active pills for an extended time to reduce number of monthly cycles
Depo-medroxyprogesterone (DMPA), Depo-Provera	150 mg IM every 12 wks	Within 9–12 mo of DMPA therapy, 75% of women will experience amenorrhea
Levonorgestrel-releasing IUS (Mirena)	Inserted into uterine cavity and may remain for up to 5 yrs	Inhibits ovulation and decreases thickness of endometrium Inhibits uterine contractions and reduces pain from menstrual cramps
Selective estrogen receptor modulators (SERMs)	Used for women not responding to NSAIDs and oral contraceptives; dosage is individualized	Adverse effects include hot flashes, nausea and vomiting, and risk of thromboembolism
Raloxifene hydrochloride (Evista); tamoxifen citrate (Nolvadex)		Research is needed to validate effectiveness, doses, side effects, and contradictions
Complementary therapies		
Thiamine (vitamin B)		
Vitamin E (tocopherols)		
Magnesium		Gives sense of control over life
Omega-3 fatty acids (fish oil)		
Lifestyle changes		
Daily exercise		
Limited salty foods		
Weight loss		
Smoking cessation		
Relaxation techniques		

Adapted from Calis, K. A., Popat, V., Dang, D. K., & Kalantaridou, S. N. (2015). Dysmenorrhea. *eMedicine*. Retrieved from http://emedicine.medscape.com/article/253812-overview; King, T. L., Brucker, M. C., Kriebs, J. M., Fahey, J. O., Gegor, C. L., & Varney, H. (2015) *Varney's midwifery* (5th ed.), Burlington, MA: Jones and Bartlett Learning; Schuiling, K. D. & Likis, F. E. (2016). *Women's gynecologic health*. (3rd ed.) Burlington, MA: Jones & Bartlett Learning.

Assess for clinical manifestations of dysmenorrhea. Affected women experience sharp, intermittent spasms of pain, usually in the suprapubic area. Pain may radiate to the back of the legs or the lower back. Pain usually develops within hours of the start of menstruation and peaks as the flow becomes heaviest during the first day or second day of the cycle (King et al., 2015). Systemic symptoms of nausea, vomiting, diarrhea, fatigue, fever, headache, or dizziness are fairly common. Explore the history for physical symptoms of bloating, water retention, weight gain, headache, muscle aches, abdominal pain, food cravings, or breast tenderness.

PHYSICAL EXAMINATION

The physical examination performed by the health care provider centers on the bimanual pelvic examination. This examination is done during the nonmenstrual phase of the cycle. Explain to the woman how it is to be performed, especially if it is her first pelvic examination. Prepare the woman in the examining room by offering her a cover gown to put on and covering her lap with a privacy sheet on the

examination table. Remain in the examining room throughout the examination to assist the health care provider with any procedures or specimens and to offer the woman reassurance.

LABORATORY AND DIAGNOSTIC TESTS

Common diagnostic tests that may be ordered to determine the cause of dysmenorrhea can include:

- Complete blood count to rule out anemia
- Urinalysis to rule out a bladder infection
- Pregnancy test (hCG level) to rule out pregnancy
- Cervical culture to exclude STI
- Erythrocyte sedimentation rate to detect an inflammatory process
- Stool guaiac test to exclude gastrointestinal bleeding or disorders
- Pelvic and/or vaginal ultrasound to detect pelvic masses or cysts
- Diagnostic laparoscopy and/or laparotomy to visualize pathology that may account for the symptoms (Tharpe et al., 2016).

What diagnostic tests might be ordered to diagnose Izzy's pelvic pain?

Nursing Management

Educating the client about the normal events of the menstrual cycle and the etiology of her pain is paramount in achieving a successful outcome. Explaining the normal menstrual cycle will teach the woman the correct terms to use so she can communicate her symptoms more accurately and will help dispel myths. Provide the woman with monthly graphs or charts to record menses, the onset of pain, the timing of medication, relief afforded, and coping strategies used. This involves the woman in her care and provides objective information so that therapy can be modified if necessary.

The nurse should explain in detail the dosing regimen and the side effects of the medication therapy selected. Commonly prescribed drugs include NSAIDs such as ibuprofen (Motrin, Advil) or naproxen (Naprosyn). These drugs alleviate dysmenorrhea symptoms by decreasing intrauterine pressure and inhibiting prostaglandin synthesis, thus reducing pain (Skidmore-Roth, 2015). The primary goal of NSAID therapy of dysmenorrhea is to preempt the production of prostaglandins; thus starting the medication prophylactically and using sufficient doses to maximally suppress prostaglandin production are essential. If pain relief is not achieved in two to four cycles, a low-dose combination OC may be initiated. Client teaching and counseling should include information about how to take pills, side effects, and danger signs to watch for.

Encourage the woman to apply a heating pad or warm compress to alleviate menstrual cramps. Additional lifestyle changes that the woman can make to restore some sense of control and active participation in her care are listed in Teaching Guidelines 4.3.

Teaching Guidelines 4.3

TIPS FOR MANAGING DYSMENORRHEA

- Exercise to increase endorphins and suppress prostaglandin release.
- Limit salty foods to prevent fluid retention.
- Increase water consumption to serve as a natural diuretic.
- Increase fiber intake with fruits and vegetables to prevent constipation.
- Use heating pads or warm baths to increase comfort.
- Take warm showers to promote relaxation.
- Sip on warm beverages, such as decaffeinated green tea.
- Keep legs elevated while lying down or lie on side with knees bent.
- Use stress management techniques to reduce emotional stress.
- Practice relaxation techniques to enhance ability to cope with pain.
- Stop smoking and decrease alcohol use which causes vasoconstriction

Abnormal Uterine Bleeding

Disturbances of menstrual bleeding manifest in a wide range of presentations. *Abnormal uterine bleeding* is the umbrella term used to describe any deviation from normal menstruation or from a normal menstrual cycle pattern. It can occur in women of any age. The key characteristics are regularity, frequency, volume or heaviness of flow, and duration of flow, but each of these may exhibit considerable variability.

Abnormal uterine bleeding (AUB) is a disorder that occurs most frequently in women at the beginning and end of their reproductive years. AUB is defined as painless endometrial bleeding that is prolonged, excessive, and irregular and not attributed to any underlying structural or systemic disease (Creatsas & Creatsa, 2015). It is frequently associated with anovulatory cycles, which are common for the first year after menarche and is associated with immaturity of the hypothalamic–pituitary–ovarian axis. It also occurs later in life as women approach menopause and experience irregular menstrual cycles.

The pathophysiology of AUB is related to a hormone disturbance. With anovulation, estrogen levels rise as usual in the early phase of the menstrual cycle. In the absence of ovulation, a corpus luteum never forms and progesterone is not produced. The endometrium moves into a hyperproliferative state, ultimately outgrowing its estrogen supply. This leads to irregular sloughing of the endometrium and excessive bleeding (King et al., 2015). If the bleeding is heavy enough and frequent enough, anemia can result. AUB is similar to several other types of uterine bleeding disorders and sometimes overlaps these conditions. They include:

- Menorrhagia (abnormally long, heavy periods, prolonged bleeding)
- Oligomenorrhea (bleeding occurs at intervals of more than 35 days)
- Metrorrhagia (bleeding between periods, irregular bleeding)

• Menometrorrhagia (excessive uterine bleeding at and between menstrual periods)
• Polymenorrhea (too frequent periods)

Etiology

The possible causes of AUB may include:
• Adenomyosis
• Pregnancy
• Hormonal imbalance
• Fibroid tumors (see Chapter 7)
• Endometrial polyps or cancer
• Endometriosis
• IUSs
• Polycystic ovary syndrome
• Morbid obesity
• Adnomyosis
• Steroid therapy
• Hypothyroidism
• Blood dyscrasias/clotting disorder
• Malignancy and hyperplasia
• Uterine polyps

Therapeutic Management

Treatment of AUB depends on the cause of the bleeding, the age of the client, and whether or not she desires future fertility. When known, the underlying cause of the disorder is treated. Otherwise, the goal of treatment is to normalize the bleeding, correct the anemia, prevent or diagnose early cancer, and restore quality of life (Schuiling & Likis, 2016).

Treatment options for AUB include combined OCs, progestogens, NSAIDs, tranexamic acid (antifibrinolytic), GnRH analogs, Danazol, and LNG-IUS (Bitzer, Heikinheimo, Nelson, et al., 2015).

Management of AUB might include medical care with pharmacotherapy or insertion of a hormone-secreting intrauterine system. OCs are used for cycle regulation as well as for contraception. They help prevent the risks associated with prolonged, unopposed estrogen stimulation of the endometrium. NSAIDs and progestin therapy (progesterone-releasing IUS [Mirena] or Depo-Provera) significantly decrease menstrual blood loss (Skidmore-Roth, 2015). The drug categories used in the treatment of AUB are:
• *Estrogens:* cause vasospasm of the uterine arteries to decrease bleeding
• *Progestins:* used to stabilize an estrogen-primed endometrium
• *OCs:* regulate the cycle and suppress the endometrium
• *NSAIDs:* inhibit prostaglandins in ovulatory menstrual cycles
• *Progesterone-releasing IUSs:* suppress endometrial growth
• *Androgens:* create a high-androgen/low-estrogen environment that inhibits endometrial growth
• *Antifibrinolytic drugs:* (tranexamic acid) prevent fibrin degradation to reduce bleeding
• *Iron replacement therapy:* replenish iron stores lost during heavy bleeding

If the client does not respond to medical therapy, surgical intervention might include dilation and curettage (D&C), endometrial ablation, uterine artery embolization, or hysterectomy. Surgery should be considered in women for whom medical treatment has failed, cannot be tolerated, or is contraindicated (Kho & Mathur, 2015). Endometrial ablation is an alternative to hysterectomy, but both would be for the woman no longer desiring fertility as both procedures can cause infertility. Techniques used for ablation include laser, electrosurgery excision procedure, freezing, heated fluid infusion, or thermal balloon ablation. Most women will have reduced menstrual flow following endometrial ablation, and up to half will stop having periods. Younger women are less likely than older women to respond to endometrial ablation. Recent scientific evidence supports that up to one quarter of clients treated with endometrial ablation require repeat ablation or subsequent hysterectomy to stop AUB. Hysterectomy should be considered a last resort for AUB (ACOG, 2015b).

Nursing Assessment

A thorough history should be taken to differentiate between AUB and other conditions that might cause vaginal bleeding, such as pregnancy and pregnancy-related conditions (abruptio placentae, ectopic pregnancy, abortion, or placenta previa); systemic conditions such as Cushing disease, blood dyscrasias, liver disease, renal disease, or thyroid disease; and genital tract pathology such as infections, tumors, or trauma (Schuiling & Likis, 2016).

Assess for clinical manifestations of AUB, which commonly include vaginal bleeding between periods, irregular menstrual cycles (usually less than 28 days between cycles), infertility, mood swings, hot flashes, vaginal tenderness, variable menstrual flow ranging from scanty to profuse, obesity, acne, stress, anorexia, thyroid disease, and diabetes. Signs of polycystic ovary syndrome might be present, because it is associated with unopposed estrogen stimulation, elevated androgen levels, and insulin resistance and is a common cause of anovulation (Tharpe et al., 2016).

Measure orthostatic blood pressure and orthostatic pulse; a drop in pressure or pulse rate may occur with anemia. The health care provider, with the nurse assisting, performs a pelvic examination to identify any structural abnormalities.

Common diagnostic/lab tests that may be ordered to determine the cause of AUB include:

- Complete blood count to detect anemia
- Prothrombin time to detect blood dyscrasias
- Pregnancy test to rule out a spontaneous abortion or ectopic pregnancy
- Thyroid-stimulating hormone level to screen for hypothyroidism
- Transvaginal ultrasound to measure endometrium
- Pelvic ultrasound to view any structural abnormalities
- Endometrial biopsy to check for intrauterine pathology
- D&C for diagnostic evaluation

Nursing Management

Educate the client about normal menstrual cycles and the possible reasons for her abnormal pattern. Inform the woman about treatment options. Do not simply encourage the woman to “live with it.” Instruct the client about any prescribed

medications and potential side effects. For example, if high-dose estrogens are prescribed, the woman may experience nausea. Teach her to take antiemetics as prescribed and encourage her to eat small, frequent meals to alleviate nausea. Adequate follow-up and evaluation are essential for women who do not respond to medical management. See Nursing Care Plan 4.1: Overview of a Woman with Abnormal Uterine Bleeding (at the end of chapter).

Concept Mastery Alert

Treatments for Premenstrual Syndrome

Possible treatment options for PMS include reduction of caffeine intake, vitamin and mineral supplements, diuretic therapy, and NSAIDs. Medication therapies that have been found to be helpful for clients with PMS are antidepressants and anxiolytics. Other medications that are used are diuretics and NSAIDs.

Take Note!

Complications such as infertility can result from lack of ovulation, severe anemia can result secondary to prolonged or heavy menses, depression and embarrassment may be secondary to the irregular and heavy bleeding, and endometrial cancer can occur associated with prolonged buildup of the endometrial lining without menstrual bleeding (Hoyt & Falconi, 2015).

Premenstrual Syndrome

Premenstrual syndrome (PMS) describes a constellation of recurrent symptoms that occur during the luteal phase or last half of the menstrual cycle and resolve with the onset of menstruation. A majority of women in their reproductive years experience a variety of premenstrual symptoms that can alter their behavior and well-being. Women have between 400 and 500 menstrual cycles over their reproductive years, and since premenstrual distress symptoms peak during 4 to 7 days prior to menses, consistently symptomatic women may spend up to 10 years of their lives in a state of compromised physical functioning and/or psychological well-being; thus it would constitute a major health problem for women (Tacani, Ribeiro, Barros Guimarães, et al., 2015). ACOG defines PMS as "the cyclic occurrence of symptoms that are sufficiently severe to interfere with some aspects of life, and that appear with consistent and predictable relationship to menses" (ACOG, 2015c). A woman experiencing PMS may have a wide variety of seemingly unrelated symptoms; for that reason, it is difficult to define and more challenging to diagnose. PMS affects millions of women during their reproductive years. Approximately 80% of women will experience cyclic fluctuations in mood, sleep, and sense of well-being, related to their menstrual cycles (King et al., 2015). The exact cause of PMS is not known. It is thought to be related to the interaction between hormonal events and neurotransmitter function, specifically serotonin. Not all women respond to serotonin reuptake inhibitors (SSRIs; Prozac, Paxil, Zoloft), however, which implies that other mechanisms may be involved (Skidmore-Roth, 2015).

As defined by the American Psychiatric Association, PMDD is a more severe variant of PMS affecting 5 to 8% of premenopausal women. Experts compare the difference between PMS and PMDD to the difference between a mild tension headache and a migraine. Risk factors identified that predispose to PMS/PMDD are

age between 25 and 35 years, a psychiatric history, a family history of PMDD, unhealthy living habits, and stressful life events (Santamaria & Lago, 2015). PMDD markedly interferes with work, school, social activities, and relationships with others.

Therapeutic Management

Treatment of PMS is often frustrating for both clients and health care providers. Clinical outcomes can be expected to improve as a result of recent consensus on the diagnostic criteria for PMS and PMDD, data from clinical trials, and the availability of evidence-based clinical guidelines.

The management of PMS or PMDD requires a multidimensional approach because these conditions are not likely to have a single cause, and they appear to affect multiple systems within a woman's body; therefore, they are not likely to be amenable to treatment with a single therapy (Naeimi, 2015). To reduce the negative impact of premenstrual disorders on a woman's life education, along with reassurance and anticipatory guidance, is needed for women to feel they have some control over their condition.

Take Note!

Because there are no diagnostic tests that can reliably determine the existence of PMS or PMDD, the woman herself must decide that she needs help during this time of the month. The woman must embrace multiple therapies and become an active participant in her treatment plan to find the best level of symptom relief.

Therapeutic interventions for PMS and PMDD address the symptoms because the exact cause of this condition is still unknown. Treatments may include vitamin supplements, diet changes, exercise, lifestyle changes, and medications (Box 4.2). Medications used in treating PMDD may include antidepressant and antianxiety drugs, diuretics, anti-inflammatory medications, analgesics, synthetic androgen agents, OCs, or GnRH agonists to regulate menses. Unlike the approach to the treatment of depression, antidepressants need not be given daily but can be effective when used cyclically, only in the luteal phase, or even limited to the duration of the monthly symptoms.

BOX 4.2

TREATMENT OPTIONS FOR PMS AND PMDD

- Lifestyle changes
  - Reduce stress.
  - Exercise three to five times each week.
  - Eat a balanced diet and increase water intake.
  - Decrease caffeine intake.
  - Stop smoking and limit the intake of alcohol.
  - Attend a PMS/women's support group.
- Vitamin and mineral supplements
  - Multivitamin daily
  - Vitamin E, 400 units daily

- Calcium, 1,200 to 1600 mg daily
- Magnesium, 200 to 400 mg daily

- Medications
  - NSAIDs taken a week prior to menses
  - Oral contraceptives (low dose)
  - Antidepressants (SSRIs)
  - Anxiolytics (taken during luteal phase)
  - Diuretics to remove excess fluid
  - Progestins
  - Gonadotropin-releasing hormone (GnRH) agonists
  - Danazol (androgen hormone inhibits estrogen production)

COMPLEMENTARY AND ALTERNATIVE THERAPIES

No single treatment is universally recognized as effective, and many clients often turn to therapeutic approaches outside of conventional medicine. Many women use dietary supplements and herbal remedies for their menstrual health and treating their bleeding disorders, although there has been little research to demonstrate their efficacy. Alternative treatments for treating PMDD include calcium supplementation, vitex agnus castus (chaste tree berry), hypericum perforatum (St John's wort), and cognitive/behavioral/relaxation therapies (Wicks & Mahady, 2015). Some other alternative therapies include the use of yoga, magnesium, vitamin B_6, evening primrose oil, vitex agnus castus, ginkgo biloba, viburnum, dandelion, stinging nettle, burdock, raspberry leaf, and skullcap (Tremellen & Pearce, 2015). Although research has not validated the efficacy of these alternative therapies, it is important for the nurse to be aware of the alternative products that many women choose to use.

Nursing Assessment

Although little consensus exists in the medical literature and among researchers about what constitutes PMS and PMDD, the physical and psychological symptoms are very real. The extent to which the symptoms debilitate or incapacitate a woman is highly variable.

More than 150 symptoms are assigned to PMS, but irritability, food cravings, mood swings, tearfulness, depression, sleep disturbances, headache, back pain, fatigue, bloating, edema of the face, abdominal area, and extremities, tension, and dysphoria (a profound state of unease and anxiety) are the most prominent and consistently described (Tacani et al., 2015). To establish the diagnosis of PMS, elicit a description of cyclic symptoms occurring before the woman's menstrual period. The woman should chart her symptoms daily for two cycles. These data will help demonstrate symptoms clustering around the luteal phase of ovulation, with resolution after bleeding starts. Ask the woman to bring her list of symptoms to the next appointment. Symptoms can be categorized using the following:

- **A**—*anxiety:* difficulty sleeping, tenseness, mood swings, and clumsiness
- **C**—*craving:* cravings for sweets, salty foods, chocolate
- **D**—*depression:* feelings of low self-esteem, anger, easily upset
- **H**—*hydration:* weight gain, abdominal bloating, breast tenderness
- **O**—*other:* hot flashes or cold sweats, nausea, change in bowel habits, aches or pains, dysmenorrhea, acne breakout (Naeimi, 2015).

The ACOG diagnostic criteria for PMS consist of having at least one of the following affective and somatic symptoms during the 5 days before menses in each of the three previous cycles:
- Affective symptoms: depression, angry outbursts, irritability, anxiety
- Somatic symptoms: breast tenderness, abdominal bloating, edema, headache
- Symptoms relieved from days 4 to 13 of the menstrual cycle (ACOG, 2015c).

In PMDD, the main symptoms are mood disorders such as depression, anxiety, tension, and persistent anger or irritability. Physical symptoms such as headache, joint and muscle pain, lack of energy, bloating, and breast tenderness are also present (Htay, 2015). It is estimated that up to 75% of reproductive-age women experience premenstrual symptoms that meet the ACOG criteria for PMS and up to 5% meet the diagnostic criteria for PMDD (Pearlstein, 2015).

According to the American Psychiatric Association, a woman must have at least five of the typical symptoms to be diagnosed with PMDD (Pearlstein, 2015). These must occur during the week before and a few days after the onset of menstruation and must include one or more of the first four symptoms:
- Affective lability: sadness, tearfulness, irritability
- Anxiety and tension
- Persistent or marked anger or irritability
- Depressed mood, feelings of hopelessness
- Difficulty concentrating
- Sleep difficulties
- Increased or decreased appetite
- Increased or decreased sexual desire
- Chronic fatigue
- Headache
- Constipation or diarrhea
- Breast swelling and tenderness (Htay, 2015).

Nursing Management

Educate the client about the management of PMS or PMDD. Advise her that lifestyle changes often result in significant symptom improvement without pharmacotherapy. Encourage women to eat a balanced diet that includes nutrient-rich foods to avoid hypoglycemia and associated mood swings. Encourage all women to participate in aerobic exercise three times a week to promote a sense of well-being, decrease fatigue, and reduce stress. Administer calcium (1,200 to 1,600 mg/day), magnesium (400 to 800 mg/day), and vitamin B_6 (50 to 100 mg/day) as prescribed. In some studies, these nutrients have been shown to decrease the intensity of PMS symptoms. NSAIDs may be useful for painful physical symptoms and spironolactone (Aldactone) may help with bloating and water retention. Herbs such as vitex agnus castus (chaste tree berry), evening primrose, and SAM-e (a dietary supplement used

to enhance mood) may be recommended; although not harmful, not all herbs have enough clinical or research evidence to document their safety or efficacy. Nutritional treatments include a diet low in salt, alcohol, caffeine, and sugar (Schuiling & Likis, 2016).

A recent research study proposes calcium (1,600 mg/day) and vitamin D (400 International Units/day) supplementation in adolescents and women in an effort to prevent PMS, but further research using a larger population needs to be conducted to validate this (Santamaria & Lago, 2015).

Explain to your client the relationship between cyclic estrogen fluctuation and changes in levels of serotonin levels, and how the different management strategies help maintain serotonin levels, thus improving symptoms. It is important to rule out other conditions that might cause erratic or dysphoric behavior. If the initial treatment regimen does not work, explain to the woman that she should return for further testing. Behavioral counseling and stress management might help women regain control during these stressful periods. Reassuring the woman that support and help are available through many community resources/support groups can be instrumental in her acceptance of this monthly disorder. Nurses can be a very calming force for many women experiencing PMS or PMDD. A holistic approach, including lifestyle modifications, pharmacotherapy, herbal therapies, and cognitive behavioral therapy, is most beneficial for symptom reduction, improvement in daily functioning, and quality of life. See Evidence-Based Practice 4.1.

EVIDENCE-BASED PRACTICE 4.1

THE EFFECT OF WHEAT GERM EXTRACT ON PREMENSTRUAL SYNDROME SYMPTOMS

STUDY

Premenstrual syndrome is one of the most common disorders in women and impairs work and social relationships. Several treatment modalities have been proposed including herbal medicines. Herbal medicines are among the most common treatments because they are economical, safe, noninvasive, and have fewer side effects than do traditional medicines. Wheat germ contains magnesium, zinc, calcium, selenium, potassium, phosphorus, chromium, and vitamins A, E, C, B12, B6, Niacin, folic acid. Considering the properties of wheat germ, this study aimed to determine the effects of wheat germ extract on the symptoms of premenstrual syndrome.

Findings

This triple blind clinical trial was conducted on 84 women that completed daily records regarding their symptoms for two consecutive months while taking 400 mg capsules of wheat germ extract or placebo three times a day from day 16 until day 5 of the next menstrual cycle. The study found that wheat germ significantly reduced the severity of physical symptoms (64%), psychological symptoms (66%), and general symptoms (65%) when compared to the placebo group within the first month of treatment. No complications were observed in either group.

Nursing Implications

Based on the study results, it seems that using wheat germ extract reduces the severity of general, psychological, and physical symptoms of premenstrual syndrome in women

that take it during their midcycle. Given the positive effects of taking B6 and E, calcium, and magnesium in previous studies to reduce the symptoms of PMS, it makes sense that wheat germ which contains all of the compounds listed would help relieve PMS symptoms. Nurses can suggest using nontraditional modalities to women that request them and cite this study's results to validate them.

Adapted from Ataollahi, M., Akbari, S. A., Mojab, F., & Alavi Majd, H. (2015). The effect of wheat germ extract on premenstrual syndrome symptoms. *Iranian Journal of Pharmaceutical Research: IJPR*, *14*(1), 159–166.

Take Note!

Adolescents and women who experience more extensive emotional symptoms with PMS should be evaluated for PMDD, because they may require antidepressant therapy.

Endometriosis

Endometriosis is one of the most common gynecologic diseases, affecting more than 6 million women in the United States, about 10% of the adult women population (Kapoor, Alderman, Hiraoka, et al., 2015). In this condition, for unknown reasons bits of functioning endometrial tissue are located outside of their normal site, the uterine cavity. This endometrial tissue is commonly found attached to the ovaries, fallopian tubes, the outer surface of the uterus, the bowels, the area between the vagina and the rectum (rectovaginal septum), and the pelvic side wall (Fig. 4.1). The places where the tissue attaches are called implants, or lesions. Endometrial tissue found outside the uterus responds to hormones released during the menstrual cycle in the same way as endometrial lining within the uterus.

At the beginning of the menstrual cycle, when the lining of the uterus is shed and menstrual bleeding begins, these abnormally located implants swell and bleed also. In short, the woman with endometriosis experiences several "mini-periods" throughout her abdomen, wherever this endometrial tissue exists. In addition to cyclic bleeding outside the uterus, scarring and adhesion formation throughout the pelvis occur. Symptoms begin as early as adolescence and typically settle after menopause.

Think back to Izzy, with her progressive pelvic pain and infertility concerns. After a pelvic examination, her health care provider suspects she has endometriosis.

Etiology and Risk Factors

It is not currently known why endometrial tissue becomes transplanted and grows in other parts of the body. Several theories exist, but to date none has been scientifically proven. However, several factors that increase a woman's risk of developing endometriosis have been identified:

- The aging process
- Family history of endometriosis in a first-degree relative
- Short menstrual cycle (less than 28 days)
- Long menstrual flow (more than 1 week)
- High dietary fat consumption

• Young age of menarche (younger than 12)
• Few (one or two) or no pregnancies (Johnston, Reid, & Hunter, 2015).

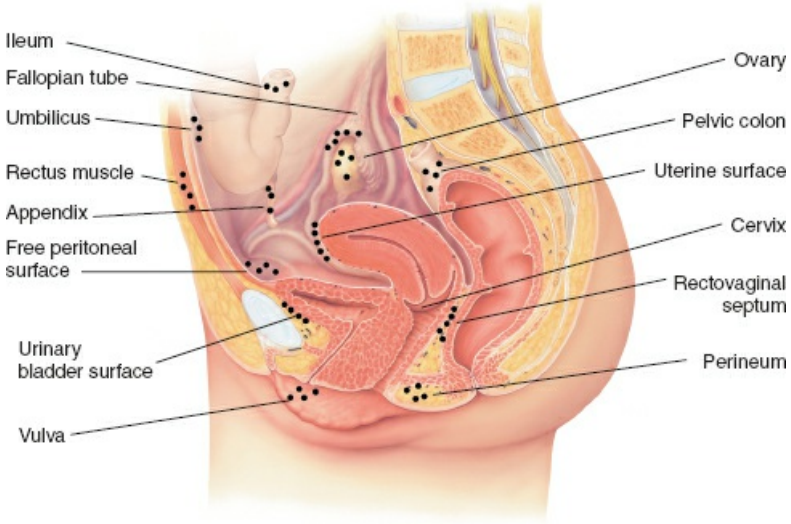

FIGURE 4.1 Common sites of endometriosis formation. (Asset provided by Anatomical Chart Co.)

Therapeutic Management

Therapeutic management of the client with endometriosis needs to take into consideration the following factors: severity of symptoms, desire for fertility, degree of disease, and the client's therapy goals. The aim of therapy is to suppress levels of estrogen and progesterone, which cause the endometrium to grow. Current treatment of endometriosis is mainly based on surgery and ovarian suppressive agents (OCs, progestins, GnRh agonists, and androgenic agents). Approximately only half of women with endometriosis experience pain relief from existing medial or surgical treatments (NICHD, 2015). Treatment can include surgical removal of ectopic endometrial tissue or medications such as NSAIDs, OCs, Depo-Provera, synthetic testosterone, GnRH agonists. Also, alternative therapies may be used, including acupuncture and supplements of vitamins, minerals, and fish oil (Elnashar, 2015). These interventions may control symptoms initially, but many have significant adverse effects and limits on duration of therapy (Table 4.2).

Nursing Assessment

Nurses encounter women with endometriosis in a variety of settings: community health settings, schools, clinics, day surgical centers, and hospitals. Health care professionals must not trivialize or dismiss the concerns of these women, because early recognition is essential to preserve fertility. The diversity of presenting symptoms and a low index of suspicion contribute to women with endometriosis falling through the cracks and not being diagnosed promptly.

HEALTH HISTORY

Obtain a health history and elicit a description of signs and symptoms to determine risk factors. Endometriosis is often asymptomatic, but it can be a severe and debilitating condition. It typically is chronic and progressive. Ask specifically about menarche, history of menstrual problems, details of pregnancies, and difficulties with conception. Assess the client for clinical manifestations, which include:

• Infertility
• Back pain
• Pain before and during menstrual periods
• Pain during or after sexual intercourse
• Painful urination
• Depression
• Fatigue
• Painful bowel movements
• Chronic pelvic pain
• Hypermenorrhea (heavy menses)
• Pelvic adhesions
• Irregular and more frequent menses
• Premenstrual vaginal spotting (Schuiling & Likis, 2016)

The two most common symptoms are infertility and pelvic pain. Endometriosis occurs in 38% of infertile women and in 71% to 87% of women with chronic pelvic pain (Kapoor et al., 2015). About 30% to 40% of women with this condition are infertile, making it one of the top three causes of female infertility (Brown & Farquhar, 2015).

TABLE 4.2 TREATMENT OPTIONS FOR ENDOMETRIOSIS

Therapy Options	Comment
Surgical intervention	
Conservative surgery	Removal of implants/lesions using laser, cautery, or small surgical instruments. This intervention will reduce pain and allows pregnancy to occur in the future
Definitive surgery	Abdominal hysterectomy, with or without bilateral salpingo-oophorectomy. Will eliminate pain but will leave a woman unable to become pregnant in the future
Medication therapy	
NSAIDs	First-line treatment to reduce pain; taken early when premenstrual symptoms are first felt
Oral contraceptives	Suppresses cyclic hormonal response of the endometrial tissue
Progestogens	Used to cast off the endometrial cells and thus destroy them
Antiestrogens	Suppresses a woman's production of estrogen, thus stopping the menstrual cycle and preventing further growth of endometrium
Gonadotropin-releasing hormone analogs (GnRH-a)	Suppresses endometriosis by creating a temporary pseudomenopause

(2015) *Varney's midwifery* (5th ed.), Burlington, MA: Jones and Bartlett Learning.

What are the two most common symptoms experienced by women with endometriosis? Is Izzy's profile typical? As a nurse, what would be your role in Izzy's continued workup?

PHYSICAL EXAMINATION AND LABORATORY AND DIAGNOSTIC TESTS

The pelvic examination typically correlates with the extent of the endometriosis.

The usual finding is nonspecific pelvic tenderness. The hallmark finding is the presence of tender nodular masses on the uterosacral ligaments, the posterior uterus, or the posterior cul-de-sac. The only definitive diagnosis is one made during surgery (Signorile & Baldi, 2015).

After a thorough history and a pelvic examination, the health care provider may suspect endometriosis, but the only certain method of diagnosing it is by seeing it. Pelvic or transvaginal ultrasound is used to assess pelvic organ structures. However, a laparoscopy is needed to diagnose endometriosis. Laparoscopy is the direct visualization of the internal organs with a lighted instrument inserted through an abdominal incision. A tissue biopsy of the suspected implant taken at the same time and examined microscopically confirms the diagnosis.

Nurses can play a role by offering a thorough explanation of the condition and explaining why tests are needed to diagnose endometriosis. The nurse can set up appointments for imaging studies and laparoscopy.

Nursing Management

In addition to the interventions outlined above, the nurse should encourage the client to adopt healthy lifestyle habits with respect to diet, exercise, sleep, and stress management. Referrals to support groups and Internet resources can help the woman to understand this condition and to cope with chronic pain. A number of organizations provide information about the diagnosis and treatment of endometriosis and offer support to women and their families. Nurses are uniquely situated to improve client outcomes by assisting women to make informed treatment decisions. A prompt diagnosis ensures appropriate care (Box 4.3).

INFERTILITY

Infertility is defined as the inability to conceive a child after 1 year of regular sexual intercourse unprotected by contraception (RESOLVE, 2015). Secondary infertility is the inability to conceive after a previous pregnancy. Many people take the ability to conceive and produce a child for granted, but infertility affects more than 6 million Americans, or up to 20% of the reproductive-age population and as many 186 million people worldwide, according to the American Society for Reproductive Medicine (ASRM, 2015). Infertility is a widespread problem that has an emotional, social, and economic impact on couples. Although male infertility contributes to more than half of all causes, infertility remains a woman's social burden. It affects relationships, leads to tension and anger between partners, and can result in severe sexual dysfunction and breakdown of the relationship. Nurses must recognize infertility and understand its causes and treatment options so that they can help couples understand the possibilities as well as the limitations of current therapies. Nurses have a central role in supporting couples through these stressful treatments. Couples will frequently confide in their nurse and can gain great benefit from a sympathetic and sensible discussion. Recent studies have found that women wish to be treated with respect and dignity and given appropriate information and support. Infertility was once considered a disorder of inconvenience, but it is now classified as a disease in the United States regulatory Americans with Disabilities Act (Turchi, 2015). Women want their distress recognized and they want to feel cared for and to have confidence in health care

providers in situations where outcomes are uncertain. The caring aspect of professional nursing is an essential component of meeting the special needs of these couples (Whitman, 2015). Prevention of infertility through education should also be incorporated into any client–nurse interaction.

  e-mail: NICHDClearinghouse@mail.nih.gov
- National Women's Health Information Center (U.S. Department of Health and Human Services)
  http://www.4women.gov

After completing several diagnostic tests, Izzy is diagnosed with endometriosis. She asks you about her chances of becoming pregnant and becoming pain-free. What treatment options would you explain to Izzy? What information can you give about her future childbearing ability?

Cultural Considerations

Infertility is not only a physiologic problem, but is one that can initiate a life crisis that is experienced with psychologic, familial, social, and cultural consequences. Cross-culturally, the expectation for couples to reproduce is an accepted norm and the inability to conceive may be considered a violation of this cultural norm. In this context, infertility represents a crisis for the couple. The manner in which different cultures, ethnic groups, and religious groups perceive and manage infertility may be very different. For example, many African Americans believe that assisted reproductive techniques are unnatural and that they remove the spiritual or divine

nature of creation from conception. For this reason, they may seek spiritual rather than medical assistance when trying to conceive. The Hispanic culture believes that children validate the marriage, so families are typically large. Like the African-American culture, Hispanics are very spiritual and may consider infertility a test of faith and seek spiritual counseling. Disappointing one's spouse is of greater concern to African-American women, whereas avoiding the stigmatization of infertility is of greatest concern to Asian-American women (Inhorn & Patrizio, 2015).

Religion often influences cultural factors and for this reason may also be considered when pursuing treatment for infertility. In the Orthodox Jewish religion procreation is considered to be a "mitzvah," a commandment to have children. However, even Orthodox Jews accept the use of contraceptives to prevent conception when it is not desired. Conservative and Reform Jews put no restrictions on contraception (McFarland & Wehbe-Alamah, 2015). Roman Catholics have a very restrictive view on the use of assisted reproductive technologies since in their view procreation cannot be separated from the relationship between parents. Thus, God wants human life to begin through the "conjugal act" and not artificially. Most religious teachings speak to the significance of procreation, thus infertility can impact the self and relational identities of the couple wishing to become parents. Therefore, the risk is present for both a crisis of identity and of faith (Dombo & Flood, 2015). Nurses must be cognizant of the client's cultural and religious background and how it may dictate which, if any, reproductive treatment options are chosen. Nurses need to include this awareness in their counseling of infertile couples.

Etiology and Risk Factors

Reproduction requires the interaction of the female and the male reproductive tracts, which involves (1) the release of a normal preovulatory oocyte, (2) the production of adequate spermatozoa, (3) the normal transport of the gametes to the ampullary portion of the fallopian tube (where fertilization takes place), and (4) the subsequent transport of the cleaving embryo into the endometrial cavity for implantation and development (Puscheck & Woodward, 2015).

Consider This

We had been married for 3 years and wanted to start a family, but much to our dismay nothing happened after a year of trying. I had some irregular periods and was finally diagnosed with endometriosis and put on Clomid for three cycles. After that time without achieving a pregnancy, I went to a fertility expert. The doctor lasered the misplaced endometriosis tissue, sent carbon dioxide through my tubes to make sure they were patent, and put me back on Clomid, but still with no luck. Finally, 2 years later, we were put on an in vitro fertilization (IVF) waiting list and prayed we would have the money for the procedure when we were chosen. By then I felt a failure as a woman. We then decided that it was more important for us to be parents than it was for me to be pregnant, so we considered adoption. We tried for another year without any results.

We went to the adoption agency to fill out the paperwork for the process to begin. Our blood was taken and we waited for an hour, wondering the whole time why it was taking so long for the results. The nurse finally appeared and handed a piece of paper to me with the word "positive" written on it. I started to cry tears of joy, for a pregnancy had started and our long journey of infertility was finally ending.

Thoughts: For many women the dream of having a child is not easily realized. Infertility can affect self-esteem, disrupt relationships, and result in depression. This couple experienced many years of frustration in trying to have a family. What help can be offered to couples during this time? What can be said to comfort the woman who feels she is a failure?

Multiple known and unknown factors affect fertility. Female-factor infertility is detected in about 40% of cases, male-factor infertility in about 40% of cases. The remaining 20% fall into a category of combined (both male and female factors) or unexplained infertility. In women, ovarian dysfunction (40%) and tubal/pelvic pathology (40%) are the primary contributing factors to infertility (ASRM, 2015).

Risk factors for infertility in women include:

- Overweight or underweight (can disrupt hormone function)
- Hormonal imbalances leading to irregular ovulation
- Uterine fibroids
- Tubal blockages
- Cervical stenosis
- Reduced oocyte quality
- Chromosomal abnormalities
- Congenital anomalies of the uterus
- Immune system disorders
- Chronic illnesses such as diabetes, thyroid disease, asthma
- STIs
- Ectopic pregnancy
- Age older than 27
- Endometriosis
- Turner syndrome
- Eating disorders
- History of PID
- Smoking and alcohol consumption
- Multiple miscarriages
- Menstrual abnormalities
- Exposure to chemotherapeutic agents
- Psychological stress (Senie, 2014)

Risk factors for infertility in men include:

- Exposure to toxic substances (lead, mercury, x-rays, chemotherapy)
- Cigarette or marijuana smoke
- Heavy alcohol consumption
- Use of prescription drugs for ulcers or psoriasis
- Exposure of the genitals to high temperatures (hot tubs or saunas)
- Hernia repair
- Obesity is associated with decreased sperm quality
- Cushing syndrome
- Frequent long-distance cycling or running
- STIs
- Undescended testicles (cryptorchidism)
- Mumps after puberty (Puscheck & Woodward, 2015)

Therapeutic Management

As noted earlier, the main causes of infertility are female factor (anovulation, tubal damage, endometriosis, and ovarian failure), male factor (low or absent numbers of motile sperm in the ejaculate, and erectile dysfunction), or unexplained infertility (Jin, 2015). The test results are presented to the couple and different treatment options are suggested. The majority of infertility cases are treated with drugs or surgery. Treatment options include lifestyle changes, such as weight loss, and smoking cessation; taking clomiphene to promote ovulation; hormone injections to promote ovulation; intrauterine insemination; and IVF. Various ovulation-enhancement drugs and timed intercourse might be used for the woman with ovulation problems. The woman should understand a drug's benefits and side effects before consenting to take it. Depending on the type of drug used and the dosage, some women may experience multiple births. If the woman's reproductive organs are damaged, surgery can be done to repair them. Still other couples might opt for the hi-tech approaches of artificial insemination (Fig. 4.2), IVF (Fig. 4.3), and egg donation or they may contract for a gestational carrier or surrogate (Jin, 2015). Table 4.3 lists selected treatment options for infertility.

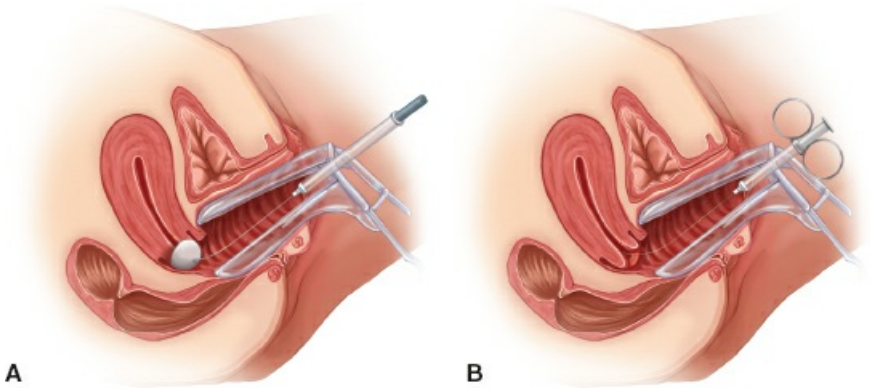

FIGURE 4.2 Artificial insemination. Sperm are deposited next to the cervix (A) or injected directly into the uterine cavity (B).

Nursing Assessment

Infertile couples are under tremendous pressure and often keep the problem a secret, considering it to be very personal. Couples are often beset by feelings of inadequacy and guilt, and many are subject to pressures from both family and friends. As the problem becomes more chronic, they may begin to blame one another, with consequent marital discord. Seeking help is often a very difficult step for them, and it may take a lot of courage to discuss something about which they feel deeply embarrassed or upset. The nurse working in this specialty setting must be aware of the conflict and problems couples present with and must be very sensitive to their needs.

A full medical history should be taken from both partners, along with a physical examination. The data needed for the infertility evaluation are very sensitive and of a personal nature, so the nurse must use very professional interviewing skills.

Infertility has numerous causes and contributing factors, so it is important to use the process of elimination, determining what problems do not exist to better comprehend the problems that do exist. At the first visit, a plan of investigation is

outlined and a complete health history is taken. This first visit forces many couples to confront the reality that their desired pregnancy may not occur naturally. Alleviate some of the anxiety associated with diagnostic testing by explaining the timing and reasons for each test.

Assessing Male Factors

The initial screening evaluation for the male partner should include a reproductive history and a semen analysis. From the male perspective, three things must happen for conception to take place: the number of sperm must be adequate; those sperm must be healthy and mature; and the sperm must be able to penetrate and fertilize the egg. Normal males have more than 20 million sperm per milliliter with greater than 50% motility (World Health Organization [WHO], 2015). Semen analysis is the most important indicator of male fertility. The man should abstain from sexual activity for 24 to 48 hours before giving the sample. For a semen examination, the man is asked to produce a specimen by ejaculating into a specimen container and delivering it to the laboratory for analysis within 1 to 2 hours. When the specimen is brought to the laboratory, it is analyzed for volume, viscosity, number of sperm, sperm viability, motility, and sperm shape. If semen parameters are normal, no further male evaluation is necessary (Puscheck & Woodward, 2015).

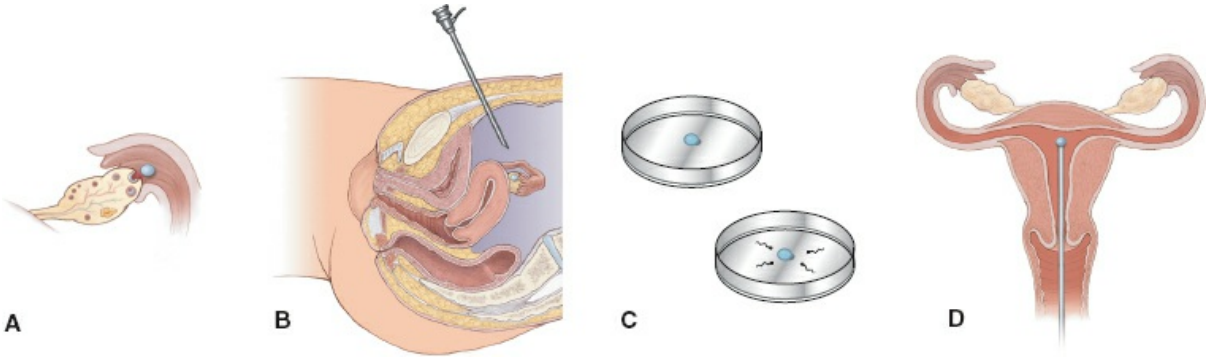

FIGURE 4.3 Steps involved in in vitro fertilization. A. Ovulation. B. Capture of the ova (done here intra-abdominally). C. Fertilization of ova and growth in culture medium. D. Insertion of fertilized ova into uterus.

TABLE 4.3 SELECTED TREATMENT OPTIONS FOR INFERTILITY

Procedure	Comments	Nursing Considerations
Fertility drugs		
Clomiphene citrate (Clomid)	A nonsteroidal synthetic antiestrogen used to induce ovulation. Clomid is typically discontinued after three cycles of use	Nurse can advise the couple to have intercourse every other day for 1 wk starting after day 5 of medication
Human menopausal gonadotropin (HMG); Pergonal	Induces ovulation by direct stimulation of ovarian follicle	Same as above
Artificial insemination	The insertion of a prepared semen sample into the cervical os or intrauterine cavity Enables sperm to be deposited closer to improve chances of conception. Husband or donor sperm can be used	Nurse needs to advise couple that the procedure might need to be repeated if not successful the first time
Assisted reproductive technologies[a]		
In vitro fertilization (IVF)	Oocytes are fertilized in the lab and transferred to the uterus Usually indicated for tubal obstruction, endometriosis, pelvic adhesions, and low sperm counts	Nurse advises woman to take medication to stimulate ovulation so the mature ovum can be retrieved by needle aspiration
Gamete intrafallopian transfer (GIFT)	Oocytes and sperm are combined and immediately placed in the fallopian tube so fertilization can occur naturally Requires laparoscopy and general anesthesia, which increases risk	Nurse needs to inform couple of risks and have consent signed
Intracytoplasmic sperm injection (ICSI)	One sperm is injected into the cytoplasm of the oocyte to fertilize it. Indicated for male factor infertility	Nurse needs to inform the male that sperm will be aspirated by a needle through the skin into the epididymis
Donor oocytes or sperm	Eggs or sperm are retrieved from a donor and the eggs are inseminated; resulting embryos are transferred via IVF Recommended for women older than 40 yrs and those with poor-quality eggs	Nurse needs to support couple in their ethical/religious discussions prior to deciding
Preimplantation genetic diagnosis (PGD)	Used to identify genetic defects in embryos created through IVF before pregnancy. This is done specifically when one or both genetic parents have a known genetic abnormality and testing is performed on an embryo to see if it also carries a genetic abnormality	Nurse should inform couple about this option and support them until test results return
Gestational carrier (surrogacy)	Laboratory fertilization takes place and embryos are transferred to the uterus of another woman, who will carry the pregnancy. Or intrauterine insemination can be done with the male sperm Medical–legal issues have resulted over the "true ownership" of the resulting infant	Nurse should encourage an open discussion regarding implications of this method with the couple

[a]When other options have been exhausted, these are considered.
Adapted from American Society for Reproductive Medicine [ASRM]. (2015). Frequently asked questions about infertility. Retrieved from http://www.asrm.org/detail.aspx?id=2322; Jin, J. (2015). Treatments for infertility. *JAMA, 313*(3), 320–320; Puscheck, E. E., & Woodward, T. L. (2015). Infertility. *eMedicine.* Retrieved from http://emedicine.medscape.com/article/274143-overview

A recent study shows that social strain and stress are highest among couples without a clear etiology for their infertility. These findings highlight the clinically significant negative sexual, personal, and social strains of a perceived infertility diagnosis for men (Cavallini, 2015). Nurses need to be very cognizant of this impact on males and address it.

The physical examination routinely includes:

- Assessment for appropriate male sexual characteristics, such as body hair distribution, development of the Adam's apple, and muscle development
- Examination of the penis, scrotum, testicles, epididymis, and vas deferens for

abnormalities (e.g., nodules, irregularities, varicocele)
- Assessment for normal development of external genitalia (small testicles)
- Performance of a digital internal examination of the prostate to check for tenderness or swelling (Dohle, 2015)

Assessing Female Factors

The initial assessment of the woman should include a thorough history of factors associated with ovulation and the pelvic organs. Diagnostic tests to determine female infertility may include:
- Assessment of ovarian function
- Ovulation predictor kits used midcycle
- Urinary LH level
- Clomiphene citrate challenge test
- Assessment of pelvic organs
- Papanicolaou (Pap) smear to rule out cervical cancer or inflammation
- Cervical culture to rule out any STIs
- Ultrasound to assess pelvic structures
- Hysterosalpingography to visualize structural defects
- Laparoscopy to visualize pelvic structures and diagnose endometriosis (Dadhich, Ramasamy, & Lipshultz, 2015)

Laboratory and Diagnostic Testing

The diagnostic procedures that should be done during an infertility workup should be guided by the couple's history. They generally proceed from less to more invasive tests.

HOME OVULATION PREDICTOR KITS

Home ovulation predictor kits contain monoclonal antibodies specific for LH and use the ELISA test to determine the amount of LH present in the urine. A significant color change from baseline indicates the LH surge and presumably the most fertile day of the month for the woman.

CLOMIPHENE CITRATE CHALLENGE TEST

The clomiphene citrate challenge test is used to assess a woman's ovarian reserve (ability of her eggs to become fertilized). FSH levels are drawn on cycle day 3 and on cycle day 10 after the woman has taken 100 mg clomiphene citrate on cycle days 5 through 9. If the FSH level is greater than 15, the result is considered abnormal and the likelihood of conception with her own eggs is very low (Schuiling & Likis, 2016).

HYSTEROSALPINGOGRAPHY

Hysterosalpingography is the gold standard in assessing patency (being open and unobstructed) of the fallopian tubes. Fallopian tube obstruction is among the most common causes of female factor infertility. Ultrasonography and magnetic resonance imaging (MRI) are used in this assessment. In hysterosalpingography, 3 to 10 mL of an opaque contrast medium is slowly injected through a catheter into the endocervical canal so that the uterus and tubes can be visualized during fluoroscopy and radiography. If the fallopian tubes are patent, the dye will ascend upward to

distend the uterus and the tubes and will spill out into the peritoneal cavity (Hemingway & Trew, 2015) (Fig. 4.4).

LAPAROSCOPY

A laparoscopy is usually performed early in the menstrual cycle. It is not part of the routine infertility evaluation. It is used when abnormalities are found on the ultrasound or the hysterosalpingogram. Because of the added risks of surgery, the need for anesthesia, and operative costs, it is only used when clearly indicated. During the procedure, an endoscope is inserted through a small incision in the anterior abdominal wall. Visualization of the peritoneal cavity in an infertile woman may reveal endometriosis, pelvic adhesions, tubal occlusion, fibroids, or polycystic ovaries (Kodaman, 2015).

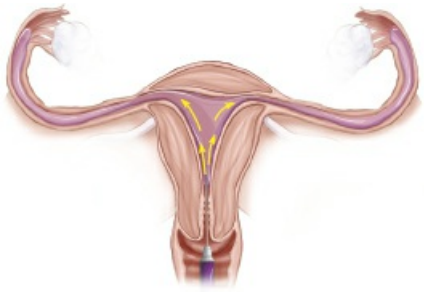

FIGURE 4.4 Insertion of a dye for a hysterosalpingogram. The contrast dye outlines the uterus and fallopian tubes on an x-ray to demonstrate patency.

Nursing Management

Nurses play an important role in the care of infertile couples. They are pivotal educators about preventive health care. A number of potentially modifiable risk factors are associated with the development of impaired fertility in women, and women need to be aware of these risks to institute change. The nurse is most effective when he or she offers care and treatment in a professional manner and regards the couple as valued and respected individuals. The nurse must be respectful of and mindful that many women may seek spiritual help for their infertility issues in addition to traditional medical modalities (King et al., 2015). The nurse's focus must encompass the whole person, not just the results of the various infertility studies. Throughout the entire process, the nurse's role is to provide information, anticipatory guidance, stress management, and counseling. The couple's emotional distress is usually very high, and the nurse must be able to recognize that anxiety and provide emotional support. The nurse may need to refer couples to a reproductive endocrinologist or surgeon, depending on the problem identified.

There is no absolute way to prevent infertility per se because so many factors are involved in conception. Nurses can be instrumental in educating men and women about the factors that contribute to infertility. The nurse can also outline the risks and benefits of treatments so that the couple can make an informed decision. As couples struggle with infertility, they frequently turn to nurses for empathy, counseling, and support. By understanding the struggles and lived experiences of women and couples experiencing infertility, the nurse can tailor his/her approach to better meet their needs so that the pregnancy and birth experience of these women is healing, transformative, and positive.

With advances in genetics and reproductive medicine also come a myriad of ethical, social, and cultural issues that will affect the couple's decisions. With this in mind, provide an opportunity for the couple to make informed decisions in a nondirective, nonjudgmental environment. It is important to encourage couples to remain optimistic throughout investigation and treatment. Through the use of advocacy and anticipatory guidance, assist and support couples through the diagnosis and treatment of infertility (Ying & Loke, 2015).

Finances and insurance coverage often dictate the choice of treatment. Help couples decipher their insurance coverage and help them weigh the costs of various procedures by explaining what each will provide in terms of their infertility problems. Assisting them to make a priority list of diagnostic tests and potential treatment options will help the couple plan their financial strategy.

BOX 4.4

ORGANIZATIONS AND WEB RESOURCES TO ASSIST THE CLIENT WITH INFERTILITY

- RESOLVE: A nationwide network of chapters dedicated to providing education, advocacy, and support for men and women facing infertility. They provide a helpline, medical referral services, and a member-to-member contact system (http://www.resolve.org).
- American Society of Reproductive Medicine (ASRM): Provides fact sheets and other resources on infertility, treatments, insurance, and other issues (http://www.asrm.org).
- International Council on Infertility Information Dissemination (INCIID): Provides information about infertility, support forums, and a directory of infertility specialists (http://www.inciid.org).
- American Fertility Association: Offers education, referrals, research, support, and advocacy for couples dealing with infertility (http://www.americaninfertility.org).
- Bertarelli Foundation—The Human Face of Infertility: Aims to promote and improve understanding of infertility by offering resources (http://www.bertarelli.edu).
- International Consumer Support for Infertility: An international network engaged in advocacy on behalf of infertile couples via fact sheets and information (http://www.icsi.ws).

Many infertile couples are not prepared for the emotional roller coaster of grief and loss that accompanies infertility treatments. Financial concerns and coping as a couple are two major areas of stress when treatment is undertaken. During the course of what may be months or even years of infertility care, it is essential to develop a holistic approach to nursing care. Stress management and anxiety reduction need to be addressed, and referral to a peer support group such as RESOLVE might be in order (Box 4.4).

CONTRACEPTION

Contraception is any method that prevents conception or childbirth, including OCs, sterilization of the female, and the male condom, which are the most popular methods in the United States (Alan Guttmacher Institute, 2015a). Additional types of contraceptives are discussed later in this chapter.

In the United States, there are approximately 68 million women in their childbearing years (between the ages of 15 and 44), and throughout those years a variety of contraceptive methods may be used. Studies have shown that 98% of sexually active women in the United States admit to having used at least one form of contraception; however, despite widespread use of contraceptives, almost half of all pregnancies in the United States are unintended, accounting for a higher unintended pregnancy rate than any other Western county (Centers for Disease Control and Prevention [CDC], 2015a). As outlined in the United Nations Population Fund (UNFPA) *State of the World Population 2014 Report,* over 7 billion people inhabit the earth now and over 80 million people are added to the world each year, more than half of whom are unintended.

In addition to unwanted pregnancies, which can result in abortion, some contraceptives also help prevent transmission of STIs and human immunodeficiency virus (HIV). The UNFPA report also shows that about 50,000 people in the United States become infected with HIV every year. Much of this suffering could be prevented by access to and consistent use of safe, efficient, appropriate, modern contraception for everyone who wants it, as well as proper education regarding benefits and instructions for use (UNFPA, 2015). In addition, climate change (extreme temperature changes and rising ocean levels) will interact with population growth in ways that put additional stress on already weak health systems and will exacerbate vulnerability to the adverse health effects of climate change. The damage done to the environment by modern society is perhaps one of the most inequitable health risks of our time (UNFPA, 2015).

Today, the voluntary control of fertility is of vital importance to modern society. From a global perspective, countries currently face a crisis of rapid population growth that has begun to threaten human survival. At the present rate, the population of the world will double in 40 years; in several of the more socioeconomically disadvantaged countries, populations will double in less than 20 years (UNFPA, 2015).

Types of Contraceptive Methods

Contraceptive methods can be divided into four types: behavioral methods, barrier methods, hormonal methods, and permanent methods. Women must decide which method is appropriate for them to meet their changing contraceptive needs throughout their life cycles. Nurses can educate and assist women during this selection process. This part of the chapter will outline the most common birth control methods available.

In an era when many women wish to delay pregnancy and avoid STIs, choices are difficult. Numerous methods of contraception are available today, and many more will be offered in the near future. The ideal contraceptive method for many women would have the following characteristics: ease of use, safety, effectiveness, minimal side effects, “naturalness,” nonhormonal method, and immediate reversibility

(Samra-Latif & Wood, 2015). Currently, no one contraceptive method offers everything. Box 4.5 outlines the contraceptive methods available today. Table 4.4 provides a detailed summary of each type, including information on failure rates, advantages, disadvantages, STI protection, and danger signs.

HEALTHY PEOPLE 2020

Objective	Nursing Significance
FP-1 Increase the proportion of pregnancies that are intended.	Would reduce number of unplanned pregnancies and girls not finishing their education. This would in turn reduce the number of single parents on state financial assistance.
FP-2 Reduce the proportion of females experiencing pregnancy despite use of a reversible contraceptive method.	Awareness of contraceptive methods and accessibility brings about better compliance and prevention of unintended pregnancies.
FP-3 Increase the proportion of publicly funded family planning clinics that offer the full range of FDA-approved methods of contraception, including emergency contraception, on site.	Would increase accessibility to contraception and prevent unintended pregnancies.
FP-7 Increase the proportion of sexually active persons who received reproductive health services.	Accessibility of reproductive resources can offer pregnancy prevention and preventive education.

Healthy People objectives based on data from http://www.healthypeople.gov

BOX 4.5

OUTLINE OF CONTRACEPTIVE METHODS

Reversible Methods

- **Behavioral**
  - Abstinence
  - Fertility awareness–based methods
  - Withdrawal (coitus interruptus)
  - Lactational amenorrhea method (LAM)

- **Barrier**
  - Condom (male and female)
  - Diaphragm
  - Cervical cap
  - Sponge
- **Hormonal**
  - Oral contraceptive
  - Injectable contraceptive
  - Transdermal patch
  - Vaginal ring
  - Implantable contraceptive
  - Intrauterine contraceptive
  - Emergency contraceptive

Permanent Methods

- Tubal ligation or Essure for women
- Vasectomy for men

TABLE 4.4 SUMMARY OF CONTRACEPTIVE METHODS

Type	Description	Failure Rate	Pros	Cons	STI Protection	Danger Signs	Comments
Abstinence	Refrain from sexual activity	None	Costs nothing	Difficult to maintain	100%	None	Must be joint couple decision
Fertility awareness–based methods	Refrain from sex during fertile period	25%	No side effects; acceptable to most religious groups	High failure rate with incorrect use	None	None	Requires high level of couple commitment
Withdrawal (coitus interruptus)	Man withdraws before ejaculation	27%	Involves no devices and is always available	Requires considerable self-control by the man	None	None	Places woman in trusting and dependent role
Lactational amenorrhea method (LAM)	Uses lactational infertility for protection from pregnancy	1–2% chance of pregnancy in first 6 mo	No cost; not coitus linked	Temporary method; effective for only 6 mo after giving birth	None	None	Mother must breast-feed infant on demand without supplementation for 6 mo
Male condom	Thin sheath placed over an erect penis, blocking sperm	15%	Widely available; low cost; physiologically safe	Decreased sensation for man; interferes with sexual spontaneity; breakage risk	Provides protection against STIs	Latex allergy	Couple must be instructed on proper use of condom
Female condom	Polyurethane sheath inserted vaginally to block sperm	21%	Use controlled by woman; eliminates postcoital drainage of semen	Expensive for frequent use; cumbersome; noisy during sex act; for single use only	Provides protection against STIs	Allergy to polyurethane	Couple must be instructed on proper use of condom
Diaphragm with spermicide	Shallow latex cup with spring mechanism in its rim to hold it in place in the vagina	16%	Does not use hormone; considered medically safe; provides some protection against cervical cancer	Requires accurate fitting by health care professional; increase in UTIs	None	Allergy to latex, rubber, polyurethane, or spermicide Report symptoms of toxic shock syndrome May become dislodged in female superior position	Woman must be taught to insert and remove diaphragm correctly

Cervical cap with spermicide	Soft cup-shaped latex device that fits over base of cervix	24%	No use of hormones; provides continuous protection while in place	Requires accurate fitting by health care professional; odor may occur if left in too long	None	Irritation, allergic reaction; abnormal Pap test; risk of toxic shock syndrome	Instructions on insertion and removal must be understood by client
Sponge with spermicide	Disk-shaped polyurethane device containing a spermicide that is activated by wetting it with water	25%	Offers immediate and continuous protection for 24 hrs; OTC	Can fall out of vagina with voiding; is not form fitting in the vagina	None	Irritation, allergic reactions; toxic shock syndrome can occur if sponge left in too long	Caution woman not to leave sponge in beyond 24 hrs
Oral contraceptives (combination)	A pill that suppresses ovulation by combined action of estrogen and progestin	8%	Easy to use; high rate of effectiveness; protection against ovarian and endometrial cancer	User must remember to take pill daily; possible undesirable side effects; high cost for some women; prescription needed	None	Dizziness, nausea, mood changes, high blood pressure, blood clots, heart attacks, strokes	Each woman must be assessed thoroughly to make sure she is not a smoker and does not have a history of thromboembolic disease
Oral contraceptives (progestin-only minipills)	A pill containing only progestin that thickens cervical mucus to prevent sperm from penetrating	8%	No estrogen-related side effects; may be used by lactating women; may be used by women with history of thrombophlebitis	Must be taken with meticulous accuracy; may cause irregular bleeding; less effective than combination pills	None	Irregular bleeding, weight gain, increased incidence of ectopic pregnancy	Women should be screened for history of functional ovarian cysts, previous ectopic pregnancy, and hyperlipidemia prior to giving prescription
Patch (Ortho Evra)	Transdermal patch that releases estrogen and progestin into circulation	8%	Easy system to remember; very effective	May cause skin irritation where it is placed; may fall off and not be noticed and thus provide no protection	None	Less effective in women weighing more than 200 lb	Instruct woman to apply patch every week for 3 wks and then not to wear one during week 4
Ring (NuvaRing)	Vaginal contraceptive ring about 2 in in diameter that is inserted into the vagina; releases estrogen and progestin	8%	Easy system to remember; very effective	May cause a vaginal discharge; can be expelled without noticing and not offer protection	None	Similar to oral contraceptives	Instruct woman to use a backup method if ring is expelled and remains out for more than 3 hrs
Depo-Provera injection	An injectable progestin that inhibits ovulation	3%	Long duration of action (3 mo); highly effective; estrogen-free; may be used by smokers; can be used by lactating women	Menstrual irregularities; return visit needed every 12 wks; weight gain, headaches, depression; return to fertility delayed up to 12 mo	None	If depression is a problem, this method may increase the depression	Inform woman that fertility is delayed after stopping the injections
Implant (Nexplanon)	A time-release implant (one rod) of levonorgestrel for 3 yrs	0.05%	Long duration of action; low dose of hormones; reversible; estrogen-free	Irregular bleeding; weight gain; breast tenderness; headaches; difficulty in removal	None	If bleeding is heavy, anemia may occur	Before insertion, assess woman to make sure she is aware that this method will produce about 3 yrs of infertility
Intrauterine contraceptives (IUCs)	A T-shaped device inserted into the uterus that releases copper or progesterone or levonorgestrel	1%	It is immediately and highly effective; allows for sexual spontaneity; can be used during lactation; return to fertility not impaired; requires no motivation by the user after insertion	Insertion requires a skilled professional; menstrual irregularities; prolonged amenorrhea; can be unknowingly expelled; may increase the risk of pelvic infection; user must regularly check string for placement; no protection against STIs; delay of fertility after discontinuing for possibly 6–12 mo	None	Cramps, bleeding, pelvic inflammatory disease; infertility; perforation of the uterus	Instruct woman how to locate string to check monthly for placement

Postcoital emergency contraceptives (ECs)	Combination of levonorgestrel-only pills; combined estrogen and progestin pills; or the copper IUS inserted within 72 hrs after unprotected intercourse	80%	Provides a last chance to prevent a pregnancy	Risk of ectopic pregnancy if EC fails	None	Nausea, vomiting, abdominal pain, fatigue, headache	Inform woman that ECs do not interrupt an established pregnancy, and the sooner they are taken the more effective they are
Permanent sterilization							
Male	Sealing, tying, or cutting the vas deferens	<1%	One-time decision provides permanent sterility; short recovery time; low long-term risks	Procedures are difficult to reverse; initial cost may be high; chance of regret; some pain/discomfort after procedures	None for both	Postoperative complications: pain, bleeding, infection	Counsel both as to permanence of procedure and urge them to think it through prior to signing consent
Female	Fallopian tubes are blocked to prevent conception	<1%

Sexual Abstinence

Sexual abstinence (not having vaginal or anal intercourse) is one of the least expensive forms of contraception and has been used for thousands of years. Basically, pregnancy cannot occur if sperm is kept out of the vagina. It also reduces the risk of contracting HIV/AIDS and other STIs, unless body fluids are exchanged through oral sex; however, some infections, like herpes and human papilloma virus (HPV), can be passed by skin-to-skin contact. Dental dams can be used to prevent transmission, however. There are many pleasurable options for sex play without intercourse ("outercourse"), such as kissing, masturbation, erotic massage, sexual fantasy, sex toys such as vibrators, and oral sex.

Many people have strong feelings about abstinence based on religious and moral beliefs. There are many good and personal reasons to choose abstinence. For some it is a way of life, whereas for others it is a temporary choice. Some people choose sexual abstinence because they want to:

- Wait until they are older
- Wait for a long-term relationship
- Avoid pregnancy or STIs
- Relieve feelings of depression or anxiety
- Follow religious or cultural expectations

Fertility Awareness–Based Methods

Fertility awareness refers to any natural contraceptive method that does not require hormones, pharmaceutical compounds, physical barriers, or surgery to prevent pregnancy. Fertility awareness–based methods (FAMs) use physical signs and symptoms that change with hormone fluctuations throughout a woman's menstrual cycle to predict a woman's fertility. Ovulation occurs on 1 day during each menstrual cycle, and the several days preceding ovulation are when intercourse is most likely to result in pregnancy. Collectively, the potentially fertile days up to and including the day of ovulation are called the "fertile window." Awareness of fertility is a better fertility-producing method than contraceptives. Less

than 1% of women in the United States who use contraception employ these methods (King et al., 2015). The unifying theme of FAMs is that a woman can reduce her chance of pregnancy by abstaining from coitus or using barrier methods during times of fertility. These methods require couples to take an active role in preventing pregnancy through their sexual behaviors and women need to have regular menstrual cycles for it to be effective. Couples agree to practice certain techniques, use calculations, and be observant of the "fertile" and the "safe" periods in a monthly menstrual cycle. Using these methods for birth control requires a strong commitment from both partners. The normal physiologic changes caused by hormonal fluctuations during the menstrual cycle can be observed and charted. This information can then be used to avoid or promote pregnancy. Fertility awareness methods rely on the following assumptions:

- A single ovum is released from the ovary 14 days before the next menstrual period. It lives approximately 24 hours.
- Women using this method must have regular menstrual cycles for it to be effective.
- Sperm can live up to 5 days after intercourse. The "unsafe period" during the menstrual cycle is thus approximately 6 days: 3 days before and 3 days after ovulation. Because body changes start to occur before ovulation, the woman can become aware of them and not have intercourse on these days or use another method to prevent pregnancy.
- The exact time of ovulation cannot be determined, so 2 to 3 days are added to the beginning and end to avoid pregnancy.

Techniques used to determine fertility include the cervical mucus ovulation method, the basal body temperature (BBT) method, the symptothermal method, standard day's method, and two-day method (Everett, 2014). Fertility awareness methods are moderately effective but are very unforgiving if not carried out as prescribed. Fertility awareness can be used in combination with coital abstinence or barrier methods during fertile days if pregnancy is not desired.

CERVICAL MUCUS OVULATION METHOD

Cervical mucus is a jellylike vaginal discharge that comes from the cervix. The **cervical mucus ovulation method** is used to assess the character of the cervical mucus. Cervical mucus changes consistently during the menstrual cycle and plays a vital role in fertilization of the egg. Studies conducted by the WHO indicate that 93% of women, regardless of their education level, are capable of identifying and distinguishing fertile and infertile cervical secretions (Planned Parenthood, 2015a). In the days preceding ovulation, fertile cervical mucus helps draw sperm up and into the fallopian tubes, where fertilization usually takes place. It also helps maintain the survival of sperm. As ovulation approaches, the mucus becomes more abundant, clear, slippery, and smooth; it can be stretched between two fingers without breaking. Under the influence of estrogen, this mucus looks like egg whites. It is called *spinnbarkeit* mucus (Fig. 4.5). After ovulation, the cervical mucus becomes thick and dry under the influence of progesterone.

The cervical position can also be assessed to confirm changes in the cervical mucus at ovulation. Near ovulation, the cervix feels soft and is high/deep in the vagina, the os is slightly open, and the cervical mucus is copious and slippery (Bieber, Sanfilippo, Horowitz, et al., 2015). This method works because the woman

becomes aware of her body changes that accompany ovulation. When she notices them, she abstains from sexual intercourse or uses another method to prevent pregnancy. Each woman is an individual, so each woman's unsafe time of the month is unique and thus must be individually assessed and determined.

FIGURE 4.5 Spinnbarkeit mucus is cervical mucus that can stretch a distance before breaking.

BASAL BODY TEMPERATURE METHOD

The **basal body temperature** (BBT) refers to the lowest temperature reached on awakening. The woman takes her temperature orally before rising and records it on a chart. Preovulation temperatures are suppressed by estrogen, whereas postovulation temperatures are increased under the influence of heat-inducing progesterone. Temperatures typically rise within a day or two after ovulation and remain elevated for approximately 2 weeks (at which point bleeding usually begins). If using this method by itself, the woman should avoid unprotected intercourse until the BBT has been elevated for 3 days. Nurses should instruct women using the BBT method that it is important to keep in mind that illness and any drugs, including alcohol, can raise their body temperature and give a false reading. Other fertility awareness methods should be used along with BBT for better results (Fig. 4.6).

SYMPTOTHERMAL METHOD

The **symptothermal method** relies on a combination of techniques to recognize ovulation, including BBT, cervical mucus changes, alterations in the position and firmness of the cervix, and other symptoms of ovulation, such as increased libido, *mittelschmerz* (midcycle, lower abdominal pain at ovulation), pelvic fullness or tenderness, and breast tenderness (Planned Parenthood, 2015a). Combining all these predictors increases awareness of when ovulation occurs and increases the effectiveness of this method. A home predictor test for ovulation is also available in most pharmacies. It measures LH levels to pinpoint the day before or the day of ovulation. These tests are widely used for fertility and infertility regimens.

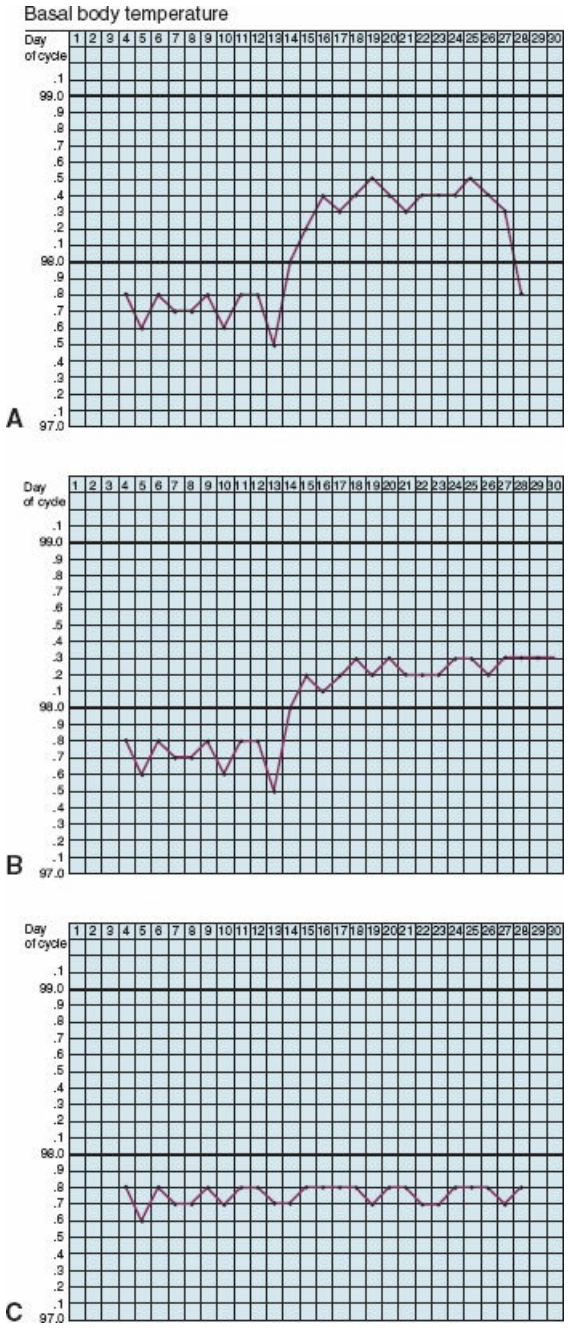

FIGURE 4.6 Basal body temperature graph. A. The woman's temperature dips slightly at midpoint in the menstrual cycle, then rises sharply, an indication of ovulation. Toward the end of the cycle (the 24th day), her temperature begins to decline, indicating that progesterone levels are falling and that she did not conceive. B. The woman's temperature rises at the midpoint in the cycle and remains at that elevated level past the time of her normal menstrual flow, suggesting that pregnancy has occurred. C. There is no preovulatory dip and no rise of temperature anywhere during the cycle. This is the typical pattern of a woman who does not ovulate.

THE STANDARD DAYS METHOD AND THE TWO-DAY METHOD

The **Standard Days Method** (SDM) and the Two-Day Method are both natural methods of contraception developed by Georgetown University Medical Center's Institute for Reproductive Health. Both methods provide women with simple, clear instructions for identifying fertile days. Women with menstrual cycles between 26 and 32 days long can use the SDM to prevent pregnancy by avoiding unprotected

intercourse on days 8 through 19 of their cycles. Most SDM users utilize a visual aid —CycleBeads—to assist their correct use of SDM. An international clinical trial of the SDM showed that the method is more than 95% effective when used correctly (Wright, Iqteit, & Hardee, 2015). SDM identifies the 12-day "fertile window" of a woman's menstrual cycle. These 12 days take into account the life span of the women's egg (about 24 hours) and the viability of the sperm (about 5 days) as well as the variation in the actual timing of ovulation from one cycle to another. For the Two-Day Method, women observe the presence or absence of cervical secretions by examining toilet paper or underwear or by monitoring their physical sensations. Every day, the woman asks two simple questions: "Did I note any secretions yesterday?" and "Did I note any secretions today?" If the answer to either question is yes, she considers herself fertile and avoids unprotected intercourse. If the answers are no, she is unlikely to become pregnant from unprotected intercourse on that day (King et al., 2015).

To help women keep track of the days on which they should avoid unprotected intercourse, a string of 32 color-coded beads (CycleBeads) is used, with each bead representing a day of the menstrual cycle. Starting with the red bead, which represents the first day of her menstrual period, the woman moves a small rubber ring one bead each day. The brown beads are the days when pregnancy is unlikely, and the white beads represent her fertile days (Stanford, 2015). This method has been used in underdeveloped countries for women with limited educational resources (Fig. 4.7).

Withdrawal (Coitus Interruptus)

In **coitus interruptus**, also known as withdrawal, a man controls his ejaculation during sexual intercourse and ejaculates outside the vagina. It is better known colloquially as "pulling out in time" or "being careful." It is one of the oldest and most widely used means of preventing pregnancy in the world and also one of the least effective methods in preventing pregnancy (Creatsas, 2015). The problem with this method is that the first few drops of the true ejaculate contain the greatest concentration of sperm, and if some pre-ejaculatory fluid escapes from the urethra before orgasm, conception may result. This method requires that the woman rely solely on the cooperation and judgment of the man. Nurses might wish to discuss emergency contraceptives be available with this couple or use a more effective method of contraception.

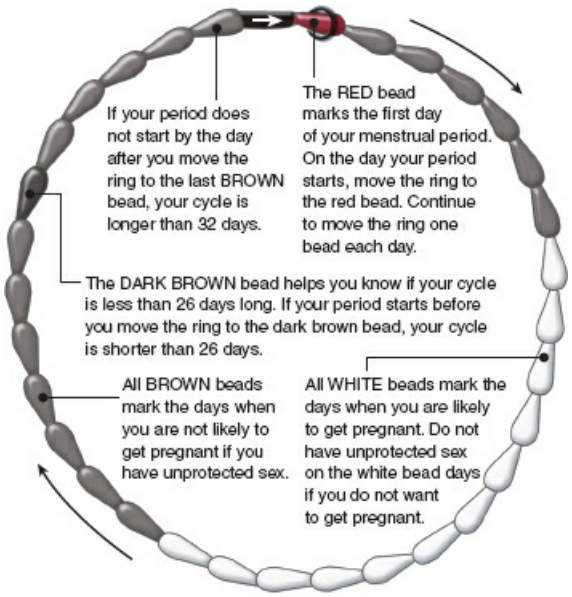

FIGURE 4.7 CycleBeads help women use the Standard Days Method.

Lactational Amenorrhea Method

The **lactational amenorrhea method** (LAM) is an effective temporary method of contraception used by breast-feeding mothers. It relies on physiologic changes associated with breast-feeding for contraception. Continuous breast-feeding usually can postpone ovulation and thus prevent pregnancy. Breast-feeding stimulates the hormone prolactin, which is necessary for milk production, and also inhibits the release of another hormone, gonadotropin, which is necessary for ovulation.

Breast-feeding as a contraceptive method can be fairly effective for up to 6 months after giving birth only if:

- A woman has not had a period since she gave birth
- Infant is younger than 6 months of age
- The woman breast-feeds her baby at least six times daily on both breasts
- She breast-feeds her baby "on demand" at least every 4 hours
- A woman does not substitute other foods for a breast-milk meal
- Nighttime feedings are provided at least every 6 hours

Also, pumping or manual expression of milk may reduce effectiveness, Do not rely on this method after 6 months (Planned Parenthood, 2015a).

Nurses can help couples to make a decision about family planning options available in the postpartum period by discussing the advantages and disadvantages of each, taking into consideration the demands of the postpartum period. The options they may consider include lactational amenorrhea, combined oral contraception, implants, intrauterine systems, injectable methods, barrier methods, emergency contraception (EC), and sterilization (Hughes, 2015).

Barrier Methods

Barrier contraceptives are forms of birth control that prevent pregnancy by preventing the sperm from reaching the ovum. Mechanical barriers include condoms, diaphragms, cervical caps, and sponges. These devices are placed over the penis or cervix to physically obstruct the passage of sperm through the cervix. Chemical barriers called spermicides may be used along with mechanical barrier

devices. They come in creams, jellies, foam, suppositories, and vaginal films. They chemically destroy the sperm in the vagina. These contraceptives are called barrier methods because they not only provide a physical barrier for sperm, but also protect against STIs. Since the HIV/AIDS epidemic started in the early 1980s, these methods have become extremely popular. Progress has been made in society's reaction to condom use as a disease prevention device now and not just as a contraceptive (Haddad, Philpott-Jones, & Schonfeld, 2015).

Many of these barrier methods contain latex. Allergy to latex was first recognized in the late 1970s, and since then it has become a major health concern, with increasing numbers of people affected. According to the American Academy of Allergy, Asthma and Immunology (AAAAI) (2015), 6% of the general population, 10% of health care workers, and 50% of spina bifida clients are sensitive to natural rubber latex. Health care workers in both the medical and dental environments, as well as specific groups of individuals including those with spina bifida, myelodysplasia, and food allergies (banana, kiwi, avocado, and others), are at increased risk of sensitization (Kim, 2015). Teaching Guidelines 4.4 provides tips for individuals with latex allergy.

Teaching Guidelines 4.4

TIPS FOR INDIVIDUALS ALLERGIC TO LATEX

Symptoms of latex allergy include:

- Skin rash, itching, hives
- Itching or burning eyes
- Swollen mucous membranes in the genitals
- Shortness of breath, difficulty breathing, wheezing
- Anaphylactic shock
- Use of or contact with latex condoms, cervical caps, and diaphragms is contraindicated for men and women with a latex allergy
- If the female partner is allergic to latex, have the male partner apply a natural condom over the latex one
- If the male partner experiences penile irritation after condom use, try different brands or place the latex condom over a natural condom.
- Use polyurethane condoms rather than latex ones.
- Use female condoms; they are made of polyurethane.
- Switch to another birth control method that is not made with latex, such as oral contraceptives, intrauterine systems, Depo-Provera, fertility awareness, and other nonbarrier methods. However, these methods do not protect against sexually transmitted infections.

CONDOMS

Condoms are barrier methods of contraceptives made for both males and females. The male condom is made from latex or polyurethane or natural membrane and may be coated with spermicide. Male condoms are available in many colors, textures, sizes, shapes, and thicknesses. When used correctly, the male condom is put on over an erect penis before it enters the vagina and is worn throughout sexual intercourse (Fig. 4.8). It serves as a barrier to pregnancy by trapping seminal fluid and sperm and offers protection against STIs. Condoms are not perfect barriers, however, because breakage and slippage can occur. Emergency postcoital contraception may need to be sought to prevent a pregnancy. In addition, the nonlatex condoms have a higher risk of pregnancy and STIs than latex condoms (Everett, 2014).

The female condom is a polyurethane pouch inserted into the vagina. It consists of an outer and inner ring that is inserted vaginally and held in place by the pubic bone. Some women complain that the female condom is cumbersome to use and makes noise during intercourse. Female condoms are readily available, are inexpensive, and can be carried inconspicuously by the woman. The female condom was the first woman-controlled method that offered protection against pregnancy and some STIs. Nurses can play a key role in educating clients on how to initiate and maintain use of the female condom, an underused method for HIV/STI and pregnancy prevention in the United States. Providing a brief education session along with free samples would go a long way to promote increased use of this device to prevent STIs transmission as well as pregnancy (Boyd, Perkins, Lawrence, et al., 2015).

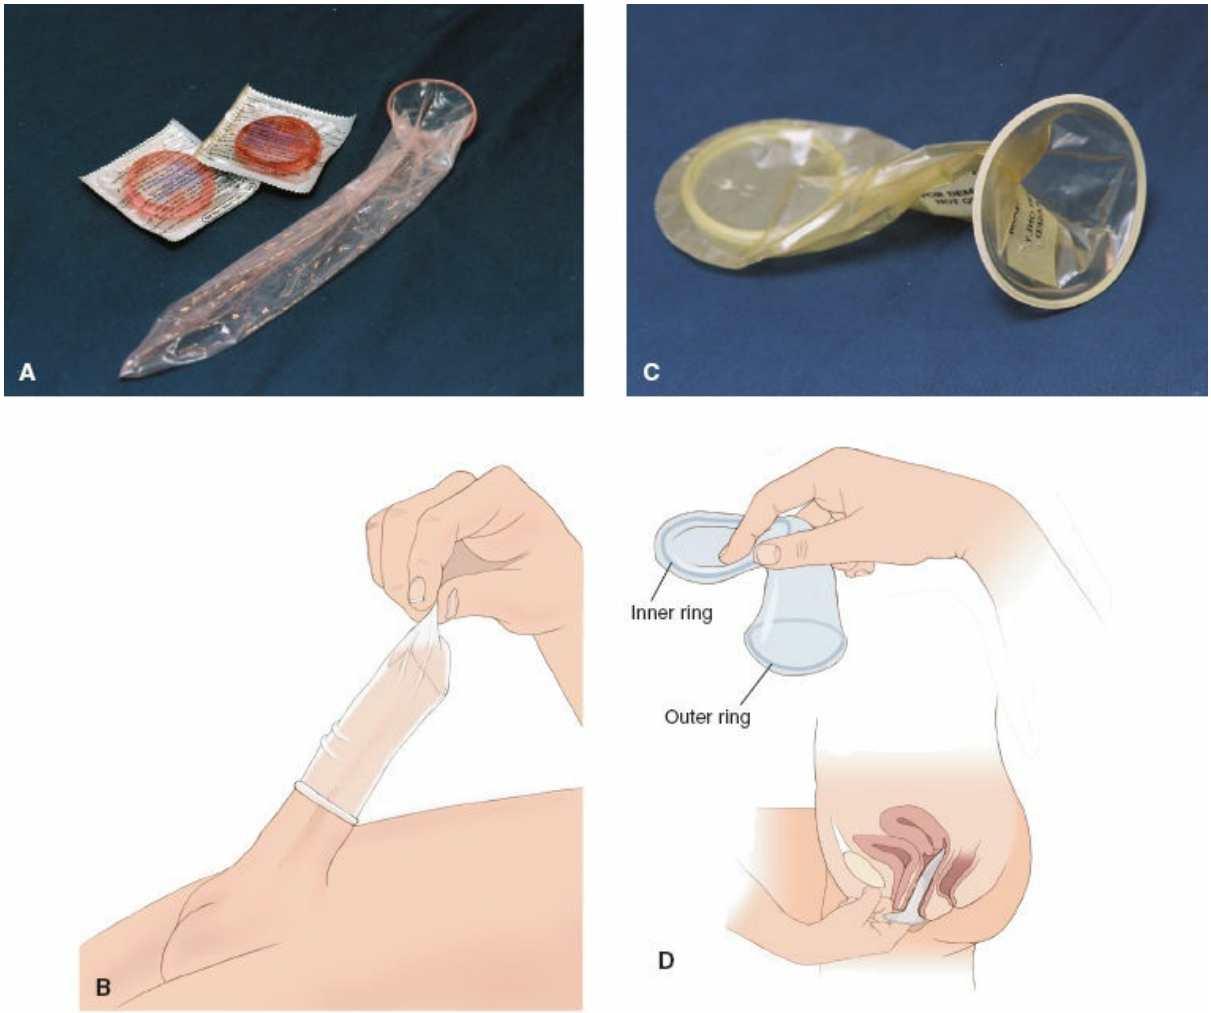

FIGURE 4.8 A. Male condom. B. Applying a male condom. Leaving space at the tip helps to ensure the condom will not break with ejaculation. C. The female condom. D. Insertion technique.

DIAPHRAGM

The **diaphragm** is a soft latex dome surrounded by a metal spring. Used in conjunction with a spermicidal jelly or cream, it is inserted into the vagina to cover the cervix (Fig. 4.9). The diaphragm may be inserted up to 4 hours before intercourse but must be left in place for at least 6 hours afterward. Diaphragms are available in a range of sizes and styles. The diaphragm is available only by prescription and must be professionally fitted by a health care provider. Women may need to be refitted with a different-sized diaphragm after pregnancy, abdominal or pelvic surgery, or weight loss or gain of 10 lb or more. As a general rule, diaphragms should be replaced every 1 to 2 years. Recently, a single-sized diaphragm used with contraceptive jelly was introduced and studied for its effectiveness. The single-sized diaphragm was deemed safe and as effective as a standard individually fitted one based on a population sample of >400 women that participated in the research study (Schwartz, Weiner, Lai, et al., 2015). The diaphragm provides both a physical and chemical barrier to sperm (Tharpe et al., 2016).

FIGURE 4.9 **Sample diaphragm used for measuring.**

Diaphragms are user-controlled, nonhormonal methods that are needed only at the time of intercourse, but they are not effective unless used correctly. Women need to receive thorough instruction about diaphragm use and should practice putting one in and taking it out before they leave the health care office (Fig. 4.10).

Results of a 2-year multisite study indicate that the effectiveness rates of the SILCS single-sized, contoured diaphragm, are similar to those of traditional diaphragms, but they also provide a long-term controlled release of the lead candidate anti-HIV microbicide dapivirine. This would make it a new multipurpose prevention device (Schwartz et al., 2015). The biggest difference with this new device is that since it is single size, a pelvic examination to assess the size is not required, and it also releases an anti-HIV microbicide that potentially is capable of preventing HIV transmission. Most women in the study were able to correctly insert, remove, and check correct position of the device by simply using the instructions (Schwartz et al., 2015).

CERVICAL CAP

The **cervical cap** is smaller than the diaphragm and covers only the cervix; it is held in place by suction. Caps are made from silicone or latex and are used with spermicide (Fig. 4.11). The FemCap is the only cervical cap device currently available in the United States and comes in three sizes (Planned Parenthood, 2016). The cap may be inserted up to 36 hours before intercourse and provides protection for 48 hours. The cap must be kept in the vagina for 6 hours after the final act of intercourse and should be replaced every year of use. A refitting may also be necessary when a woman experiences pregnancy, abortion, or weight changes. The dome of the cap is filled about one third full with spermicide. Spermicide should not

be applied to the rim because it might interfere with the seal that must form around the cervix. The cap is available only by prescription and must be fitted by a health care provider. Contraindications to the use of a cervical cap include cervical cancer, recent urinary tract infection, latex allergy, pelvic-organ prolapse, and history of toxic shock syndrome. Using the cervical cap during menstruation may increase the risk of toxic shock syndrome and, therefore, should be avoided (Schuiling & Likis, 2016).

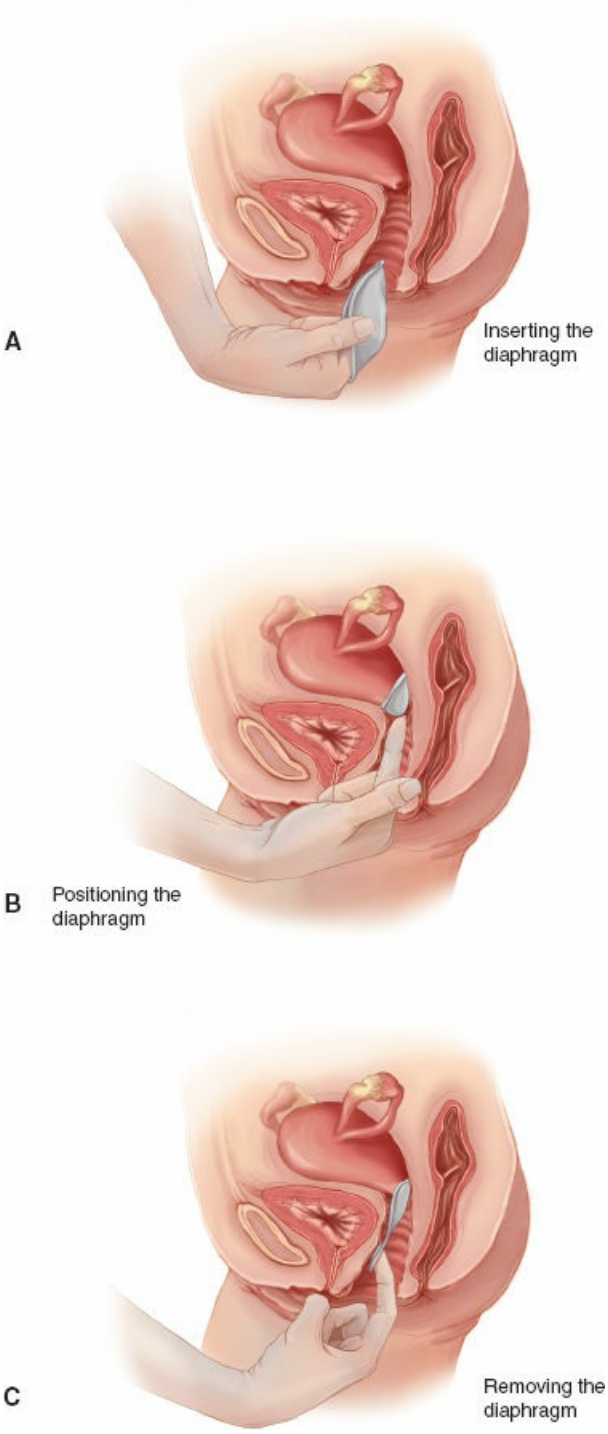

FIGURE 4.10 Application of a diaphragm. A. To insert, fold the diaphragm in half, separate the labia with one hand, then insert upward and back into the vagina. B. To position, make certain the diaphragm securely covers the cervix. C.

To remove, hook a finger over the top of the rim and bring the diaphragm down and out.

FIGURE 4.11 A cervical cap is placed over the cervix and used with a spermicidal jelly, the same as a diaphragm.

CONTRACEPTIVE SPONGE

The **contraceptive sponge** is a nonhormonal, nonprescription device that includes both a barrier and a spermicide. When it was removed from the market in 1995, it was the most popular OTC female contraceptive in America (Everett, 2014). The manufacturer, Wyeth, stopped making the sponge rather than upgrade its manufacturing plant after the Food and Drug Administration (FDA) found deficiencies, but the device's effectiveness and safety were never questioned. After receiving reapproval from the FDA in 2009, the contraceptive sponge is once again being marketed to women.

The contraceptive sponge is a soft concave device that prevents pregnancy by covering the cervix and releasing spermicide. The sponge, made of polyurethane saturated with nonoxynol-9 (1,000 mg), releases 125 mg of the spermicide over 24 hours of use. Unlike the diaphragm, the sponge can be used for more than one coital act within 24 hours without the insertion of additional spermicide, and the sponge does not require fitting or a prescription from a health care provider (Zieman, 2015). While it was less effective than several other methods and does not offer protection against STIs, the sponge achieved a wide following among women who appreciated the spontaneity with which it could be used and its easy availability. When compared with the diaphragm in a recent study, the sponge was found to be less effective than the diaphragm in preventing pregnancy. Discontinuation rates were higher at 12 months as well (Sharma & Walmsley, 2015).

To use the sponge, the woman first wets it with water, and then inserts it into the vagina with a finger, using a cord loop attachment. It can be inserted up to 24 hours before intercourse and should be left in place for at least 6 hours following intercourse. The sponge provides protection for up to 12 hours, but should not be left in for more than 30 hours after insertion to avoid the risk of toxic shock syndrome (Moses, 2015c).

Hormonal Methods

Several options are available to women who want long-term but not permanent protection against pregnancy. These methods of contraception work by altering the

hormones within a woman's body. They rely on estrogen and progestin or progestin alone to prevent ovulation. When used consistently, these methods are a reliable way to prevent pregnancy. Hormonal methods include OCs, injectables, implants, vaginal rings, and transdermal patches.

ORAL CONTRACEPTIVES

As early as 1937, scientists recognized that the injection of progesterone inhibited ovulation in rabbits and provided contraception. The first hormonal pill, called *Enovid,* was approved by the FDA in May 1960. It contained high levels of estrogen to prevent ovulation. Since that time, it has evolved through gradual lowering of estrogen and is now combined with many different progestins. Breakthrough bleeding was reported in early clinical trials in women, and the role of estrogen in cycle control was launched. This established the rationale for modern-combination OCs that contains both estrogen and progesterone (Stewart & Black, 2015).

Development of hormonal contraception marked a revolutionary step in social change that has improved the lives of women and families worldwide. Since the first OC was introduced, hormonal contraception has undergone various stages of advancement. Today, OC regimens are safer and more tolerable, with equal or improved efficacy, than the early formulations. Incremental decreases in the estrogen dosage helped to alleviate some of the unwanted side effects of the pill (Craik & Melvin, 2015). Today, over 30 combination OCs are available in the United States. The most notable change in over 50 years of OC improvement has been the lowering of the estrogen dose to as low as 10 mcg and the introduction of new progestins.

FIGURE 4.12 **Oral contraceptive.**

Oral contraception is the most popular method of nonsurgical contraception, used by approximately 25 million women in the United States (Samra-Latif & Wood, 2015) (Fig. 4.12). Unlike the original OCs that women took decades ago, the new low-dose forms carry fewer health risks.

OC, although most commonly prescribed for contraception, has long been used in the management of a wide range of conditions and has many health benefits, such as:

- Reduced incidence of ovarian and endometrial cancer
- Prevention and treatment of endometriosis
- Decreased incidence of acne and hirsutism

• Decreased incidence of ectopic pregnancy
• Decreased incidence of acute PID and possible protection against PID
• Reduced incidence of fibrocystic breast disease
• Decreased perimenopausal symptoms
• Reduced risk of developing uterine fibroids
• Maintenance of bone mineral density (BMD)
• Improvement in asthmatic symptoms
• Delayed onset of multiple sclerosis and arthritis
• Increased menstrual cycle regularity
• Lower incidence of colorectal cancer
• Decreased number of pregnancy-related deaths by preventing pregnancy
• Reduced iron-deficiency anemia by treating menorrhagia
• Reduced incidence of dysmenorrhea (Evans & Sutton, 2015).

OCs work primarily by suppressing ovulation by adding estrogen and progesterone to a woman's body, thus mimicking pregnancy. This hormonal level stifles GnRH, which in turn suppresses FSH and LH and thus inhibits ovulation. Cervical mucus also thickens, which hinders sperm transport into the uterus. Implantation is inhibited by suppression of the maturation of the endometrium and alterations of uterine secretions (Everett, 2014).

The combination pills are prescribed as monophasic pills, which deliver fixed dosages of estrogen and progestin, or as multiphasic ones. Multiphasic pills (e.g., biphasic and triphasic OCs) alter the amount of progestin and estrogen within each cycle. To maintain adequate hormonal levels for contraception and enhance adherence to the regimen, OCs should be taken at the same time daily.

OCs that contains progestin only are sometimes called mini-pills. Progestin-only pills (POPs) have both advantages and disadvantages when compared with combined pills. The pill-taking regimen is simple and fixed; no pill color changes or days without pill-taking occur. These pills are appropriate for women who cannot take estrogen in combined OCs, for example, a woman older than 35 years who smokes cigarettes. They are prescribed for women who cannot take estrogen at all. These OCs work primarily by thickening the cervical mucus to prevent penetration of the sperm and make the endometrium unfavorable for implantation. Progestin-only pills must be taken at a certain time every 24 hours. Breakthrough bleeding and a higher risk of pregnancy have made these OCs less popular than combination OCs (Craik & Melvin, 2015).

Extended OC regimens have been used for the management of menstrual disorders and endometriosis for years but now are attracting wider attention. Surveys asking women about their willingness to reduce their menstrual cycles from 12 to 4 annually were returned with a resounding "yes!" (Zorbas, Economopoulos, & Vlahos, 2015). Research has confirmed that the extended use of active OC pills carries the same safety profile as the conventional 28-day regimens. OCs taken continuously or in long cycles offer benefits with regard to menstrual symptoms and the recurrence of symptoms related to endometriosis (Zieman, 2015). The extended regimen consists of 84 consecutive days of active combination pills, followed by 7 days of placebos. The woman has four withdrawal-bleeding episodes a year. Seasonale and Seasonique, a combination OC, is on the market for women who choose to reduce the number of periods that they have. In 2009, the makers of

Seasonique came out with LoSeasonique. LoSeasonique consists of 84 orange tablets containing 0.1 mg levonorgestrel and 0.02 mg ethinyl estradiol and 7 yellow tablets containing 0.01 mg ethinyl estradiol. The risk profile is similar to those of its sister products, Seasonale and Seasonique; however, the risk of unplanned breakthrough bleeding is increased (Samra-Latif & Wood, 2015).

COMPARISON CHART 4.1

ADVANTAGES AND DISADVANTAGES OF ORAL CONTRACEPTIVES

Advantages	Disadvantages
Regulate and shorten menstrual cycle	Offer no protection against STIs
Decrease severe cramping and bleeding	Pose slightly increased risk of breast cancer
Reduce anemia	
Reduce ovarian and colorectal cancer risk	Modest risk for venous thrombosis and pulmonary emboli
Decrease benign breast disease	Increased risk for migraine headaches
Reduce risk of endometrial cancer, colorectal cancer, and ovarian cancer	
Improve acne and reduces incidence of menstrual headaches	Increased risk for myocardial infarction, stroke, and hypertension for women who smoke
Minimize perimenopausal symptoms	May increase risk of depression
Decrease incidence of rheumatoid arthritis	User must remember to take pill daily
Improve PMS symptoms	High cost for some women
Protect against loss of bone density and reduces risk of osteoporosis	

Adapted from Jick, S. (2015). Oral contraceptives and the risk of venous thromboembolism. In *Medicines for women* (pp. 181–201). Springer International Publishing.; Zieman, M. (2015) *Managing contraception on the go* (13th ed.), New York, NY: Ardnet Media; Everett, S. (2014) *Handbook of contraception and sexual health* (3rd ed.), New York, NY: Routledge.

Lybrel was the first FDA-approved OC with 365-day combination dosing. It contains a low combined daily dose of the hormones levonorgestrel and ethinyl estradiol (90 mcg and 20 mcg, respectively). It provides women with more hormonal exposure on a yearly basis (13 additional weeks of hormone intake per year) than conventional cyclic OCs that contain the same strength of synthetic estrogens and similar strength of progestins (Samra-Latif & Wood, 2015). There is no physiologic requirement for cyclic hormonal withdrawal bleeds while taking OCs (Skidmore-Roth, 2015).

A growing body of evidence indicates that an over-the-counter access to OC pills is safe and effective and that women are interested in obtaining pills this way. With half of all pregnancies being unintended—a figure that has remained unchanged for decades—innovation is needed to address this statistic. Although an over-the-counter contraceptive pill may sound revolutionary in the United States, over-the-counter access is already a reality in more than 100 countries and has been for

decades. ACOG supports over-the-counter access to contraceptive pills, but numerous social and professional groups oppose it (Foster, Biggs, Phillips, et al., 2015). Even after ACOG's support, women will probably not be seeing an over-the-counter OC product on the local pharmacy shelf any time soon, despite its cost-effectiveness and impact on reduction in unintended pregnancies.

The balance between the benefits and the risks of OCs must be determined for each woman when she is being assessed for this type of contraceptive. It is a highly effective contraceptive when taken properly but can aggravate many medical conditions, especially in women who smoke. Comparison Chart 4.1 lists advantages and disadvantages of OCs. A thorough history and pelvic examination, including a Pap smear, are not required before the medication is prescribed, but a regular medical follow-up is advised. Women should also be counseled that the effectiveness of OCs is decreased when the woman is taking antibiotics; thus, the woman will need to use an alternative or secondary method during this period to prevent pregnancy.

Nurses need to provide OC users with a great deal of education before they leave the health care facility. They need to be able to identify early signs and symptoms that might indicate a problem.

Take Note!

The mnemonic "ACHES" can help women remember the early warning signs that necessitate a return to the health care provider (Box 4.6).

BOX 4.6

EARLY SIGNS OF COMPLICATIONS FOR USERS OF ORAL CONTRACEPTIVES

A = Abdominal pain may indicate liver or gallbladder problems.
C = Chest pain or shortness of breath may indicate a pulmonary embolus.
H = Headaches may indicate hypertension or impending stroke.
E = Eye problems may indicate hypertension or an attack.
S = Severe leg pain may indicate a thromboembolic event.

INJECTABLE CONTRACEPTIVE

Injectable contraception includes progestin-only and combination estrogen and progestin agents that provide safe and highly effective birth control for up to 3 months. Injectable agents are widely available and play an important role in family planning worldwide. They offer a discreet, convenient, reversible, and non–coital-dependent method of birth control.

Depo-Provera is the trade name for an intramuscular injectable of a progesterone-only contraceptive given every 12 weeks which contains 150 mg/1 mL. Depo-subQ Pronera is a lower-dose injectable given subcutaneously delivering 104 mg/0.65 mL every 12 weeks. They are the only injectable agents available in the United States. Depo-Provera works by suppressing ovulation and the production

of FSH and LH by the pituitary gland, by increasing the viscosity of cervical mucus and causing endometrial atrophy. A single injection of 150 mg into the buttocks acts like other progestin-only products to prevent pregnancy for 3 months at a time (Fig. 4.13). The primary side effect of Depo-Provera is menstrual cycle disturbance.

Recent clinical studies have raised concerns about whether Depo-Provera reduces BMD. This evidence has prompted the manufacturer and the FDA to issue a warning about the long-term use (>2 years) of Depo-Provera and bone loss (Wolfe & Cansino, 2015). It is not entirely clear if this loss in BMD is reversible because there have not been any long-term prospective studies in current and past users. It is highly recommended that bone density scans be done while on Depo-Provera (U.S. Selected Practice Recommendations for Contraceptive Use, 2014).

FIGURE 4.13 **Injectable contraceptive.**

TRANSDERMAL PATCHES

Transdermal delivery of contraceptive hormones avoids hepatic first-pass metabolism, allowing a lower total hormone doses when compared to that of oral products that are metabolized in the liver. A **transdermal patch**, Ortho Evra, is available in the United States. It is a matchbox-sized patch containing hormones that are absorbed through the skin when placed on the lower abdomen, upper outer arm, buttocks, or upper torso (avoiding the breasts). The patch is applied weekly for 3 weeks, followed by a patch-free week during which withdrawal bleeding occurs. The patch delivers continuous levels of progesterone and estrogen. Transdermal absorption allows the drug to enter the bloodstream directly, avoiding rapid inactivation in the liver known as first-pass metabolism. Because estrogen and progesterone are metabolized by liver enzymes, avoiding first-pass metabolism was thought to reduce adverse effects. However, recent evidence suggests that the risk of venous thrombosis and embolism is increased with the patch and the risk of skin burns occurring if undergoing an MRI, but still less than the risk of venous thromboembolism during pregnancy (Nelson, 2015). Additional studies are under way to understand the clinical significance of these latest findings, but in the interim nurses need to focus on ongoing risk assessment and should be prepared to discuss current research findings with clients.

Adherence to the regimen of combination contraceptive patch use has been shown to be significantly greater than adherence with OCs. In addition, research suggests that overweight and obese women with weights exceeding 198 lb should be advised of the potentially decreased effectiveness of the patch and increase incidence of

venous thromboembolism and weight gain (Pocius & Dutton, 2015). The patch provides combination hormone therapy with a side-effect profile similar to that of OCs (Fig. 4.14).

VAGINAL RINGS

Approved in 2001 by the FDA, the **vaginal ring** contains both estrogen and progesterone hormones. The contraceptive vaginal ring, NuvaRing, is a flexible, soft, transparent ring that is inserted by the user for a 3-week period of continuous use followed by a ring-free week to allow withdrawal bleeding (Fig. 4.15). Ethinyl estradiol and etonogestrel are rapidly absorbed through the vaginal epithelium and result in a steady serum concentration. Because the hormones are released directly into the vagina, a lower daily dose of hormones is required in comparison with OC doses. Studies have demonstrated that the efficacy and safety of the ring are equivalent to those of OCs. Clients report being highly satisfied with the vaginal ring and report fewer systemic side effects than do OC users. The ring provides effective cycle control as well as symptom relief for women with menorrhagia, dysmenorrhea, and polycystic ovarian syndrome. Reported problems associated with the use of vaginal rings include erosion of vaginal wall, ring expulsion, interference with coitus, unpleasant ring odor, and premature discontinuation due to vaginal discomfort (Khan & Krupanidhi, 2015). The ring can be inserted by the woman and does not have to be fitted. The woman compresses the ring and inserts it into the vagina, behind the pubic bone, as far back as possible, but precise placement is not critical. The hormones are absorbed through the vaginal mucosa. It is left in place for 3 weeks and then removed and discarded. Effectiveness and adverse events are similar to those seen with combination OCs. Clients need to be counseled regarding timely insertion of the ring and what to do in case of accidental expulsion. Recent studies suggest that a vaginal ring containing etonogestrel and ethinyl estradiol used in an extended regimen is a safe contraceptive method that offers good cycle control and can be an option for women who have gastric intolerance or other side effects when using oral hormonal contraceptives (King et al., 2015).

FIGURE 4.14 **Transdermal patch.**

FIGURE 4.15 **Vaginal ring.**

IMPLANTABLE CONTRACEPTIVES

The **implant** is a subdermal time-release method that delivers synthetic progestin that inhibits ovulation. Once in place, it delivers 3 years of continuous, highly effective contraception. Like progestin-only pills, implants act by inhibiting ovulation and thickening cervical mucus so sperm cannot penetrate. A single-rod progestin implant (Nexplanon) is currently available in the United States. Nexplanon is 4 cm long and 2 mm in diameter, and contains 68 mg of the hormone progestin. The implant is radio-opaque and is over 99% effective (King et al., 2015). The side effects are also similar to those of progestin-only pills: irregular bleeding, headaches, weight gain, breast tenderness, and depression. Fertility is restored quickly after it is removed. Implants require a minor surgical procedure for both insertion and removal. The implants do not offer any protection against STIs.

Hormonal side effects are not exclusive to implants but tend to be a problem with all hormonal contraceptives. Preinsertion counseling by the nurse is essential to prepare the woman for any such side effects. Expert counseling should cover the one-side effect most likely to cause discontinuation: initial irregular bleeding and the possibility of amenorrhea with longer use (Craik & Rowlands, 2015).

INTRAUTERINE CONTRACEPTIVES

Intrauterine contraceptives are classified as either hormonal or nonhormonal. Both types prevent pregnancy via inhibition of sperm mobility and sperm viability and change the speed of transport of the ovum in the fallopian tube. An intrauterine contraceptive (IUC) is a small plastic T-shaped object that is placed inside the uterus to provide contraception (Fig. 4.16). It prevents pregnancy by making the endometrium of the uterus hostile to implantation of a fertilized ovum by causing a nonspecific inflammatory reaction and inhibiting sperm and ovum from meeting (Wildemeersch & Jandi, 2015). The hormonal IUC will make monthly periods lighter, shorter, and less painful, making this a useful method for women with heavy, painful periods. The implants contain either copper or progesterone to enhance their effectiveness. One or two attached strings protrude into the vagina so that the user can check for placement.

Currently three intrauterine contraceptives are available in the United States: the copper ParaGard-TCu-380A, the LNG-IUS marketed as Mirena, and another LNG-IUD marketed as Skyla. The ParaGard-TCu-380A is approved for 10 years of use and is nonhormonal. Its mechanism of action is based on the release of copper ions,

which alone are spermicidal. Additionally, the device causes an inflammatory action leading to a hostile uterine environment. The TCu-380A is also approved for use as EC. Mirena provides intrauterine conception for 5 years, but has been shown to be effective for as long as 7 years. Skyla has been approved for 3 years of pregnancy prevention. Both devices release a low dose of progestin causing thinning of the endometrium and thickening of cervical mucus, which inhibits sperm entry into the upper genital tract. Their use results in a major reduction in menstrual flow and dysmenorrhea, suggesting that they are viable alternative to hysterectomy and endometrial ablation in women with menorrhagia (Atkin, Beal, Long-Middleton, et al., 2015). An advantage of these hormonally impregnated intrauterine systems is that they are relatively maintenance-free: users must consciously discontinue using them to become pregnant rather than making a daily decision to avoid conception (Alan Guttmacher Institute, 2015a).

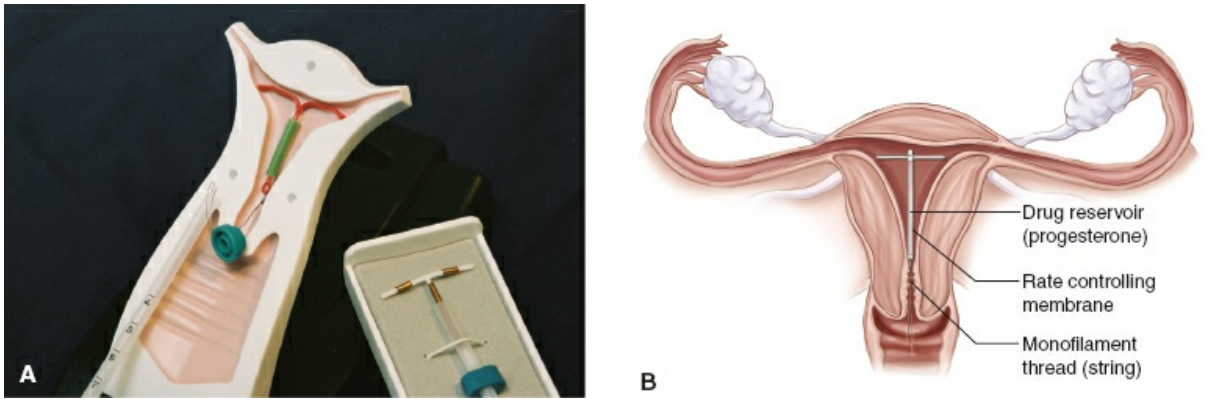

FIGURE 4.16 A. Intrauterine contraceptive. B. An IUC in place in the uterus.

The intrauterine contraceptives provide a safe, highly effective, long-lasting, yet reversible method of contraception. Expanding access to intrauterine contraception is an important measure to reduce the rate of unintended pregnancy in the United States. Nurses should consider including them in their discussion to appropriate candidates, including women who are nulliparous, adolescent, immediately postpartum, or postabortion and those who desire EC, and as an alternative to permanent sterilization. Limitations Barriers to obtaining intrauterine contraception such as requiring cervical cancer screening before insertion, routine testing for gonorrhea and chlamydial infection in low-risk women, or scheduling insertion only during menses are unnecessary. IUC insertion can take place on any day of the menstrual cycle, if absence of pregnancy is confirmed (Cheng & Van Leuven, 2015). Box 4.7 highlights the warning signs of the potential complications of IUCs.

EMERGENCY CONTRACEPTION

Unplanned pregnancy is a major health, economic, and social issue for women. Approximately one third of all unplanned pregnancies end in abortion (CDC, 2015b). Using an emergency contraceptive provides a woman a second chance to prevent an unintended pregnancy. **Emergency contraception** (EC) reduces the risk of pregnancy after unprotected intercourse or contraceptive failure such as condom breakage (Raymond & Cleland, 2015). It is used within 72 hours of unprotected intercourse to prevent pregnancy. The sooner ECs are taken, the more effective they are. They reduce the risk of pregnancy for a single act of unprotected sex by almost

80% (Samra-Latif & Wood, 2015). The methods available in the United States are progestin-only pills, Plan B One-Step (Fig. 4.17), Next Choice, Next Choice One Dose; combined estrogen and progestin pills, or insertion of a copper-releasing intrauterine system up to 7 days after unprotected intercourse. Ulipristal acetate (marketed as Ella) is a selective progesterone receptor modulator that, when taken as a single 30-mg dose, is a new, safe, and effective emergency contraceptive that can be used from the first day and up to 5 days following unprotected intercourse. The older progesterone-only emergency contraceptive, levonorgestrel, is taken as two 0.75-mg pills 12 hours apart (Next Choice; Watson Pharmaceuticals Inc., Morristown, NJ, USA) or as a single 1.5-mg pill (Plan B One-Step; Watson Pharmaceuticals Inc.), and is approved for only 72 hours after unprotected intercourse (Mulligan, 2015).

BOX 4.7

WARNINGS FOR INTRAUTERINE SYSTEM USERS OF POTENTIAL COMPLICATIONS

P = Period late, pregnancy, abnormal spotting or bleeding
A = Abdominal pain, pain with intercourse
I = Infection exposure, abnormal vaginal discharge
N = Not feeling well, fever, chills
S = String length shorter or longer or missing

Adapted from King, T. L., Brucker, M. C., Kriebs, J. M., Fahey, J. O., Gegor, C. L., & Varney, H. (2015) *Varney's midwifery* (5th ed.). Burlington, MA: Jones & Bartlett Learning.

FIGURE 4.17 Emergency contraceptive kit.

Access to emergency contraceptives has been controversial for minors. Prior to 2013, the pills were available by prescription only, and even when approved for nonprescription status, access was restricted based on age. In 2013, several judicial courts and the FDA ruled in favor of nonprescription access to EC by all women regardless of age. At this time, the federal government has not appealed these rulings, but many states have placed restrictions on access of EC (Casey & Isaacs, 2015). The only contraindication to the use of any of the four EC methods is a known pregnancy as defined as implantation.

Although access to EC has increased with nonprescription status and approval of Plan B One-Step without age restrictions, many barriers remain in public awareness and unintended pregnancies continue to rise. Because of the lack of awareness of EC and the politics surrounding it, EC is not used as widely as would be warranted by the incidence of unprotected coitus. Nurses need to educate their female clients to bring about increased awareness of this second chance method. Table 4.5 lists recommended oral medication and intrauterine regimens.

Prime points to stress-concerning ECs are:

- ECs do not offer any protection against STIs or future pregnancies.
- ECs should not be used in place of a regular birth control method, because they are less effective.
- ECs may delay the next menses, so evaluation for pregnancy is needed if menses does not occur within 3 weeks after EC use.
- Report any severe abdominal pain to health care provider immediately.
- ECs are regular birth control pills given at a higher dose.
- ECs are contraindicated during pregnancy (Ilic, 2015).

Take Note!

Contrary to popular belief, ECs do not induce abortion and are not related to mifepristone or RU-486, the so-called abortion pill approved by the FDA in 2000.

Mifepristone chemically induces abortion by blocking the body's progesterone receptors, which are necessary for pregnancy maintenance. ECs simply prevent embryo creation and uterine implantation from occurring in the first place. There is no evidence that ECs have any effect on an already implanted ovum. The side effects are nausea and vomiting.

Sterilization

Sterilization is a permanent, safe, and highly effective method of contraception for those who are certain they do not want any or any more, children. Vasectomy is the only highly reliable form of male contraception. Approximately 600,000 tubal occlusions and 200,000 vasectomies are performed in the United States annually and over 220 million worldwide (Shoupe & Mishell, 2016). It is the most widely used method of family planning in the world in both developed and developing countries. Sterilization refers to surgical procedures intended to render the person infertile. Laparoscopic, abdominal, and hysteroscopic methods of female sterilization are available in the United States, with most of these procedures performed outside the hospital. Sterilization is a safe and effective form of permanent birth control. In the United States, it is still the second most commonly used form of contraception overall and is the most frequently used method among married women and among women over 30 years of age (McKay & Schunmann, 2015). More women than men undergo surgical sterilization. According to the CDC (2015b) approximately 18% of women undergo female sterilization in comparison with 7% of men in the United States. Sterilization should be considered a permanent end to fertility because reversal surgery is difficult, expensive, and not always successful. Because these methods are intended to be irreversible, all couples should be appropriately counseled about the permanency of sterilization and the

availability of highly effective, long-acting, reversible methods of contraception before their decision is made.

TABLE 4.5 EMERGENCY POSTCOITAL CONTRACEPTION OPTIONS

Product	Dosage (Within 72 hrs)	Comments
Combined estrogen and progestin pills (Yuzpe regimen)	OCs are taken in various formulations to prevent conception	Interfere with the cascade of events that result in ovulation and fertilization
Plan B One-Step	1.5 mg pill taken	Can cause nausea and vomiting
Intrauterine		
Copper-bearing IUS (ParaGard-TCu-380A)	Inserted within 5 days after unprotected sexual episode	Can be left in for long-term contraception (10 yrs)

Adapted from King, TL., Brucker, MC., Kriebs, JM., Fahey, JO., Gegor, CL., & Varney, H. (2015) *Varney's midwifery* (5th ed.). Burlington, MA: Jones & Bartlett Learning; Ilic, K. (2015). Emergency contraception. In *Medicines for Women* (pp. 203–225). Springer International Publishing.

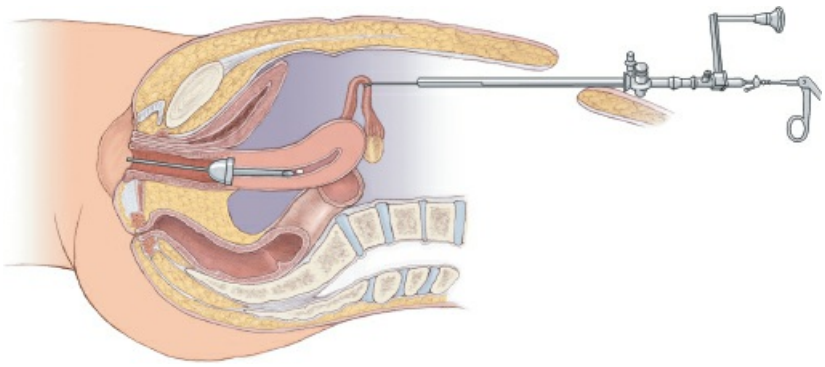

FIGURE 4.18 Laparoscopy for tubal sterilization.

TUBAL LIGATION

Tubal ligation, the sterilization procedure for women, can be performed postpartum, after an abortion, or as an interval procedure unrelated to pregnancy. Mini-laparotomies and laparoscopies are the two most common techniques. In the laparoscopy procedure, the abdomen is filled with carbon dioxide gas so that the abdominal wall balloons away from the tubes provide a view of the fallopian tubes. They are grasped and sealed with a cauterizing instrument or with rings, bands, or clips or cut and tied (Fig. 4.18).

ESSURE

Essure is a nonsurgical, nonhormonal, permanent birth control method that is 99% effective. This method is for women who desire no more children as it is a permanent method of birth control. It offers several advantages over a conventional tubal ligation: general anesthesia and incisions are not needed, thereby increasing safety, lowering costs, and improving access to sterilization. A tiny coil (Essure) is introduced and released into the fallopian tubes through the cervix. The coil promotes tissue growth in the fallopian tubes, and over a period of 3 months, this growth blocks the tubes. The buildup of tissue creates a barrier that keeps sperm from the reaching the ovum, thus preventing conception (Thurkow, 2015). This less-invasive technique uses a hysteroscopy under local anesthesia in an office setting.

Sterilization does not occur immediately after this procedure, so women must be educated to use additional contraception for 3 months until permanent tubal occlusion is verified.

VASECTOMY

Male sterilization is accomplished with a surgical procedure known as a **vasectomy**. More than 500,000 men have a vasectomy performed in the United States each year (McFarlane, 2015). It is usually performed under local anesthesia in a urologist's office, and most men can return to work and normal activities in a day or two. The procedure involves making a small incision into the scrotum and cutting the vas deferens, which carries sperm from the testes to the penis (Fig. 4.19). Complications from vasectomy are rare and minor in nature. Immediate risks include infection, hematoma, and pain. After vasectomy, semen no longer contains sperm. This is not immediate, though, and the man must submit semen specimens for analysis 8 to 16 weeks after a vasectomy until two specimens show that no sperm is present. When the specimen shows azoospermia, the man's sterility is confirmed (Whitaker, 2015).

Nursing Management of the Woman Choosing a Contraceptive Method

The choice of a contraceptive method is a very personal one involving many factors. What makes a woman choose one contraceptive method over another? In making contraceptive choices, couples must balance their sexual lives, their reproductive goals, and each partner's health and safety. The search for a choice that satisfies all three objectives is challenging. A method that works for a sexually active teenage girl may not meet her needs later in life. Several considerations influence a person's choice of contraceptives:

- Motivation
- Cost
- Cultural and religious beliefs (Box 4.8)
- Convenience
- Effectiveness
- Side effects
- Desire for children in the future
- Safety of the method
- Comfort level with sexuality
- Protection from STIs
- Interference with spontaneity

BOX 4.8

SELECTED RELIGIOUS CHOICES FOR FAMILY PLANNING AND ABORTION

- Roman Catholic—Abstinence and natural family planning; no abortion
- Judaism (Orthodox)—Family planning and abortion accepted in first trimester. Conservative and Reform Judaism accept both family planning and abortion
- Islam—Family planning accepted; abortion only for serious reasons

• Protestant Christianity—Firmly in favor of family planning; mixed on abortion
• Buddhism—Long experience with family planning and abortion
• Hinduism—Accept both family planning and abortion
• Native American religions—Accept both family planning and abortion
• Chinese religions—Taoism and Confucianism accept both

Adapted from McFarland, M. R., & Wehbe-Alamah, H. B. (2015) *Leininger's cultural care diversity and universality: A worldwide nursing theory* (3rd ed.), Burlington, MA: Jones & Bartlett Learning; McFarlane, D.R. (2015) *Global population and reproductive health*. Burlington, MA: Jones & Bartlett Learning.

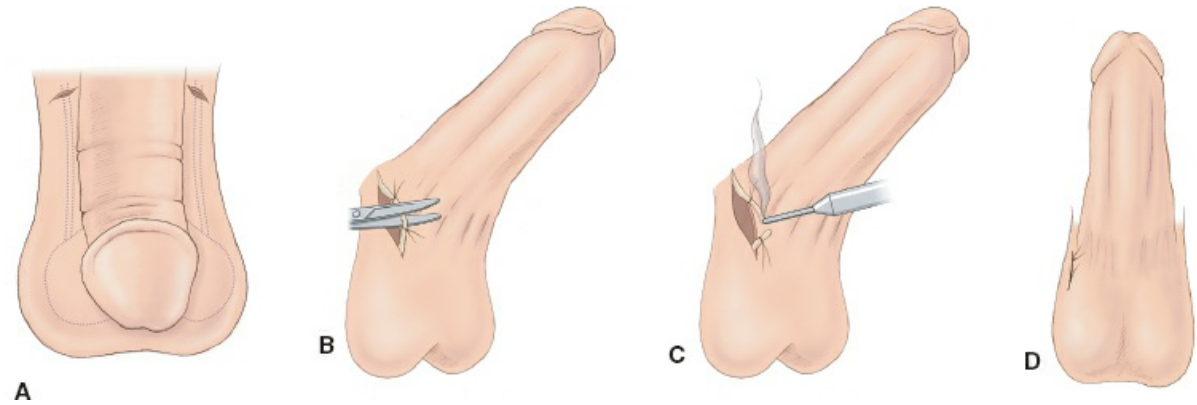

FIGURE 4.19 Vasectomy. A. Site of vasectomy incisions. B. The vas deferens is cut with surgical scissors. C. Cut ends of the vas deferens are cauterized to ensure blockage of the passage of sperm. D. Final skin suture.

If a contraceptive is to be effective, the woman must understand how it works, must be able to use it correctly and consistently, and must be comfortable and confident with it. If a client cannot adhere to taking a pill daily, consider a method used once a week (transdermal patches), once every 3 weeks (transvaginal ring), or once every 3 months (Depo-Provera injection). Another option may be a progesterone intrauterine contraceptive that lasts 3 to 5 years and reduces menstrual flow significantly.

Regardless of which method is chosen, the client's needs should be paramount in the discussion. The nurse can educate clients about which methods are available and their advantages and disadvantages, efficacy, cost, and safety. Knowledge of contraceptive effectiveness is crucial to making an informed choice. The couple has to comprehend the pros and cons of the contraceptive methods being considered. Choice may be influenced by understanding the likelihood of pregnancy with each method and factors that influence effectiveness. Counseling can help the woman choose a contraceptive method that is efficacious and fits her preferences and lifestyle.

Nursing Assessment

When assessing which contraceptive method might meet the client's needs, the nurse might ask:
• Do your religious beliefs interfere with any methods?
• Will this method interfere with your sexual pleasure?
• Are you aware of the various methods currently available?
• Is cost a major consideration, or does your insurance cover it?

- Does your partner influence which method you choose?
- Are you in a stable, monogamous relationship?
- Have you heard anything troubling about any of the methods?
- How comfortable are you touching your own body?
- What are your future plans for having children?

Although deciding on a contraceptive is a very personal decision between a woman and her partner, nurses can assist in this process by performing a complete health history and physical examination, and by educating the woman and her partner about necessary laboratory and diagnostic testing. Areas of focus during the nursing assessment are as follows:

- Medical history: smoking status, cancer of reproductive tract, diabetes mellitus, migraines, hypertension, thromboembolic disorder, allergies, risk factors for cardiovascular disease (CVD)
- Family history: cancer, CVD, hypertension, stroke, diabetes
- OB/GYN history: menstrual disorders, current contraceptive, previous STIs, PID, vaginitis, sexual activity
- Personal history: use of tampons and female hygiene products, plans for childbearing, comfort with touching herself, number of sexual partners and their involvement in the decision
- Physical examination: height, weight, blood pressure, breast examination, thyroid palpation, pelvic examination
- Diagnostic testing: urinalysis, complete blood count, Pap smear, wet mount to check for STIs, HIV/AIDS tests, lipid profile, glucose level

Figure 4.20 shows an example of a family planning flow record that can be used during the assessment. After collecting the assessment data above, consider the medical factors to help decide if the woman is a candidate for all methods or whether some should be eliminated. For example, if she reports she has multiple sex partners and a history of pelvic infections, she would not be a good candidate for an intrauterine contraceptive. Barrier methods (male or female condoms) of contraception might be recommended to this client to offer protection against STIs.

Nursing Diagnoses

A few nursing diagnoses that might be appropriate based on the nurse's assessment during the decision-making process include:

- Deficient knowledge related to:
  - Methods available
  - Side effects/safety
  - Correct use of method chosen
  - Previous myths believed
- Risk for infection related to:
  - Unprotected sexual intercourse
  - Past history of STIs
  - Methods offering protection

Nursing diagnoses applicable to the contraceptive would be:

- Health-seeking behaviors related to:
  - Perceived need for limiting number of children

  - Overall health relative to contraceptives
- Risk for ineffective health maintenance related to:
  - Not being familiar with the various contraceptive methods
  - Being unaware of high-risk sexual behavior leading to STIs
- Fear related to:
  - Not understanding the correct procedure to use
  - Unintended pregnancy occurring if not used correctly
  - General health concerning the long-term side effects

Nursing Interventions

Contraception is an important issue for all couples, and the method used should be decided by the woman and her partner jointly. Facilitate this process by establishing a trusting relationship with the client and by providing unbiased, accurate information about all methods available. As a nurse, reflect honestly on your feelings about contraceptives while allowing the client's feelings to be paramount. Be aware of the practical issues involved in contraceptive use, and avoid making assumptions, making decisions on the woman's behalf, and making judgments about her and her situation. To do so, it is important to keep up to date on the latest methods available and convey this information to clients. Encourage female clients to take control of their lives by sharing information that allows them to plan their futures.

The following guidelines are helpful in counseling and educating the client or couple about contraceptives:

- Encourage the client/couple to participate in choosing a method.
- Provide client education. The client/couple must become informed users before the method is chosen. Education should be targeted to the client's level so it is understood. Provide step-by-step teaching and an opportunity for practice for certain methods (cervical caps, diaphragms, vaginal rings, and condoms). See Teaching Guidelines 4.5 and Figure 4.21.
- Obtain written informed consents, which are needed for intrauterine contraceptives, implants, abortion, or sterilization. Informed consent implies that the client is making a knowledgeable, voluntary choice; has received complete information about the method, including the risks; and is free to change her mind before using the method or having the procedure (Schuiling & Likis, 2016).
- Discuss contraindications for all selected contraceptives.
- Consider the client's cultural and religious beliefs when providing care.
- Address myths and misperceptions about the methods under consideration in your initial discussion of contraceptives.

Teaching Guidelines 4.5
TIPS FOR THE USE OF CERVICAL CAPS, DIAPHRAGMS, VAGINAL RINGS, AND CONDOMS

Cervical Cap Insertion/Removal Technique

- It is important to be involved in the fitting process.
- To insert the cap, pinch the sides together, compress the cap dome, insert into the vagina, and place over the cervix.
- Use one finger to feel around the entire circumference to make sure there are no gaps between the cap rim and the cervix.
- After a minute or two, pinch the dome and tug gently to check for evidence of suction. The cap should resist the tug and not slide off easily.
- To remove the cap, press the index finger against the rim and tip the cap slightly to break the suction. Gently pull out the cap.
- The woman should practice inserting and removing the cervical cap three times to validate her proficiency with this device.

Client Teaching and Counseling Regarding the Cervical Cap

- Fill the dome of the cap up about one third full with spermicide cream or jelly. Do not apply spermicide to the rim, since it may interfere with the seal.
- Wait approximately 30 minutes after insertion before engaging in sexual intercourse to be sure that a seal has formed between the rim and the cervix.
- Leave the cervical cap in place for a minimum of 6 hours after sexual intercourse. It can be left in place for up to 48 hours without additional spermicide being added.
- Do not use during menses due to the potential for toxic shock syndrome. Use an alternative method such as condoms during this time.
- Replace the cervical cap after each year of use.
- Inspect the cervical cap prior to insertion for cracks, holes, or tears.
- After using the cervical cap, wash it with soap and water, dry thoroughly, and store in its container.

Diaphragm Insertion/Removal Technique

- Always empty the bladder prior to inserting the diaphragm.
- Inspect diaphragm for holes or tears by holding it up to a light source, or fill it with water and check for a leak.
- Place approximately a tablespoon of spermicidal jelly or cream in the dome and around the rim of the diaphragm.
- The diaphragm can be inserted up to 6 hours prior to intercourse.
- Select the position that is most comfortable for insertion:
  - Squatting
  - Leg up, raising the nondominant leg up on a low stool
  - Reclining position, lying on back in bed
  - Sitting forward on the edge of a chair
- Hold the diaphragm between the thumb and fingers and compress it to form a “figure-eight” shape.
- Insert the diaphragm into the vagina, directing it downward as far as it will go.
- Tuck the front rim of the diaphragm behind the pubic bone so that the rubber hugs the front wall of the vagina.
- Feel for the cervix through the diaphragm to make sure it is properly placed.
- To remove the diaphragm, insert the finger up and over the top side and move

slightly to the side, breaking the suction.
• Pull the diaphragm down and out of the vagina.

Client Teaching and Counseling Regarding the Diaphragm

• Avoid the use of oil-based products, such as baby oil, because they may weaken the rubber.
• Wash the diaphragm with soap and water after use and dry thoroughly.
• Place the diaphragm back into the storage case.
• The diaphragm may need to be refitted after weight loss or gain or childbirth.
• Diaphragms should not be used by women with latex allergies.

Vaginal Ring Insertion/Removal Technique and Counseling

• Each ring is used for one menstrual cycle, which consists of 3 weeks of continuous use followed by a ring-free week to allow for menses.
• No fitting is necessary—one size fits all.
• The ring is compressed and inserted into the vagina, behind the pubic bone, as far back as possible.
• Precision placement is not essential.
• Backup contraception is needed for 7 days if the ring is expelled for more than 3 hours during the 3-week period of continuous use.
• The vaginal ring is left in place for 3 weeks, then removed and discarded.
• The vaginal ring is not recommended for women with uterine prolapse or lack of vaginal muscle tone (Schuiling & Likis, 2016).

Male Condom Insertion/Removal Technique and Counseling

• Always keep the condom in its original package until ready to use.
• Store in a cool, dry place.
• Spermicidal condoms should be used if available.
• Check expiration date before using.
• Use a new condom for each sexual act.
• Condom is placed over the erect penis prior to insertion.
• Place condom on the head of the penis and unroll it down the shaft.
• Leave a half-inch of empty space at the end to collect ejaculate.
• Avoid use of oil-based products, because they may cause breakage.
• After intercourse, remove the condom while the penis is still erect.
• Discard condom after use.

Female Condom Insertion/Removal Technique and Counseling

• Practice wearing and inserting prior to first use with sexual intercourse.
• Condom can be inserted up to 8 hours before intercourse.
• Condom is intended for one-time use.
• It can be purchased over the counter—one size fits all.
• Avoid wearing rings to prevent tears; long fingernails can also cause tears.
• Spermicidal lubricant can be used if desired.
• Insert the inner ring high in the vagina, against the cervix.
• Place the outer ring on the outside of the vagina.
• Make sure the erect penis is placed inside the female condom.

• Remove the condom after intercourse. Avoid spilling the ejaculate.

Education and Counseling of Women Using Injectable Contraceptives

• Consume a diet high in calcium and vitamin D to prevent bone mineral loss
• Know the conditions that need to be reported to the health care provider
  • Significant headaches
  • Menorrhagia
  • Depression
  • Severe abdominal pain
• Awareness of any infection present at injection site

FIGURE 4.21 **The nurse demonstrates insertion of a vaginal ring during client teaching.**

It is also important to clear up common misconceptions about contraception and pregnancy. Clearing up misconceptions will permit new learning to take hold and a better client response to whichever methods are explored and ultimately selected. Some common misconceptions include:
• Breast-feeding protects against pregnancy.
• Pregnancy can be avoided if the male partner "pulls out" before he ejaculates.
• Pregnancy cannot occur during menses.
• Douching after sex will prevent pregnancy.
• Pregnancy will not happen during the first sexual experience.
• Taking birth control pills protects against STIs.
• The woman is too old to get pregnant.
• If female orgasm is not reached, conception is not likely.
• Irregular menstruation prevents pregnancy.

When discussing in detail each method of birth control, focus on specific information for each method outlined. Include information such as how this particular method works to prevent pregnancy under normal circumstances of use; the noncontraceptive benefits to overall health; advantages and disadvantages of all methods; the cost involved for each particular method; danger signs that need to be reported to the health care provider; and the required frequency of office visits needed for the particular method.

In addition, outline factors that place the client at risk for method failure. Contraceptives can fail for any of many reasons. Use Table 4.6 to provide client education concerning a few of the reasons for contraceptive failure. Help clients

who have chosen abstinence or fertility awareness methods to define the sexual activities in which they do or do not want to participate. This helps them set sexual limits or boundaries. Help them to develop communication and negotiation skills that will allow them to be successful. Supporting, encouraging, and respecting a couple's choice of abstinence is vital for nurses.

TABLE 4.6 CONTRACEPTIVE PROBLEMS AND EDUCATIONAL NEEDS

Contraceptive Failure Problem	Client Education Needed
Not following instructions for use of contraceptive correctly	Take pill the same time every day Use condoms properly and check condition before using Make sure diaphragm or cervical cap covers cervix completely Check IUD for placement monthly
Inconsistent use of contraceptive	Contraceptives must be used regularly to achieve maximum effectiveness All it takes is one unprotected act of sexual intercourse to become pregnant Two to 5% of condoms will break or tear during use
Condom broke during sex	Check expiration date Store condoms properly Use only a water-based lubricant Watch for tears caused by long fingernails Use spermicides to decrease possibility of pregnancy Seek emergency postcoital conception
Use of antibiotics or other herbs taken with OCs	Use alternative methods during the antibiotic therapy, plus 7 additional days. Implement on day 1 of taking antibiotics
Belief that you can't get pregnant during menses or that it is safe "just this one-time"	It may be possible to become pregnant on almost any day of the menstrual cycle

After clients have chosen a method of contraception, it is important to address the following:

- Emphasize that a second method to use as a backup is always needed.
- Provide both oral and written instructions on the method chosen.
- Discuss the need for STI protection if not using a barrier method.
- Inform the client about the availability of ECs.

Steady progress in contraception research has been achieved over the past several years. Hormonal and nonhormonal contraceptives have improved women's lives by reducing different health conditions that contribute to morbidity. However, the contraceptives available today are not suitable to all users, and the need to expand contraceptive choices still exists. It is hoped that the introduction of newer methods in the near future with additional health benefits will continue to help women and couples meet their family planning needs.

ABORTION

Abortion is defined as the expulsion of an embryo or fetus before it is viable (Alexander, LaRosa, Bader, et al., 2014). Abortion can be a medical or surgical procedure. The purpose of abortion is to terminate a pregnancy. More than 40% of all women will end a pregnancy by abortion at some time in their reproductive lives. Both in the United States and globally, more than one fifth of all known pregnancies end in abortion (McFarlane, 2015). Surgical abortion is the most common procedure performed in the United States (approximately 1.3 million

annually) and might be the most common surgical procedure in the world (Alan Guttmacher Institute, 2015b). Both medical and surgical abortions are safe and legal in the United States; an abortion is considered a woman's constitutional right based on the fundamental right to privacy. Eighty-nine percent of abortions occur in the first 12 weeks of pregnancy (Alan Guttmacher Institute, 2015b).

Since the landmark U.S. Supreme Court decision *Roe v. Wade* legalized abortion in 1973, debate has continued over how and when abortions are provided. Every state has laws regulating some aspects of the provision of abortion, and many have passed restrictions such as parental consent or notification requirements, mandated counseling and waiting periods, and limits on funding for abortion. Each state addresses these matters independently, and the laws that are passed or enforced are legislative decisions and a function of the political system. Although opponents of abortion continue to be very much a part of the current debates, recently they have refocused their attention on "regulation legislation" among the states to reduce the number of abortions not medically necessary (Kreitzer, 2015).

Surgical Abortion

Two types of surgical abortion are available: vacuum aspiration or dilation, and evacuation (D&C). Method selection is based on gestational age. It is an ambulatory procedure done under local anesthesia. The cervix is dilated prior to surgery and then the products of conception are removed by suction evacuation. The uterus may gently be scraped by curettage to make sure that it is empty. The entire procedure lasts about 10 minutes. The overall risk of complications is less than 1% for surgical termination (Upadhyay, Desai, Zlidar, et al., 2015). The major risks and complications in the first trimester are infection, retained tissue, or hemorrhage, uterine perforation, retained products of conception, or cervical tear (Udoh, Effa, Oduwole, et al., 2015). For women whose blood is Rh negative, *RhoGAM* is indicated prior to start of either medical or surgical termination.

Medical Abortion

Medical abortions are achieved through administration of medication either vaginally or orally. The administration of medication occurs in the clinic or doctor's office, may require two to four office visits, and costs between $300 and $800 (Planned Parenthood, 2015b). Three drugs are currently used to terminate a pregnancy during the first trimester. The first drug is methotrexate (an antineoplastic agent; Rheumatrex) followed by misoprostol (a prostaglandin agent; Cytotec) given as a vaginal suppository or in oral form 3 to 7 days later. Methotrexate induces abortion because of its toxicity to trophoblastic tissue, the growing embryo. Misoprostol works by causing uterine contractions, which helps to expel the products of conception. This method is 90% to 98% successful in completing an abortion (Patil & Edelman, 2015).

The second drug used to induce first-trimester abortions involves using mifepristone (a progesterone antagonist; Mifeprex, RU-486) followed 48 hours later by misoprostol (a prostaglandin agent), which causes contractions of the uterus and expulsion of the uterine contents. Currently, the most widely used method of medication abortion in the United States is the administration of mifepristone in conjunction with misoprostol. Another frequent method used includes the

combination of methotrexate with misoprostol (Schuiling & Likis, 2016). Mifepristone, the generic name for RU-486, is sold under the brand names Mifeprex and Early Option. Mifepristone is an antiprogestin and blocks the action of progesterone, which is necessary for the maintenance of the pregnancy. This method is 95% effective when used within 49 days after the last menstrual cycle (Patil & Edelman, 2015).

Another drug frequently used is misoprostol (Cytotec), which is a prostaglandin analog that softens the cervix and causes uterine contractions, which results in the expulsion of uterine contents. There is no standard protocol for use of misoprostol (Cytotec) alone for termination of early pregnancy, and it is not FDA-approved for this purpose (King et al., 2015). Complications of medical abortions include incomplete expulsion of uterine contents; uterine infection; and heavy bleeding (Ganatra, Guest, & Berer, 2015).

The assessment of the woman with an unintended pregnancy should be performed with cautious sensitivity. It is essential to explore the women's feelings about pregnancy before congratulating or consoling her. The encounter should be guided by the feelings of the client, not by the assumptions and values of the nurse.

Abortion is a very emotional, deeply personal issue. Give support and accurate information. If for personal, religious, or ethical reasons you feel unable to actively participate in the care of a woman undergoing an abortion, you still have the professional responsibility to ensure that the woman receives the nursing care and help she requires. This may necessitate a transfer to another area or a staffing reassignment. Nurses must keep in mind that all women have the right to have access to unbiased, factual information about available reproductive health choices, whether they seek to end or start a pregnancy, from which they can then make informed decisions about their own reproductive health.

MENOPAUSAL TRANSITION

Menopause is a natural process that occurs in all women's lives as part of normal aging. *Meno* is derived from the Greek word for "month," and *pause* is derived from the Greek word for "pause" or "halt." Menopause is the technical term for a point in time at which menses and fertility cease (King et al., 2015). The change of life. The end of fertility. The beginning of freedom. Whatever people call it, menopause is a unique and personal experience for every woman. The term **menopausal transition** refers to the transition from a woman's reproductive phase of her life to her final menstrual period. This period is also referred to as *perimenopause.* It is the end of her menstruation and childbearing capacity. The average age of natural menopause—defined as 1 year without a menstrual period—is 51.4 years old. The average age of natural menopause has remained constant for the last several hundred years despite improvements in nutrition and health care (Alexander et al., 2014). With current female life expectancy at 84 years, this event comes in the middle of a woman's adult life. Many women go through the menopausal transition with few or no symptoms, while some have significant or even disabling symptoms (Kessenich, 2015).

Take Note!

Humans are virtually the only species to outlive their reproductive capacities.

Menopause signals the end of an era for many women. It concludes their ability to reproduce, and some women find advancing age, altered roles, and these physiologic changes to be overwhelming events that may precipitate depression and anxiety (Woods & Mitchell, 2015). Menopause does not happen in isolation. Midlife is often experienced as a time of change and reflection. Change happens in many arenas: children are leaving or returning home, employment pressures intensify as career moves or decisions are required, older adult parents require more care or the death of a parent may have a major impact, and partners are retrenching or undergoing their own midlife crises. Women must negotiate all these changes in addition to menopause. Managing these stressful changes can be very challenging for many women as they make the transition into midlife.

A woman is born with approximately 2 million ova, but only about 400 ever mature fully to be released during the menstrual cycle. The absolute number of ova in the ovary is a major determinant of fertility. Over the course of her premenopausal life there is a steady decline in the number of immature ova (Wood, 2015). No one understands this depletion, but it does not occur in isolation. Maturing ova are surrounded by follicles that produce two major hormones: estrogen, in the form of estradiol, and progesterone. The cyclic maturation of the ovum is directed by the hypothalamus. The hypothalamus triggers a cascade of neurohormones, which act through the pituitary and the ovaries as a pulse generator for reproduction. This hypothalamic–pituitary–ovarian axis begins to break down long before there is any sign that menopause is imminent. Some scientists believe that the pulse generator in the hypothalamus simply degenerates; others speculate that the ovary becomes more resistant to the pituitary hormone FSH and simply shuts down (Schuiling & Likis, 2016). The final act in this well-orchestrated process is amenorrhea.

As menopause approaches, more and more of the menstrual cycles become anovulatory. This period of time, usually 2 to 8 years before cessation of menstruation, is termed *perimenopause* (McNamara, Batur, & DeSapri, 2015). In perimenopause, the ovaries begin to fail, producing irregular and missed periods and an occasional hot flash. When menopause finally appears, viable ova are gone. Estrogen levels plummet by 90%, and estrone, produced in fat cells, replaces estradiol as the body's main form of estrogen. The major hormone produced by the ovaries during the reproductive years is estradiol; the estrogen found in postmenopausal women is estrone. Estradiol is much more biologically active than estrone (Hoyt & Falconi, 2015). In addition, testosterone levels decrease with menopause.

Menopausal transition, with its dramatic decline in estrogen, affects not only the reproductive organs, but also other body systems:

- Brain: hot flashes, disturbed sleep, mood and memory problems
- Cardiovascular: lower levels of HDL and increased risk of CVD
- Skeletal: rapid loss of bone density that increases the risk of osteoporosis
- Breasts: replacement of duct and glandular tissues by fat
- Genitourinary: vaginal dryness, stress incontinence, cystitis
- Gastrointestinal: less absorption of calcium from food, increasing the risk for fractures
- Integumentary: dry, thin skin and decreased collagen levels
- Body shape: more abdominal fat; waist size that swells relative to hips

Therapeutic Management

Menopausal transition should be managed individually. In the past, despite the wide diversity of symptoms and risks, the traditional reaction was to reach for the one-size-fits-all therapy: hormone therapy. Today the medical community is changing its thinking in light of the Women's Health Initiative (WHI) study and the Heart and Estrogen/Progestin Replacement Study Follow-Up (HERS II), which reported that long-term hormone therapy (HT) increased the risks of heart attacks, strokes, and breast cancer; in short, the overall health risks of HT exceeded the benefits (Kyvernitakis, Kostev, Hars, et al., 2015). In addition, HT did not protect against the development of coronary artery disease (CAD), nor did it prevent the progression of CAD, as it was previously touted to do.

A recent research finding examined the timing of HT in relation to CAD in women and it found that the earlier initiation of HT was associated with less CAD in women with natural but not surgical menopause. A Cochrane Review study found that hormone therapy in postmenopausal women overall, had little benefit in CAD prevention, but caused an increase in the risk of stroke and venous thromboembolic events (Boardman Hartley, Eisinga, et al., 2015). As expected, the fallout from this study and others forced practitioners to reevaluate their usual therapies and tailor treatment to each client's history, needs, and risk factors. A current study, however, shows that the incidence of fractures among menopausal transition and postmenopausal women increased significantly in the 3 years after publication of the WHI and HERS II results. This trend followed a decline in the use of hormone therapy, concurrent with an increase in the use of other bone-modifying agents (Bakour & Williamson, 2015). There is considerable evidence that estrogen or hormone therapy reduces the risk of postmenopausal osteoporotic fracture of both the spine and hip (Mirkin, Archer, Pickar, et al., 2015).

A number of treatment options are available, but factors in the client's history should be the driving force when determining therapy. Women need to educate themselves about the latest research findings and collaborate with their health care provider on the right menopause therapy. The following factors should be considered in management:

- The risk/benefit ratio is highest in younger women who begin HT not long after menopause.
- HT is approved for two indications: relief of vasomotor symptoms and prevention of osteoporosis.
- Research suggests that HT may be beneficial for preventing diabetes, improving mood, or avoiding urinary tract problems.
- Using HT long beyond menopause carries increased risks, which, for some women, may be outweighed by the benefits (Bakour & Williamson, 2015).

Many women consider nonhormonal therapies such as bisphosphonates and selective estrogen receptor modulators (SERMs). Consider weight-bearing exercises, calcium, vitamin D, smoking cessation, and avoidance of alcohol to treat or prevent osteoporosis. Annual breast examinations and mammograms are essential. Local estrogen creams can be used for vaginal atrophy. Consider herbal therapies for symptoms, although none have been validated by rigorous research studies (Ismail, Taylor-Swanson, Thomas, et al., 2015).

ACOG recently revised guidelines on treating menopausal symptoms. Their

recommendations include systemic HT, with estrogen or estrogen plus progestin, which is the most effective approach for treating vasomotor symptoms; the lowest effective dose for the shortest duration is the best regimen; thromboembolic disease and breast cancer are risks for combined systemic HT; and local estrogen therapy is advised for isolated atrophic vaginal symptoms (2014).

Although numerous symptoms have been attributed to menopause (Box 4.9), some of them are more closely related to the aging process than to estrogen deficiency. A few of the more common menopausal conditions and their management are discussed next.

BOX 4.9

COMMON SYMPTOMS OF MENOPAUSE

- Hot flashes or flushes of the head and neck
- Dryness in the eyes and vagina
- Personality changes
- Anxiety and/or depression
- Loss of libido
- Decreased lubrication
- Weight gain and water retention
- Night sweats
- Atrophic changes—loss of elasticity of vaginal tissues
- Fatigue
- Irritability
- Poor self-esteem
- Insomnia
- Stress incontinence
- Heart palpitations

Managing Hot Flashes and Night Sweats

The emergence of hot flashes and night sweats (also known as vasomotor symptoms) coincides with a period in life that is also marked by dynamic changes in hormone and reproductive function that interconnect with the aging process, changes in metabolism, lifestyle behaviors, and overall health (Wood, 2015). Hot flashes and night sweats are classic signs of estrogen deficiency and the predominant complaint of perimenopausal women. A hot flash is a transient and sudden sensation of warmth that spreads over the body, particularly the neck, face, and chest. Hot flashes are caused by vasomotor instability. This instability causes inappropriate peripheral vasodilation of superficial blood vessels, which gives the sensation of heat. Nearly 85% of menopausal women experience them (Alexander et al., 2014). Hot flashes are an early and acute sign of estrogen deficiency. These flashes can be mild or extreme and can last from 2 to 30 minutes and may occur as

frequently as every hour to several times per week. On average, women experience hot flashes for a period of 6 months to 2 years, but the symptoms may last up to 10 years or more. Severe vasomotor symptoms can have a significant and detrimental effect on quality of life. Factors that trigger vasomotor symptoms include caffeine and alcohol consumption, intake of hot drinks and spicy foods, hot environment, depression, stress and anxiety (Avis, Crawford, Greendale, et al., 2015).

Many options are available for treating hot flashes. Treatment must be based on symptom severity, the client's medical history, and the client's values and concerns. Although the gold standard in the treatment of hot flashes is estrogen, this is not recommended for all women who have high risk factors in their history.

TRADITIONAL THERAPIES FOR THE MANAGEMENT OF HOT FLASHES

The following are traditional therapies for the management of hot flashes:

- Pharmacologic options
- HT unless contraindicated
- Androgen therapy (potentiates estrogen)
- Estrogen and androgen combinations
- Progestin therapy (Depo-Provera injection every 3 months)
- Clonidine (central alpha-adrenergic agonist) weekly patch
- Neurontin (antiseizure) decreased hot flashes
- Propranolol (beta-adrenergic blocker)
- Brisdelle: FDA-approved nonhormonal medication
- Short-term sleep aids: Ambien, Dalmane
- Gabapentin (Neurontin): antiseizure drug
- SSRIs: venlafaxine (Effexor) and paroxetine (Paxil) have shown promise (King & Brucker, 2016).

COMPLEMENTARY AND ALTERNATIVE THERAPIES FOR MANAGEMENT OF HOT FLASHES

Many women are choosing alternative treatments for managing menopausal symptoms. Bioidentical hormones have the ability to bind to receptors in the human body and function in the same way as a woman's natural hormones. They simulate three estrogens (estradiol, estriol, and estrone), as well as progesterone, testosterone, dehydroepiandrosterone (DHEA), thyroxine, and cortisol. Bioidentical hormones are not, however, natural hormones. The estrogens are derived via a chemical process from soybeans (*Glycine max*) and progesterone from Mexican yam (*dioscorea villosa*). As with conventional hormones, however, bioidentical hormones are available only with a physician's prescription and through a pharmacy. Because of their natural origin, women perceive that alternative treatments are safer. The interest in phytoestrogens came about because of the low prevalence of hot flashes in Asian women, which was attributed to their diet being rich in phytoestrogens. Recent studies have found that black cohosh, multibotanical herbs, and increased soy intake do not reduce the frequency or severity of menopausal hot flashes or night sweats.

Other remedies for easing menopausal symptoms might include red clover, motherwort, ginseng, sarsaparilla root, valerian root, L-tryptophan, calcium-magnesium, and kelp tablets (Ismail et al., 2015). Again, research thus far has been

skeptical about their efficacy, but many women report they ease their symptoms and their use has skyrocketed. Although some benefits may accrue from their use, evidence of the efficacy of alternative products in menopause is largely anecdotal. Small, preliminary clinical trials might demonstrate the safety of some of the nonpharmacologic products. Nurses should be aware of the purported action of these agents as well as any adverse effects or drug interactions.

The following are lifestyle changes and CAM therapies for the treatment of hot flashes:

- Lifestyle changes
- Lower room temperature; use fans.
- Wear clothing in layers for easy removal.
- Limit caffeine and alcohol intake.
- Drink 8 to 10 glasses of water daily.
- Stop smoking or cut back.
- Avoid hot drinks and spicy food.
- Take calcium (1,200 to 1,600 mg) and vitamin D (400 to 600 International Units).
- Exercise daily, but not just before bedtime.
- Maintain a healthy weight.
- Identify stressors and learn to manage them.
- Keep a diary to identify triggers of hot flashes.
- Phytoestrogens: isoflavones, ligands, coumetrols
- Black cohosh
- Chamomile: mild sedative to alleviate insomnia
- Unopposed transdermal progesterone
- Compounded bioidentical hormones
- Try relaxation techniques, deep breathing, and meditation
- Acupuncture may reduce the frequency of hot flashes
- Vitamin E: 100 mg daily
- DHEA
- Chaste tree berry (vitex): balances progesterone and estrogen
- Dong quai: acts as a form of phytoestrogen
- Ginseng: purported to improve memory
- St. John's wort: reduces depression and fatigue
- Wild yam: treats menopausal symptoms
- Valerian root: induces sleep and relaxation (Wood, 2015).

Managing Urogenital Changes

Menopausal transition can be a physically and emotionally challenging time for women. In addition to the psychological burden of leaving behind the reproductive phase of life and the stigma of an aging body, sexual difficulties resulting from urogenital changes plague most women but are frequently not addressed. Sexual desire is affected by endocrine and psychosocial factors. Menopausal hormonal changes are relevant to the causes of sexual dysfunction during reproductive aging. The frequency of sexual intercourse declines as women enter midlife. Whereas partner availability and function probably play a role, menopausal symptoms, such as vaginal dryness, are also present (Comhaire & Depypere, 2015).

Vaginal atrophy occurs during menopause because of declining estrogen levels. These changes include thinning of the vaginal walls, an increase in pH, irritation,

increased susceptibility to infection, **dyspareunia** (difficult or painful sexual intercourse), loss of lubrication with intercourse, vaginal dryness, and a decrease in sexual desire related to these changes. Decreased estrogen levels can also influence a woman's sexual function as well. Delayed clitoral reaction, decreased vaginal lubrication, diminished circulatory response during sexual stimulation, and reduced contractions during orgasm have all been linked to low estrogen levels (Coney, 2015).

Management of these changes might include the use of estrogen vaginal tablets (Vagifem) or Premarin cream; Estring, an estrogen-releasing vaginal ring that lasts for months; testosterone patches; and over-the-counter moisturizers and lubricants (Astroglide) (King et al., 2015). A positive outlook on sexuality and a supportive partner are also needed to make the sexual experience enjoyable and fulfilling. Nurses can improve the sexual health and quality of life in menopausal women by educating them about their symptoms and offering them choices about managing them.

Take Note!

Sexual health is an important aspect of the human experience. By keeping an open mind, listening to women, and providing evidence-based treatment options, the nurse can help improve quality of life for menopausal women.

Preventing and Managing Osteoporosis

Osteoporosis has been recognized as a significant worldwide public health problem. As the world's population ages, both in the United States and internationally, the prevalence of osteoporosis is expected to increase significantly. **Osteoporosis** is the state of diminished bone density. This disorder is a systemic skeletal disease characterized by low bone mass and microarchitectural deterioration of bone tissue with a consequent increase in bone fragility and susceptibility to fracture (National Osteoporosis Foundation [NOF], 2015a).

According to recent information from NOF (2015a), osteoporosis is a major medical problem that affects 10 million women and 2 million men in the United States. An additional 34 million Americans have low bone mass. Each year, an estimated 1.5 million individuals in the United States experience a fragility fracture secondary to osteoporosis, resulting in an annual cost of $18 billion. By 2025, experts predict that osteoporosis will be responsible for approximately 3 million fractures and $26 billion in costs each year (NOF, 2015a). With the rapidly aging population, the problem of osteoporosis is now reaching epidemic proportions. Seventy-five million baby boomers are entering the stage in their lives when they are most at risk for osteoporosis. One half of all women and one third of all men will sustain a fragility fracture during their lifetimes. Osteoporosis continues to be underdiagnosed and undertreated because it is often not recognized until the first fracture occurs.

Women are greatly affected by osteoporosis after menopause. Osteoporosis is a condition in which bone mass declines to such an extent that fractures occur with minimal trauma. Bone loss begins in the third or fourth decade of a woman's life and accelerates rapidly after menopause (Alexander et al., 2014). This condition puts many women into long-term care, with a resulting loss of independence. Figure 4.22 shows the skeletal changes associated with osteoporosis.

Most women with osteoporosis do not know they have the disease until they sustain a fracture, usually of the wrist or hip. Risk factors include:

- Increasing age
- Postmenopausal status without hormone replacement
- Small, thin-boned frame
- Low BMD
- White or Asian with small bone frame
- Impaired eyesight that would increase risk of falling
- Rheumatoid arthritis
- Family history of osteoporosis
- Sedentary lifestyle
- History of treatment with:
  - Antacids with aluminum
  - Heparin
  - Long-term use of steroids >3 months
  - Thyroid replacement drugs
- Smoking and consuming alcohol
- Low calcium and vitamin D intake
- Excessive amounts of caffeine
- Personal history of nontraumatic fracture
- Anorexia nervosa or bulimia (NOF, 2015a)

FIGURE 4.22 Skeletal changes associated with osteoporosis. (John Radcliffe Hospital/Photo Researcher Inc.)

Currently, no method exists for directly measuring bone mass. Instead a BMD measurement is used. BMD is a two-dimensional measurement of the average content of mineral in a section of bone. BMD evaluations are made at the hip, femoral neck, and spine. There is a significant relationship between BMD and fracture: as BMD is reduced, the risk of fracture increases (Sullivan, Lehman, Thomas, et al., 2015). Screening tests to measure bone density are not good predictors for young women who might be at risk for developing this condition. Dual-energy x-ray absorptiometry (DXA or DEXA) is a screening test that calculates

the mineral content of the bone at the spine and hip. It is highly accurate, fast, and relatively inexpensive. The dual-energy x-ray absorptiometry scan (DEXA scan) is the gold standard radiologic method for identifying osteoporosis through measuring BMD (U.S. Preventive Services Task Force, 2015).

Hip fracture is the most devastating of the fragility fractures secondary to osteoporosis. A number of medical, social, and economic consequences follow a hip fracture. Of women older than 50 years, on average, 24% die within the first year after hip fracture (Wang, Chen, Cheng, et al., 2015). The concern surrounding osteoporosis is not the rate of fracture alone but also the potential for lifelong disability secondary to fracture. The incidence of hip fracture is estimated to double by the year 2025 and nearly double again by 2050. For women, this is a projected 240% increase (NOF, 2015a).

The best management for this painful, crippling, and potentially fatal disease is prevention.

Women can modify many risk factors by doing the following:

- Engage in daily weight-bearing exercise, such as walking to increase osteoblast activity.
- Increase calcium and vitamin D intake.
- Avoid smoking and excessive alcohol (more than two drinks per day).
- Discuss bone health with a health care provider.
- When appropriate, have a bone density test and take medication if needed (NOF, 2015b).

Medications that can help in preventing and managing osteoporosis include:

- HT (Premarin)
- SERMs (raloxifene [Evista])
- Calcium and vitamin D supplements (Tums)
- Estrogen agonist/antagonist (SERM) (Evista)
- Bisphosphonates (Actonel, Fosamax, Boniva, or Reclast)
- Parathyroid hormone (Forteo)
- Calcitonin (Miacalcin) (King & Brucker, 2016).

Preventing and Managing Cardiovascular Disease

Despite the dramatic decrease in annual CVD mortality and total cardiovascular mortality for American women each year since 2000, CVD remains the number-one killer of women, accounting for 1 in 3 deaths in the United States. This is likely due to increased rates of obesity, sedentary lifestyle, diabetes, and high cholesterol levels (Chomistek, Chiuve, Eliassen, et al., 2015). More women die from heart disease and stroke than the next five causes of death combined, including breast cancer. Half a million women die annually in the United States of CVD, with strokes accounting for about 20% of the deaths (Alexander et al., 2014). This translates into approximately one death every minute. While men's mortality from CVD has decreased since the 1980s, women's mortality from CVD has climbed. This has resulted in a sex-related CVD mortality gap, with women having higher mortality than men since 1984. Contributing to this female-majority CVD mortality gap is a lack of awareness among women and their physicians of the risk for CVD. Awareness campaigns, such as the Heart Truth and the Red Dress symbol, appear to have improved recognition of CVD risk in women. Further, female-specific

guidelines have been developed to prevent and reduce CVD in women. Though the current understanding of the role of menopause in CVD is controversial, studies suggest that menopause does not exacerbate CVD independent of aging, and HT is not effective for secondary prevention of CVD (Hale & Shufelt, 2015).

For the first half of a woman's life, estrogen seems to be a protective substance for the cardiovascular system by smoothing, relaxing, and dilating blood vessels. It even helps boost HDL and lower HDL levels, helping to keep the arteries clean from plaque accumulation. But when estrogen levels plummet as women age and experience menopause, the incidence of CVD increases dramatically. Women are more likely to have atypical cardiovascular symptoms compared with men. This may lead to a delayed or misdiagnosis of CAD and suboptimal treatment. These symptoms may include:

- A—Angina (chest pain)
- B—Breathlessness
- C—Chronic fatigue
- D—Dizziness
- E—Edema of hands and feet
- F—Fluttering of the heart
- G—Gastric upset
- H—Heavy pain in back and shoulders

Menopause is not the only factor that increases a woman's risk for CVD. Lifestyle and medical history factors such as the following play a major role:

- Smoking
- Obesity
- High-fat diet
- Sedentary lifestyle
- High cholesterol levels
- Family history of CVD
- Hypertension
- Apple-shaped body
- Diabetes

Two of the major risk factors for coronary heart disease are hypertension and dyslipidemia. Both are modifiable and can be prevented by lifestyle changes and, if needed, controlled by medication. This is why prevention is essential. In addition, women who experience early menopause lose the protection afforded by endogenous estrogen to the cardiac system and are at greater risk for more extensive atherosclerosis. Major preventive strategies include a healthy diet, increased activity, exercise, smoking cessation, decreased alcohol intake, and weight reduction.

Nurses, particularly those caring for women during their reproductive years, are uniquely positioned to provide education and support for women's long-term cardiovascular health. Raising awareness of heart disease in women is an essential role for nurses. The good news is that CVD is largely preventable. Because CVD is a chronic disease that develops over time, primary prevention lifestyle modification interventions are most effective if initiated before the development of overt disease. Stressing the importance of lifestyle modifications must begin early in life and should be reinforced from the beginning of a young woman's reproductive years

through menopause (CDC, 2015b). Nurses are in an ideal position to teach the importance of good nutrition, healthy weight, and daily exercise before CVD becomes clinically evident.

Nursing Assessment

Menopausal transition is a universal and irreversible part of the overall aging process involving a woman's reproductive system. Although not a disease state, menopausal transition does place women at greater risk for the development of many conditions of aging. Nurses can help the woman become aware of her risk for postmenopausal diseases, as well as strategies to prevent them. The nurse can be instrumental in assessing risk factors and planning interventions in collaboration with the client. These might include:

- Screening for osteoporosis, CVD, and cancer risk:
  - Assessment of blood pressure to identify hypertension
  - Blood cholesterol test to identify hyperlipidemia risk
  - Mammogram to find a cancerous lesion
  - Pap smear to identify cervical cancer
  - Pelvic examination to identify endometrial cancer or masses
  - Digital rectal examination to assess for colon cancer
  - Bone density testing as a baseline at menopause to identify osteopenia (low bone mass), which might lead to osteoporosis
- Assessing lifestyle to plan strategies to prevent chronic conditions:
  - Dietary intake of fat, cholesterol, and sodium
  - Weight management
  - Calcium intake
  - Use of tobacco, alcohol, and caffeine
  - Amount and type of daily exercise routines

Nursing Management

There is no "magic bullet" in managing menopause. Nurses can counsel women about their risks and help them to prevent disease and debilitating conditions with specific health maintenance education. Women should make their own decisions, but the nurse should make sure they are armed with the facts to do so intelligently. Nurses can offer a thorough explanation of the menopausal process, including the latest research findings, to help women understand and make decisions about this inevitable event.

If the woman decides to use HT to control her menopausal symptoms, after being thoroughly educated, she will need frequent reassessment. There are no hard-and-fast rules that apply to meeting a woman's individual needs. The nurse can provide realistic expectations of the therapy to reduce the woman's anxiety and concern.

It is also useful to emphasize the value of friends to gain support and share information and resources. Often just talking about emotional difficulties such as the death of a parent or problematic relationships helps solve problems. It also shows the woman that her emotional responses are valid.

Healthy lifestyles and stress management techniques are vital to health and longevity, and it is important to keep these on the client's agenda when discussing menopause (North American Menopause Society, 2015). Evidence-based

interventions include lifestyle modifications, risk management therapies, and preventive drug interventions, such as the following:

- Participate actively in maintaining health.
- Exercise regularly to prevent CVD and osteoporosis.
- Take supplemental calcium and eat appropriately to prevent osteoporosis.
- Stop smoking to prevent lung and heart disease.
- Reduce caffeine and alcohol intake to prevent osteoporosis.
- Monitor blood pressure, lipids, and diabetes (drug therapy management).
- Use low-dose aspirin to prevent blood clots.
- Reduce dietary intake of fat, cholesterol, and sodium to prevent CVD.
- Maintain a healthy weight for body frame.
- Perform breast self-examinations for breast awareness.
- Control stress to prevent depression (Worel & Hayman, 2015; Houseman & Odum, 2016).

These life approaches may seem low-tech, but they can stave off menopause-related complications such as CVD, osteoporosis, and depression. These tips for healthy living work well, but the client needs to be motivated to stick with them.

NURSING CARE PLAN 4.1

Overview of a Woman with Abnormal Uterine Bleeding

Stacy, a 52-year-old obese woman, comes to her gynecologist with the complaint of heavy erratic bleeding. Her periods were fairly regular until about 4 months ago, and since that time they have been unpredictable, excessive, and prolonged. Stacy reports she is tired all the time, can't sleep, and feels "out of sorts" and anxious. She is fearful she has cancer.

NURSING DIAGNOSIS: Fear related to current signs and symptoms possibly indicating a life-threatening condition

Outcome Identification and Evaluation

The client will acknowledge her fears as evidenced by statements made that fear and anxiety have been lessened after explanation of diagnosis.

Interventions: *Reducing Fear and Anxiety*

- Distinguish between anxiety and fear to determine appropriate interventions.
- Check complete blood count and assess for possible anemia secondary to excessive bleeding to determine if fatigue is contributing to anxiety and fear. Fatigue occurs because the oxygen-carrying capacity of the blood is reduced.
- Reassure client that symptoms can be managed to help address her current concerns.
- Provide client with factual information and explain what to expect to assist client with identifying fears and help her to cope with her condition.
- Provide symptom management to reduce concerns associated with the cause of bleeding.
- Teach client about early manifestations of fear and anxiety to aid in prompt recognition and to minimize escalation of anxiety.
- Assess client's use of coping strategies in the past and reinforce use of effective ones to help control anxiety and fear.
- Instruct client in relaxation methods, such as deep-breathing exercises and imagery, to provide her with

additional methods for controlling anxiety and fear.

NURSING DIAGNOSIS: Deficient knowledge related to menopausal transition and its management

Outcome Identification and Evaluation

The client will demonstrate understanding of her symptoms as evidenced by making health-promoting lifestyle choices, verbalizing appropriate health care practices, and adhering to measures and complying with therapy.

Interventions: ***Providing Client Education***

- Assess client's understanding of menopausal transition and its treatment to provide a baseline for teaching and developing a plan of care.
- Review instructions about prescribed procedures and recommendations for self-care, frequently obtaining feedback from the client to validate adequate understanding of information.
- Outline link between anovulatory cycles and excessive buildup of uterine lining in menopausal transition women to assist client in understanding the etiology of her bleeding.
- Provide written material with pictures to promote learning and help client visualize what is occurring to her body during menopausal transition.
- Inform client about the availability of community resources and make appropriate referrals as needed to provide additional education and support.
- Document details of teaching and learning to allow for continuity of care and further education, if needed.

KEY CONCEPTS

- Establishing good health habits and avoiding risky behaviors early in life will prevent chronic conditions later in life.
- PMS has more than 150 symptoms, and at least two different syndromes have been recognized: PMS and PMDD.
- Endometriosis is a condition in which bits of functioning endometrial tissue are located outside their normal site, the uterine cavity.
- Infertility is a widespread problem that has an emotional, social, and economic impact on couples.
- More than half of all unintended pregnancies occur in women who report using some method of birth control during the month of conception.
- Hormonal methods include OCs, injectables, implants, vaginal rings, and transdermal patches.
- Recent studies have shown that the extension of active extended cycle OC pills carries the same safety profile as the conventional 28-day regimens (Shoupe, 2016).
- Currently three intrauterine contraceptives are available in the United States: the copper ParaGard-TCu-380A, the LNG-IUS marketed as Mirena, and another LNG-IUD marketed as Skyla (King et al., 2015).
- OCs, sterilization, and male condoms are the most popular methods of contraception in the United States and worldwide (Alan Guttmacher Institute, 2015a).
- Menopause, with a dramatic decline in estrogen levels, affects not only the reproductive organs but also other body systems.
- Most women with osteoporosis do not know they have the disease until they sustain a fracture, usually of the wrist or hip (NOF, 2015a).
- Half a million women die annually in the United States of CVDs, with strokes accounting for about 20% of the deaths (Alexander et al., 2014).
- Nurses should aim to have a holistic approach to the sexual health of women from menarche through menopause.

CHAPTER WORKSHEET

MULTIPLE-CHOICE QUESTIONS

1. A couple is considered infertile after how many months of trying to conceive?
   a. 6 months
   b. 12 months
   c. 18 months
   d. 24 months

2. A couple reports that their condom broke while they were having sexual intercourse last night. What would you advise to prevent pregnancy?
   a. Inject a spermicidal agent into the woman's vagina immediately.
   b. Obtain emergency contraceptives and take them immediately.
   c. Douche with a solution of vinegar and hot water tonight.
   d. Take a strong laxative now and again at bedtime.

3. Which of the following combination contraceptives has been approved for extended continuous use?
   a. Seasonale
   b. Triphasil
   c. Ortho Evra
   d. Mirena

4. Which of the following measures helps prevent osteoporosis?
   a. Supplementing with iron
   b. Sleeping 8 hours nightly
   c. Eating lean meats only
   d. Walking daily

5. Which of the following activities will increase a woman's risk of cardiovascular disease if she is taking oral contraceptives?
   a. Eating a high-fiber diet
   b. Smoking cigarettes
   c. Taking daily multivitamins
   d. Drinking alcohol

6. The nurse is preparing to teach a class to a group of middle-aged women regarding the most common vasomotor symptoms experienced during menopause and possible modalities of treatment available. Which of the following would be a vasomotor symptom experienced by menopausal women?
   a. Weight gain
   b. Bone density
   c. Hot flashes
   d. Heart disease

7. Throughout life, a woman's most proactive activity to promote her health would be to engage in:
   a. Consistent exercise
   b. Socialization with friends
   c. Quality quiet time with herself
   d. Consuming water
8. What comment by a woman would indicate that a diaphragm is not the best contraceptive device for her?
   a. "My husband says it is my job to keep from getting pregnant."
   b. "I have a hard time remembering to take my vitamins daily."
   c. "Hormones cause cancer and I don't want to take them."
   d. "I am not comfortable touching myself down there."
9. The most common cause of menstrual abnormality in a reproductive–age woman is:
   a. Ectopic pregnancy
   b. Coagulopathy
   c. Carcinoma
   d. Anovulation

The correct response is "D" because abnormal uterine bleeding typically occurs when menstrual ovulation doesn't occur within the monthly cycle. Chronic anovulation causes a variety of abnormal bleeding patterns. Response "A" is incorrect because amenorrhea would be present secondary to the pregnancy, although misplaced. Response "B" is incorrect because other symptoms would be present due to a coagulation problem systemically. Response "C" is incorrect since most uterine cancers occur in postmenopausal women, not reproductive–aged women.

CRITICAL THINKING EXERCISE

1. Ms. London, age 25, comes to your family planning clinic requesting to have an intrauterine contraceptive (IUC) inserted because "birth control pills give you cancer." In reviewing her history, you note she has been into the STI clinic three times in the past year with vaginal infections and was hospitalized for PID last month. When you question her about her sexual history, she reports having sex with multiple partners and not always using protection.
   a. Is an IUC the most appropriate method for her? Why or why not?
   b. What myths/misperceptions will you address in your counseling session?
   c. Outline the safer sex discussion you plan to have with her.

STUDY ACTIVITIES

1. Develop a teaching plan for an adolescent with premenstrual syndrome and dysmenorrhea.
2. Arrange to shadow a nurse working in family planning for the morning. What questions does the nurse ask to ascertain the kind of family planning method that is right for each woman? What teaching goes along with each method? What follow-up care is needed? Share your findings with your classmates during a

clinical conference.

3. Surf the Internet and locate three resources for infertile couples to consult that provide support and resources.
4. Sterilization is the most prevalent method of contraception used by married couples in the United States. Contact a local urologist and gynecologist to learn about the procedure involved and the cost of a male and female sterilization. Which procedure poses less risk to the person and costs less?
5. Take a field trip to a local drugstore to check out the variety and costs of male and female condoms. How many different brands did you find? What was the range of costs?
6. Noncontraceptive benefits of combined oral contraceptives include which of the following? Select all that apply.

   a. Protection against ovarian cancer
   b. Protection against endometrial cancer
   c. Protection against breast cancer
   d. Reduction in incidence of ectopic pregnancy
   e. Prevention of functional ovarian cysts
   f. Reduction in deep venous thrombosis
   g. Reduction in the risk of colorectal cancer

BRINGING IT ALL TOGETHER: A CASE STUDY

L.H. is a 66-year-old White female who presents to the Women's Health Primary Care Clinic for her annual gynecologic examination. She states that she is fairly healthy with no active medical conditions other than hypertension controlled with medication. She is postmenopausal and feels she is doing well, but has a few questions and concerns. Her primary concern is that she is bothered by vaginal dryness and pain with sexual intercourse. Over-the-counter lubricants and moisturizers have not been useful. She never took HT since her hot flashes were not severe, but asks if she should start taking it now to reduce her vaginal dryness.

ASSESSMENT

L.H.'s family history includes an aunt who had breast cancer at the age of 60 and her mother who died of a heart attack at the age of 71. L.H. is a nonsmoker and drinks a glass of wine at dinner daily. Her last DXA bone scan indicated osteopenia and her pelvic examination demonstrated extensive atrophic changes in her vulvovaginal tissue. Her vital signs were within normal range; her weight was 125; her height was 5 feet 2 inches tall. She states she seemed to be taller previously as her slacks seem to be too long and she needs to hem them now.

1. What is this woman's chief complaint today? What is the etiology of it?
2. Any concerns about this woman's history or her family history?
3. Based on her height and weight, is there a health concern here?

L.H. has significant vulvovaginal atrophy that is not responding to OTC lubricants and is not likely to improve with anything other than estrogen therapy. She has an unfavorable family history of cancer and cardiovascular disease. Her bone density results indicate osteoporosis.

PLAN

1. What health issues should the nurse address with this woman after her examination?
2. What health promotion measures are needed to reduce her risk of osteoporosis?
3. What medications might be prescribed for this woman?
4. When would you have this woman return for follow-up care?

The nurse should discuss vaginal estrogen products such as vaginal cream, tablets, and the vaginal ring to address L.H.'s vaginal atrophy. It should be up to the client to decide which form of estrogen she is comfortable with. These therapies provide local, vaginal effects, not systemic effects, which may place her at risk based on her family history.

To build or maintain bone health, the nurse should encourage her to take 1,200 to 1,600 mg of calcium and 600 to 1,000 IU of vitamin D, through diet and/or supplements. She should also be instructed to walk daily with a gradual increase in distance.

L.H. is also a candidate for osteoporosis pharmacotherapy. The risks and benefits should be discussed. The initial drug prescribed might be a bisphosphonate. An annual return appointment is needed with a repeat DXA in 2 years to monitor her response to therapy.

5

Sexually Transmitted Infections

WOW

Words of Wisdom

Unconditional self-acceptance in clients is the core to reducing risky behavior and fostering peace of mind.

KEY TERMS

bacterial vaginosis
cervicitis
chlamydia
genital/vulvovaginal candidiasis
gonorrhea
pelvic inflammatory disease (PID)
sexually transmitted infection (STI)
syphilis
trichomoniasis
vaginitis

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Evaluate the spread and control of sexually transmitted infections.
2. Identify risk factors and outline appropriate client education needed in common sexually transmitted infections.
3. Describe how contraceptives can play a role in the prevention of sexually transmitted infections.
4. Analyze the physiologic and psychological aspects of sexually transmitted infections.
5. Outline the nursing management needed for women with sexually transmitted infections.

***Sandy*, a 19-year-old, couldn't imagine what these "things" were that appeared "down there" in her genital area last week. She was too embarrassed to tell anyone, so she stopped by the college health service today to find out what they were.**

INTRODUCTION

Sexually transmitted infections (STIs) are a significant global health challenge. STIs are bacterial, viral, and parasitic infections of the reproductive tract caused by microorganisms transmitted through vaginal, anal, or oral sexual intercourse (Centers for Disease Control and Prevention [CDC], 2014a). STIs pose a serious threat not only to women's sexual health, but also to the general health and well-being of millions of people worldwide. STIs are responsible for genital tract infections that may lead to later complications in women such as **pelvic inflammatory disease (PID)** or infertility. They may also cause chronic liver diseases and cancer due to hepatitis B virus (HBV) and hepatitis C virus (HCV) infections: genital cancer associated with human papillomavirus (HPV), and AIDS caused by HIV. STIs constitute an epidemic of tremendous magnitude globally with approximately 500 million new cases of curable STIs each year. An estimated 65 million people live with an incurable STI, and another 20 million are infected each year in the United States. STIs cost the U.S. health care system $17 billion annually (CDC, 2014b), and their incidence continues to rise.

STIs are biologically sexist, presenting greater risk and causing more complications among women than among men. Women are diagnosed with two thirds of the estimated 19 million new cases of STIs annually in the United States. After only a single exposure, women are twice as likely as men to acquire infections from pathogens causing **gonorrhea**, **chlamydia** infection, hepatitis B, HPV, and **syphilis** (Oyelowo & Johnson, 2016). STIs may contribute to cervical cancer, infertility, ectopic pregnancy, chronic pelvic pain, and death. Certain infections can be transmitted in utero to the fetus or during childbirth to the newborn (Table 5.1). STIs know no class, racial, ethnic, or social barriers—all individuals are vulnerable if exposed to the infectious organism. Safer-sex practices that include limiting the number of sexual partners and using latex condoms during sexual activity must be recommended to all sexually active individuals. The problem of STIs has still not

been tackled adequately on a global scale, and until this is done, numbers worldwide will continue to increase.

A special section on STIs and adolescents is presented next, followed by discussion of specific STIs categorized according to the CDC framework. The CDC groups STIs according to the major symptom manifested (Box 5.1). The CDC classifies STIs according to their clinical symptoms – See Box 5.1 for the categories. A section on preventing STIs is included at the end of the chapter.

SEXUALLY TRANSMITTED INFECTIONS AND ADOLESCENTS

Individuals aged 15 to 24 years represent almost half of all cases of new STIs acquired (CDC, 2014b). Today, 4 in 10 sexually active teen girls have an STI that can cause infertility and even death. Adolescent males make up more than three fourths of HIV diagnosis among 13- to 19-year-olds (U.S. Department of Health and Human Services Office of Adolescent Health, 2015). In the United States, teens who are sexually active experience high rates of STIs, and some groups are at higher risk, including African American, American Indian/Alaska Native, and Hispanic youths, youths living in poverty, and those with limited educational attainment (CDC, 2015m).

TABLE 5.1 EFFECTS OF SEXUALLY TRANSMITTED INFECTIONS ON THE FETUS OR NEWBORN

STI	Effects on Fetus or Newborn
Chlamydia	Newborn can be infected during delivery Eye infections (neonatal conjunctivitis), pneumonia, low birth weight, increased risk of premature rupture of the membranes (PROM), preterm birth, and stillbirth
Gonorrhea	Newborn can be infected during delivery. Increased risk of miscarriage, PROM, and preterm birth Rhinitis, vaginitis, urethritis, inflammation of sites of fetal monitoring Gonococcal ophthalmia neonatorum can lead to blindness and sepsis (including arthritis and meningitis)
Herpes type II (genital herpes)	Contamination can occur during birth. Newborn may develop skin or mouth sores Mental retardation, premature birth, low birth weight, blindness, death
Syphilis	Can be passed in utero Can result in fetal or infant death Congenital syphilis symptoms include skin ulcers, rashes, fever, weakened or hoarse cry, swollen liver and spleen, jaundice and anemia, various deformations
Trichomoniasis	Low birth weight, increased risk of PROM, and preterm birth
Venereal warts	May develop warts in throat (laryngeal papillomatosis); uncommon but life-threatening

Adapted from March of Dimes. (2015). *Your top STD questions answered*. Retrieved http://newsmomsneed.marchofdimes.org/?tag=stis

BOX 5.1

CDC CLASSIFICATION OF STIS

- Infections characterized by vaginal discharge
  - Vulvovaginal candidiasis
  - Trichomoniasis
  - Bacterial vaginosis

- Infections characterized by cervicitis
  - Chlamydia
  - Gonorrhea
- Infections characterized by genital ulcers
  - Genital herpes simplex
  - Syphilis
- Pelvic inflammatory disease (PID)
- Human immunodeficiency virus (HIV)
- Human papillomavirus infection (HPV)
- Vaccine-preventable STIs
  - Hepatitis A
  - Hepatitis B
- Ectoparasitic infections
- Pediculosis pubis
- Scabies

Take Note!

It is estimated that before graduating from high school, 25% of adolescents will contract an STI (Guttmacher Institute, 2014).

Biologic, social, and behavioral factors place teenagers at high risk. Female adolescents are more susceptible to STIs due to their anatomy. During adolescence and young adulthood, women's columnar epithelial cells are especially sensitive to invasion by sexually transmitted organisms, such as chlamydia and gonococci, because they extend out over the vaginal surface of the cervix, where they are unprotected by cervical mucus; these cells recede to a more protected location as women age. Social factors such as poverty, lack of education, social inequality, and limited access to health care services impact the prevalence of STIs in this high-risk population. Adolescent females may perceive that they have limited power over when and where intercourse occurs with their partners. They typically lack negotiating skills and self-confidence needed to successfully negotiate for safer sex practices and thus are exposed to STIs (Petrova & Garcia-Retamero, 2015).

Behaviorally, adolescents and young adults tend to think they are invincible and deny the risks of their behavior. This risky behavior exposes them to STIs and HIV/AIDS. Adolescents frequently have unprotected intercourse, they engage in partnerships of limited duration, and they face many obstacles that prevent them from using the health care system (CDC, 2015o) (*Healthy People 2020*).

Nursing Assessment

Many health care providers fail to assess adolescent sexual behavior and STI risks, to screen for asymptomatic infection during clinic visits, or to counsel adolescents on STI risk reduction. Nurses need to remember that they play a key role in the detection, prevention, and treatment of STIs in adolescents. All states allow adolescents to give consent to confidential STI testing and treatment. Table 5.2 discusses clinical manifestations of common STIs in adolescents.

HEALTHY PEOPLE 2020

Objective	Significance
Reduce the proportion of adolescents and young adults with *Chlamydia trachomatis* infections.	Provide confidential care to all adolescents.
Reduce gonorrhea.	Assess for sexual behaviors and STI risks during clinic visits; take every opportunity to educate the risks of STIs and risk reduction.
Reduce sustained domestic transmission of primary and secondary syphilis.	Be direct and nonjudgmental and tailor your approach to the client.
(Developmental) Reduce the proportion of females with human papillomavirus (HPV) infection.	Encourage adolescents to postpone initiation of sexual intercourse for as long as possible. For teens who have already had sexual intercourse, encourage abstinence at this point.
Reduce the proportion of young adults with genital herpes infection due to herpes simplex type 2 virus	Encourage adolescents to minimize their lifetime number of sexual partners.
Increase the proportion of sexually active persons aged 15–19 yrs who use condoms to both effectively prevent pregnancy and provide barrier protection against disease.	Educate about the importance of correct and consistent condom use.

TABLE 5.2 SEXUALLY TRANSMITTED INFECTIONS COMMON IN ADOLESCENTS

Disease	Causative Organism	Transmission Mode	Diagnostic Testing and Recommended Screening for Sexually Active Adolescent
Chlamydia Curable STI Seen frequently among sexually active adolescents and young adults	*Chlamydia trachomatis* (bacteria)	Vaginal, anal, and oral sex and by childbirth	Culture fluid from urethral swabs in males or endocervical swabs for females Noninvasive, non–culture-based testing is available using nucleic acid amplification and testing (NAAT) from urine—single test can test for chlamydia and gonorrhea Conjunctival secretions in neonates Females: screen annually Males: screen high-risk adolescents
Gonorrhea Curable STI Adolescent often coinfected with *Chlamydia trachomatis*	*Neisseria gonorrhoeae* (bacteria)	Vaginal, anal, and oral sex and by childbirth	Gram stain or culture directly for the bacterium or same noninvasive, non–culture-based test, NAAT, as chlamydia Females: screen annually Male: screen high-risk adolescents
Herpes type 2 (genital herpes) Lifelong recurrent viral disease Most people have not been diagnosed There is no cure	Herpes simplex virus 1 and 2 (HSV-1 and HSV-2)	HSV-1 is spread through oral secretions; can be spread to genitals through poor handwashing of infected person or oral-genital contact HSV-2 is spread by having sexual contact (vaginal, oral, or anal) with someone who is shedding the herpes virus either during an outbreak or during a period with no symptoms; can be spread to an infant through childbirth	Visual inspection and symptoms or culture from swabs taken from lesions (success depends stage of lesion—optimum is during vesicular stage) Polymerase chain reaction is more sensitive than culture Serologic tests, such as antibody-based testing (herpes Western blot assay is the most sensitive) Type specific laboratory testing important Routine screening not recommended

Female Symptoms	Male Symptoms	Recommended Treatment
May be asymptomatic Dysuria, urinary frequency. dyspareunia Cervical discharge (mucus or pus) Endocervicitis May lead to pelvic inflammatory disease, ectopic pregnancy, infertility Can cause inflammation of the rectum and conjunctiva Can infect the throat from oral sexual contact with an infected partner	May be asymptomatic Dysuria, urethral itching Penile discharge (mucus or pus) Urethral tingling May lead to epididymitis and sterility Can cause inflammation of the rectum and conjunctiva Can infect the throat from oral sexual contact with an infected partner	Azithromycin (Zithromax) Doxycycline (Vibramycin) Erythromycin (EES) Levofloxacin Ofloxacin (Floxin) Sexual partners need evaluation, testing, and treatment also Abstinence from sexual activity until therapy complete and symptoms no longer present Retesting in 3 months to rule out recurrence
May be asymptomatic or no recognizable symptoms until serious complications such as pelvic inflammatory disease Dysuria Urinary frequency Vaginal discharge (yellow and foul) Dyspareunia Endocervicitis Arthritis May lead to pelvic inflammatory disease, ectopic pregnancy, infertility Symptoms of rectal infection include discharge, anal itching, and occasional painful bowel movements with fresh blood	Most produce symptoms, but can be asymptomatic Dysuria Penile discharge (pus) Arthritis May lead to epididymitis and sterility Symptoms of rectal infection include discharge, anal itching, and occasional painful bowel movements with fresh blood	At this time, due to concerns about N. gonorrhoeae resistance to certain antimicrobials, the CDC currently recommends only one regimen, dual therapy with ceftriaxone and azithromycin Sexual partners need evaluation, testing, and treatment also Abstinence from sexual activity until therapy complete and symptoms no longer present Retesting in 3 months to rule out recurrence
Initial symptoms include itching, tingling, and pain in genital area followed by small pustules and blister-like genital lesions that then crust over and gradually heal. Recurrence episodes are usually milder than the initial episode Dysuria, dyspareunia, and urine retention Fever, headache, malaise, muscle aches	Same as female	Antivirals used to treat first episode, recurrence, and suppression Acyclovir, Valacyclovir, and Famciclovir mainstay in treatment Does not cure; just controls symptoms Counseling important to help adolescent cope and to prevent transmission Sexual partners benefit from evaluation and counseling. If symptomatic, need treatment If asymptomatic, offer testing and education

Syphilis	*Treponema pallidum* (spirochete bacteria)	Sexual contact with an infected person	Serologic testing mainstay for diagnosis Venereal Disease Research Laboratory (VDRL), rapid plasma reagin (RPR), and treponemal tests (e.g., fluorescent treponemal antibody absorbed [FTA-ABS]) can lead to a presumptive diagnosis and are useful for screening. Use of 2 tests required Darkfield examination and direct fluorescent antibody tests of lesion exudate or tissue provide definitive diagnosis of early syphilis New tests are in development such as enzyme immunoassay Screen based on epidemiology and personal risk factors
Trichomoniasis	*Trichomonas vaginalis* (protozoa)	Vaginal intercourse with an infected partner May be picked up from direct genital contact with damp or moist objects, such as towels or wet clothing, or	Highly sensitive and specific testing available and recommended, such as NAAT Microscopic evaluation of vaginal secretions or culture still common but less sensitive
Venereal warts (condylomata acuminata) One of the most common STIs in the United States Could lead to cancers of the cervix, vulva, vagina, anus, or penis No cure; warts can be removed but virus remains	Human papillomavirus	Vaginal, anal, or oral sex with an infected partner	Visual inspection Abnormal pap smear may indicate cervical infection of human papillomavirus (HPV)

Adapted from Centers for Disease Control and Prevention. (2015). *Sexually Transmitted Diseases Treatment Guidelines, 2015. Morbidity and Mortality Weekly Report (MMWR), 64*(3), 1–137. Retrieved from http://www.cdc.gov/std/tg2015/tg-2015-print.pdf; and Grossman, L. C. (2014). Chapter 55: Sexually transmitted infections. In S. Grossman, & C. M. Porth (Eds.), *Porth's Pathophysiology: Concepts of altered health states* (9th ed., pp. 1416–1429). Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins.

	Course of disease divided into stages **Primary infection:** • Chancre on place of entrance of bacteria (usually vulva or vagina but can develop in other parts of the body) **Secondary infection:** • Maculopapular rash (hands and feet) • Sore throat • Lymphadenopathy • Flu-like symptoms **Latent infection:** • No symptoms • Can be infective during first 1–2 years of latency • Many people if not treated will suffer no further signs and symptoms Some people will go on to develop tertiary or late syphilis **Tertiary infections:** • Tumors of skin, bones, and liver • Central nervous system symptoms • Cardiovascular symptoms • Usually not reversible at this stage	Course of disease divided into stages **Primary infection:** • Chancre on place of entrance of bacteria (usually on penis but can develop in other parts of the body) **Secondary, latent, and tertiary infections:** All similar to female symptoms	Benzathine penicillin G injection (if penicillin allergy, doxycycline, tetracycline, or erythromycin) Sexual partners need evaluation and testing
	Many women have symptoms but some may be asymptomatic Dysuria Frequency Vaginal discharge (yellow, green, or gray and foul odor) Dyspareunia Irritation or itching of genital area	Most men infected are asymptomatic Dysuria Penile discharge (watery white)	Metronidazole (Flagyl) or tinidazole Sexual partners need evaluation, testing, and treatment also Abstinence recommended until therapy complete
	Wart-like lesions that are soft, moist, or flesh colored and appear on the vulva and cervix, and inside and surrounding the vagina and anus Sometimes appear in clusters that resemble cauliflower-like bumps, and are either raised or flat, small or large	Wart-like lesions that are soft, moist, or flesh colored and appear on the scrotum or penis. They sometimes appear in clusters that resemble cauliflower-like bumps, and are either raised or flat, small or large	May disappear without treatment Treatment is aimed at removing the lesions rather than HPV itself No optimal treatment has been identified, but there are several ways to treat depending on size and location Most methods rely on chemical or physical destruction of the lesion: Imiquimod cream 20% Podophyllin antimitotic solution 0.5% Podofilox solution 5% 5-fluorouracil cream Trichloroacetic acid (TCA) Small warts can be removed by: • Freezing (cryosurgery) • Burning (electrocautery) • Laser treatment • Surgical excision Large warts that have not responded to treatment may be removed surgically Vaccination recommended starting around age 12 and may lead to decrease in cancer associated with HPV Abstinence from sexual activity during treatment to promote healing

Nursing Management

Nurses working with adolescents need to convey their willingness to discuss sexual habits. Provide effective guidance that promotes sexual health so that primary and/or repeat infections can be avoided. Adolescents bear disproportionate burdens when it comes to STIs, so nurses need to educate them to protect their client's reproductive futures.

Encourage the client to complete the antibiotic prescription (specific management for each type of STI is discussed further in the chapter).

Prevention of STIs among adolescents is critical. Health care providers have a unique opportunity to provide counseling and education to their clients. Adapt the style, content, and message to the adolescent's developmental level. Identify risk

factors and risk behaviors and guide the adolescent to develop specific individualized actions of prevention. The nurse's interaction and conversation with the adolescent needs to be direct and nonjudgmental.

Encourage adolescents to postpone initiation of sexual intercourse for as long as possible, but if they choose to have sexual intercourse, explain the necessity of using barrier methods, such as male and female condoms (Teaching Guidelines 5.1). For teens who have already had sexual intercourse, the clinician can encourage abstinence at this point. If adolescents are sexually active, they should be directed to teen clinics where contraceptive options can be explained. In areas where specialized teen clinics are not available, nurses should feel comfortable discussing sexuality, safety, and contraception with teens. Encourage adolescents to minimize their lifetime number of sexual partners, to use barrier methods consistently and correctly, and to be aware of the connection between drug and alcohol use and the incorrect use of barrier methods. Table 5.3 discusses barriers to condom use and means to overcome them.

Teaching Guidelines 5.1
PROPER CONDOM USE

- Use latex condoms.
- Use a new condom with each act of vaginal, anal or oral sex. Never reuse a condom.
- Handle condoms with care to prevent damage from sharp objects such as fingernails and teeth.
- Ensure condom has been stored in a cool, dry place away from direct sunlight. Do not store condoms in wallet or automobile or anywhere where they would be exposed to extreme temperatures.
- Do not use a condom if it appears brittle, sticky, or discolored. These are signs of aging.
- Put condom on before any genital contact.
- Put condom on when penis is erect with rolled side out. Ensure it is placed so it will readily unroll.
- Hold the tip of the condom while unrolling. Ensure there is a space at the tip for semen to collect (about ½ in), but make sure no air is trapped in the tip (air bubbles can cause breakage).
- Ensure adequate lubrication during intercourse. If external lubricants are used, use only water-based lubricants such as KY jelly with latex condoms. Oil-based or petroleum-based lubricants, such as body lotion, massage oil, or cooking oil, can weaken latex condoms.
- If you feel the condom break, stop immediately, withdraw, remove broken condom, and replace.
- Withdraw while penis is still erect, and hold condom firmly against base of penis. Remove carefully to ensure no semen spills out. Dispose of properly.

Think back to Sandy, who was introduced at the beginning of the chapter. How should the nurse handle Sandy's anxious state? What specific questions should the nurse ask Sandy to determine the source of the possible infection in her genital area?

INFECTIONS CHARACTERIZED BY VAGINAL DISCHARGE

Vaginitis is a generic term that means inflammation and infection of the vagina. There can be hundreds of causes for vaginitis, but more often than not the cause is infection by one of three organisms:

- Candida, a fungus
- Trichomonas, a protozoa
- Gardnerella, a bacterium

The complex balance of microbiologic organisms in the vagina is a key element in the maintenance of health. Subtle shifts in the vaginal environment may allow organisms with pathologic potential to proliferate, causing infectious symptoms.

The nurse's role in managing vaginitis is one of primary prevention and education to limit recurrences of these infections. Primary prevention begins with changing the sexual behaviors that place women at risk for infection. In addition to assessing women for the common signs and symptoms and risk factors, the nurse can help women to avoid vaginitis or to prevent a recurrence by teaching them to take the precautions highlighted in (Teaching Guidelines 5.2).

TABLE 5.3 BARRIERS TO CONDOM USE AND MEANS TO OVERCOME THEM

Perceived Barrier	Intervention Strategy
Decreases sexual pleasure (sensation) Note: Often perceived by those who have never used a condom	• Encourage client to try • Put a drop of water-based lubricant or saliva inside the tip of the condom or on the glans of the penis before putting on the condom • Try a thinner latex condom or a different brand or more lubrication
Decreases spontaneity of sexual activity	• Incorporate condom use into foreplay • Remind client that peace of mind may enhance pleasure for self and partner
Embarrassing, juvenile, "unmanly"	• Remind client that it is "manly" to protect himself and others.
Poor fit (too small or too big, slips off, uncomfortable)	• Smaller and larger condoms are available.
Requires prompt withdrawal after ejaculation	• Reinforce the protective nature of prompt withdrawal and suggest substituting other postcoital sexual activities.
Fear of breakage may lead to less vigorous sexual activity	• With prolonged intercourse, lubricant wears off and the condom begins to rub. Have a water-soluble lubricant available to reapply.
Nonpenetrative sexual activity	• Condoms have been advocated for use during fellatio; unlubricated condoms may prove best for this purpose due to the taste of the lubricant • Other barriers, such as dental dams or an unlubricated condom, can be cut down the middle to form a barrier; these have been advocated for use during certain forms of nonpenetrative sexual activity (e.g., cunnilingus and anolingual sex)
Allergy to latex	• Polyurethane male and female condoms are available • A natural skin condom can be used together with a latex condom to protect the man or woman from contact with latex

Teaching Guidelines 5.2
PREVENTING VAGINITIS

- Avoid douching to prevent altering the vaginal environment.
- Use condoms to avoid spreading the organism.
- Avoid tights, nylon underpants, and tight clothes.
- Wipe from front to back after using the toilet.
- Avoid powders, bubble baths, and perfumed vaginal sprays.
- Wear clean cotton underpants.
- Change out of wet bathing suits as soon as possible.
- Become familiar with the signs and symptoms of vaginitis.
- Choose to lead a healthy lifestyle.

Genital/Vulvovaginal Candidiasis (VVC)

Genital/VVC is one of the most common causes of vaginal discharge. It is also referred to as yeast, monilia, and a fungal infection. It is not considered an STI because Candida is a normal constituent in the vagina and becomes pathologic only when the vaginal environment becomes altered. An estimated 75% of women will have at least one episode of VVC, and 40% to 50% will have two or more episodes in their lifetime (CDC, 2016).

Therapeutic Management

Treatment of candidiasis includes one of the following medications:
• Miconazole cream or suppository
• Clotrimazole tablet or cream
• Terconazole cream or intravaginal suppository
• Fluconazole oral tablet (CDC, 2015a)

Most of these medications are used intravaginally in the form of a cream, tablet, or suppositories for 3 to 7 days. If fluconazole is prescribed, a 150-mg oral tablet is taken as a single dose.

Topical azole preparations are effective in the treatment of VVC, relieving symptoms and producing negative cultures in 80% to 90% of women who complete therapy (CDC, 2015a). If VVC is not treated effectively during pregnancy, the newborn can develop an oral infection known as thrush during the birth process; that infection must be treated with a local azole preparation after birth.

Nursing Assessment

Assess the client's health history for predisposing factors for VVC, which include:
• Pregnancy
• Use of oral contraceptives with a high estrogen content
• Use of broad-spectrum antibiotics
• Diabetes mellitus
• Obesity
• Use of steroid and immunosuppressive drugs
• HIV infection
• Wearing tight, restrictive clothes and nylon underpants
• Trauma to vaginal mucosa from chemical irritants or douching

Assess the client for clinical manifestations of VVC. Typical symptoms, which can worsen just before menses, include:
• Pruritus
• Vaginal discharge (thick, white, curd-like)
• Vaginal soreness
• Vulvar burning
• Erythema in the vulvovaginal area
• Dyspareunia
• External dysuria

Figure 5.1 shows the typical appearance of VVC.

Speculum examination will reveal white plaques on the vaginal walls. The vaginal pH remains within normal range. Definitive diagnosis is made by a wet smear, which reveals the filamentous hyphae and spores characteristic of a fungus when viewed under a microscope.

Nursing Management

Teach preventive measures to women with frequent VVC infections, including:
• Reduce dietary intake of simple sugars and soda.
• Wear white, 100% cotton underpants.
• Avoid wearing tight pants or exercise clothes with spandex.
• Shower rather than taking tub baths.

• Wash with a mild, unscented soap and dry the genitals gently.
• Avoid the use of bubble baths or scented bath products.
• Wash underwear in unscented laundry detergent and hot water.
• Dry underwear in a hot dryer to kill the yeast that clings to the fabric.
• Remove wet bathing suits promptly.
• Practice good body hygiene.
• Avoid vaginal sprays/deodorants.
• Avoid wearing pantyhose (or cut out the crotch to allow air circulation).
• Use white, unscented toilet paper and wipe from front to back.
• Avoid douching (which washes away protective vaginal mucus).
• Avoid the use of super-absorbent tampons (use pads instead).

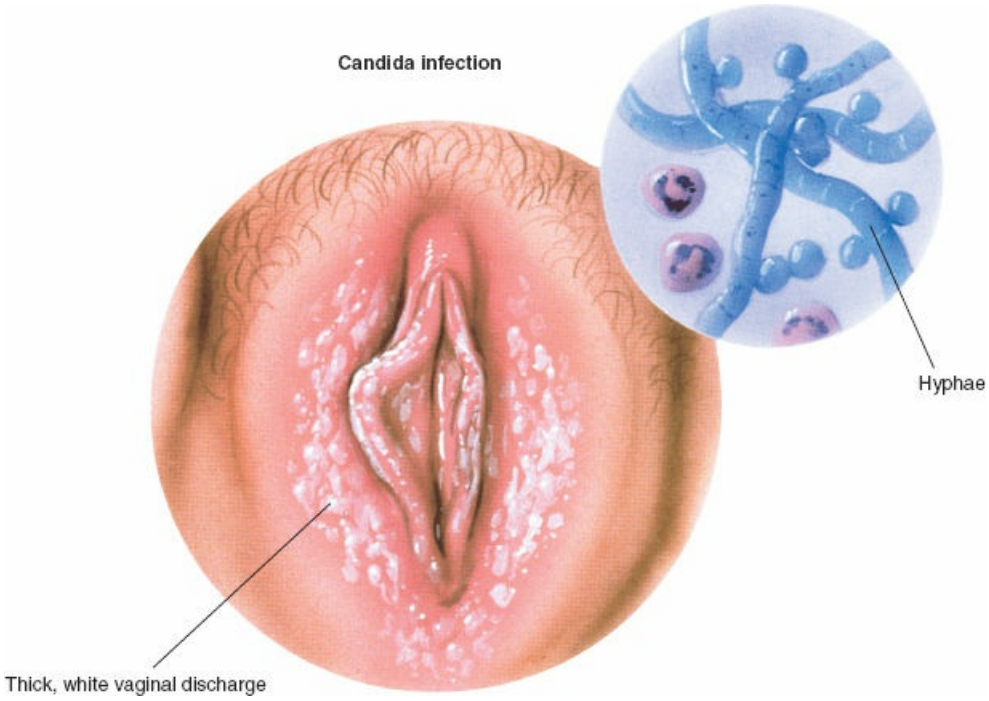

FIGURE 5.1 Vulvovaginal candidiasis. (Asset provided by Anatomical Chart Co.)

Trichomoniasis

Trichomoniasis is another common vaginal infection that causes a discharge, but is not always sexually transmitted. The organism can live on damp/wet surfaces and poorly cleaned/maintained hot tubs and drains. The woman may be markedly symptomatic or asymptomatic. When symptoms are present, they include vulvar itching and a malodorous foamy vaginal discharge. Men are asymptomatic carriers. Although this infection is localized, there is increasing evidence of preterm birth and postpartum endometritis in women with this vaginitis (CDC, 2015a). The high prevalence of this infection globally and frequency of coinfection with other STIs make trichomoniasis a public health concern. Notably, research finds that an infection with trichomoniasis increases the risk of HIV transmission in both men and women (Smith & Ramos, 2015). *Trichomonas vaginalis* is an ovoid, single-cell protozoan parasite that can be observed under the microscope making a jerky swaying motion.

Therapeutic Management

A single 2-g dose of oral metronidazole or tinidazole for both partners is a common treatment for this infection. Sex partners of women with trichomoniasis should be treated to avoid recurrence of infection.

Nursing Assessment

Assess the client for clinical manifestations of trichomoniasis, which include:
- A heavy yellow/green or gray frothy or bubbly discharge
- Vaginal pruritus and vulvar soreness
- Dyspareunia
- Cervix may bleed on contact
- Dysuria
  - Vaginal odor, described as foul
  - Vaginal or vulvar erythema
- Petechiae on the cervix

Figure 5.2 shows the typical appearance of trichomoniasis.

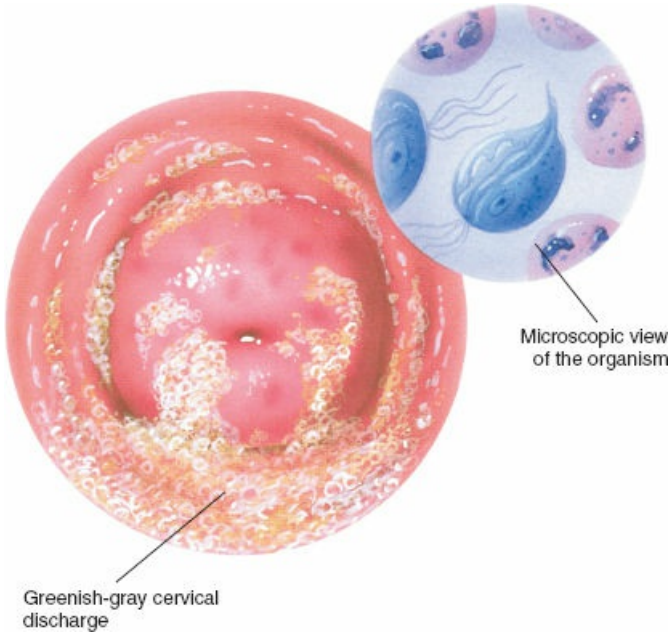

FIGURE 5.2 Trichomoniasis. (Asset provided by Anatomical Chart Co.)

The diagnosis is confirmed when a motile flagellated trichomonad is visualized under the microscope. In addition, a vaginal pH of greater than 4.5 is a typical finding. FDA-cleared tests for trichomoniasis in women include OSOM Trichomonas Rapid Test (Genzyme Diagnostics, Cambridge, Massachusetts), an immunochromatographic capillary flow dipstick technology, and the Affirm VP III (Becton Dickenson, San Jose, California), a nucleic acid probe test that evaluates for *T. vaginalis, Gardnerella vaginalis,* and *Candida albicans.* Each of these tests, which are performed on vaginal secretions, have a sensitivity of 83% and a specificity of 97%. Both tests are considered point-of-care diagnostics (CDC, 2015a).

Nursing Management

Instruct clients to avoid sexual activity until they and their sex partners are cured (i.e., when therapy has been completed and both partners are symptom-free) and also to avoid consuming alcohol during treatment because mixing the medications and alcohol causes severe nausea and vomiting (CDC, 2015a). In addition, it is important to provide information regarding infection cause and transmission, effects on reproductive organs and future fertility, and the need for partner notification and treatment. Follow-up testing is not indicated if symptoms resolve with treatment. See Evidence-Based Practice 5.1 for interventions for trichomoniasis in pregnancy.

Bacterial Vaginosis

A third common infection of the vagina is **bacterial vaginosis** caused by the gram-negative bacillus *G. vaginalis*. It is the most prevalent cause of vaginal discharge or malodor, but up to 50% of women are asymptomatic. Bacterial vaginosis is a sexually associated infection characterized by alterations in vaginal flora in which lactobacilli in the vagina are replaced with high concentrations of anaerobic bacteria. The cause of the microbial alteration is not fully understood, but is associated with having multiple sex partners, douching, and lack of vaginal lactobacilli. Bacterial vaginosis can increase a woman's susceptibility to other STIs such as HIV, herpes, chlamydia, and gonorrhea (CDC, 2015a). Research suggests that bacterial vaginosis is associated with preterm labor, premature rupture of membranes (PROM), chorioamnionitis, postpartum endometritis, and PID (CDC, 2015a).

Therapeutic Management

Treatment for bacterial vaginosis includes metronidazole (oral or gel) or clindamycin cream. Treatment of the male partner has not been beneficial in preventing recurrence because sexual transmission of bacterial vaginosis has not been proven (CDC, 2015a).

Nursing Assessment

Assess the client for clinical manifestations of bacterial vaginosis. Primary symptoms are a thin, white homogeneous vaginal discharge and a characteristic "stale fish" odor. Figure 5.3 shows the typical appearance of bacterial vaginosis.

To diagnose bacterial vaginosis, three of the four criteria must be met:

- Thin, white homogeneous vaginal discharge
- Vaginal pH 4.5
- Positive "whiff test" (secretion is mixed with a drop of 10% potassium hydroxide on a slide, producing a characteristic stale fishy odor)
- The presence of clue cells on wet-mount examination (CDC, 2015a)

EVIDENCE-BASED PRACTICE 5.1

ANTENATAL LOWER GENITAL TRACT INFECTION SCREENING AND TREATMENT PROGRAMS FOR PREVENTING PRETERM DELIVERY

A genital tract infection during pregnancy can cross into the amniotic fluid and result in prelabor rupture on the membranes and is associated with preterm births. Preterm

births are associated with poor infant health, admissions to NICUs in the first weeks of life, prolonged hospital stays, and long-term neurologic disabilities.

STUDY

In this review, 4,155 women were randomly assigned to either an intervention group whereby they were treated for bacterial vaginosis, trichomoniasis, and candidiasis, or into a control group where they received screening but results were not revealed and treatment not instituted.

Findings

There was evidence that infection screening and treatment for pregnant women before 20 weeks' gestation reduced preterm births and low-weight infants. Infection screening and treatment programs are associated with cost savings when used for prevention of preterm births. The numbers of low-weight infants were significantly lower in the intervention group when compared to the control group.

Nursing Implications

A simple infection screening and treatment program done during routine prenatal care may reduce preterm births and preterm low-weight infants. Nurses can apply this study's findings when educating women preconceptually how important prenatal care is and screening for vaginal infections that may be asymptomatic. It is important to establish a link between preterm birth prevention measures to improve maternal–infant outcomes in all pregnant women.

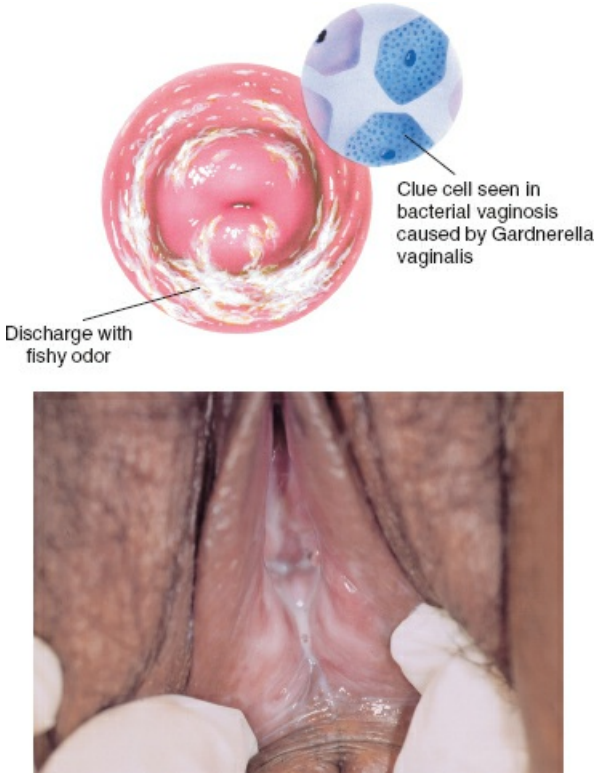

FIGURE 5.3 Bacterial vaginosis. (Illustration provided by Anatomical Chart Co. Photograph from Sweet, R. L., Gibbs,

R. S. (2005). *Atlas of infectious diseases of the female genital tract*. Philadelphia, PA: Lippincott Williams & Wilkins.)

Nursing Management

The nurse's role is one of primary prevention and education to limit recurrences of these infections. Primary prevention begins with changing the sexual behaviors that place women at risk for infection. In addition to assessing women for common signs, symptoms, and risk factors, the nurse can help women to avoid vaginitis or to prevent a recurrence by teaching them to take the precautions highlighted in Teaching Guidelines 5.2.

INFECTIONS CHARACTERIZED BY CERVICITIS

Cervicitis is a catchall term that implies the presence of inflammation or infection of the cervix. It is used to describe everything from symptomless erosions to an inflamed cervix that bleeds on contact and produces quantities of purulent discharge containing organisms not ordinarily found in the vagina. Cervicitis is usually caused by gonorrhea or chlamydia, as well as almost any pathogenic bacterial agent and a number of viruses. The treatment of cervicitis involves the appropriate therapy for the specific organism that has caused it.

Chlamydia

Chlamydia is the most commonly reported bacterial STI in the United States. The CDC (2014b) estimates that there are 2.8 million cases in the United States annually; the highest predictor for this infection is age. The highest rates of infection are among those aged 15 to 19 years, mainly because their sexual relations are often unplanned and are sometimes the result of pressure or force, and typically happen before they have the experience and skills to protect themselves. The rates are highest among this group regardless of demographics or location (CDC, 2014a). The young have the most to lose from acquiring STIs, since they will suffer the consequences the longest and might not reach their full reproductive potential. The most common risk factors associated with chlamydia are age less than 25 years, recent change in sexual partner or multiple sexual partners, poor socioeconomic conditions, exchange of sex for money, nonwhite race, single status, and lack of use of barrier contraception. Worldwide, it is likely the most common infectious cause of infertility in women. An estimated 106 million cases of chlamydia occur globally among both men and women each year, so the global burden is substantial (Brunham, 2015).

Asymptomatic infection is common among both men and women. Men primarily develop urethritis. In women, chlamydia is linked with cervicitis, acute urethral syndrome, salpingitis, ectopic pregnancy, PID, and infertility (Qureshi, 2015). Chlamydia causes half of the 1 million recognized cases of PID in the United States each year, and treatment costs run over $701 million yearly. The CDC (2014a) recommends yearly chlamydia testing of all sexually active women aged 25 years or younger, older women with risk factors for chlamydial infections (those who have a new sex partner or multiple sex partners), and all pregnant women.

Chlamydia trachomatis is the bacterium that causes chlamydia. It is an intracellular parasite that cannot produce its own energy and depends on the host for survival. It is often difficult to detect, and this can pose problems for women due to the long-

term consequences of untreated infection. Moreover, lack of treatment provides more opportunity for the infection to be transmitted to sexual partners. Newborns delivered to infected mothers may develop conjunctivitis which occurs in 25% to 50% of all newborns. Ophthalmia neonatorum is an acute mucopurulent conjunctivitis occurring in the first month of birth. It is essentially an infection acquired during vaginal delivery. The most frequent infectious agents involved in are Chlamydia trachomatis and Neisseria gonorrhea (Thomas, Bates, & Mathew, 2015).

Therapeutic Management

Antibiotics are usually used in treating this STI. The CDC treatment options for chlamydia include doxycycline 100 mg orally twice a day for 7 days or azithromycin 1 g orally in a single dose. Because of the common coinfection of chlamydia and gonorrhea, a combination regimen of ceftriaxone with doxycycline or azithromycin is prescribed frequently (CDC, 2015a). Additional CDC guidelines for client management include annual screening of all sexually active women aged 20 to 25 years old; screening of all high-risk people; and treatment with antibiotics effective against both gonorrhea and chlamydia for anyone diagnosed with a gonococcal infection (CDC, 2014a). Except in pregnant women, test-of-cure (repeat testing 3 to 4 weeks after completing therapy) is not recommended for women treated with the recommended or alterative regimens, unless therapeutic compliance is in question, symptoms persist, or reinfection is suspected (CDC, 2015a).

Nursing Assessment

Assess the health history for significant risk factors for chlamydia, which may include:

- Being an adolescent
- Having multiple sex partners
- Having a new sex partner
- Engaging in sex without using a barrier contraceptive (condom)
- Using oral contraceptives
- Being pregnant
- Having a history of another STI (King et al., 2015).

Assess the client for clinical manifestations of chlamydia. The majority of women (70% to 80%) are asymptomatic (CDC, 2014a). If the client is symptomatic, clinical manifestations include:

- Mucopurulent vaginal discharge
- Urethritis
- Bartholinitis
- Endometritis
- Salpingitis
- Dysfunctional uterine bleeding

The diagnosis can be made by urine testing or swab specimens collected from the endocervix or vagina. Culture, direct immunofluorescence, enzyme immunoassay (EIA), or nucleic acid amplification methods such as GenProbe or Pace2) are highly

sensitive and specific when used on urethral and cervicovaginal swabs. They can also be used with good sensitivity and specificity on first-void urine specimens (Qureshi, 2015). The chain reaction tests are the most sensitive and cost-effective. The CDC (2015b) strongly recommends screening of asymptomatic women at high risk in whom infection would otherwise go undetected.

Chlamydia is an important preventable cause of infertility and other adverse reproductive health outcomes. Effective prevention interventions are available to reduce the burden of chlamydia and its sequelae, but they are underutilized. Although many prevention programs are available, improvements can be made in raising awareness about chlamydia, increasing screening coverage, and enhancing partner services. In addition, nurses can focus their efforts on reaching disproportionately affected racial/ethnic groups. To break the cycle of chlamydia transmission in the United States, health care providers should encourage annual chlamydia screening for all sexually active females aged >25 years, maximize use of effective partner treatment services, and rescreen infected females and males 3 months after treatment (CDC, 2015b).

Gonorrhea

Gonorrhea is a serious, and potentially very severe, bacterial infection. It is the second most commonly reported infection in the United States, and is an urgent problem globally because it is now capable of developing resistance to multiple antibiotic classes. Gonorrhea is highly contagious and is a reportable infection to the health department authorities. Gonorrhea increases the risk for PID, infertility, ectopic pregnancy, and HIV acquisition and transmission (CDC, 2015f). It is rapidly becoming more and more resistant to cure. In the United States, an estimated 800,000 new gonorrhea infections occur annually (CDC, 2015f). In common with all other STIs, it is an equal-opportunity infection—no one is immune to it, regardless of race, creed, gender, age, or sexual preference.

The cause of gonorrhea is an aerobic gram-negative intracellular diplococcus, *Neisseria gonorrhoeae*. The site of infection is the columnar epithelium of the endocervix. Gonorrhea is almost exclusively transmitted by sexual activity. In pregnant women, gonorrhea is associated with chorioamnionitis, premature labor, PROM, and postpartum endometritis (Ross et al., 2015). It can also be transmitted to the newborn in the form of ophthalmia neonatorum during birth by direct contact with gonococcal organisms in the cervix. Ophthalmia neonatorum is highly contagious and if untreated leads to blindness in the newborn.

Therapeutic Management

Gonorrhea can be cured with the right treatment. CDC now recommends dual therapy (i.e., using two drugs as the treatment for gonorrhea). Dual therapy is recommended to prevent drug resistance and is also effective against chlamydia. The treatment of choice for uncomplicated gonococcal infections is azithromycin 1 g orally in a single dose and ceftriaxone 250 mg intramuscular (IM) in a single dose (CDC, 2015a).

Azithromycin orally or doxycycline should accompany all gonococcal treatment regimens if chlamydial infection is not ruled out (CDC, 2015a). Pregnant women with gonorrhea should not be treated with quinolones or tetracyclines. Pregnant

women with a positive test for gonorrhea should be treated with the same recommended dual therapy of ceftriaxone with either azithromycin or amoxicillin (CDC, 2015a). To prevent gonococcal ophthalmia neonatorum, a prophylactic agent should be instilled into the eyes of all newborns; this procedure is required by law in most states. Erythromycin or tetracycline ophthalmic ointment in a single application is recommended (King et al., 2015). With use of recommended treatment, follow-up testing to document eradication of gonorrhea is no longer recommended. Instead, rescreening in 2 to 3 months to identify reinfection is suggested (CDC, 2015a).

Nursing Assessment

Assess the client's health history for risk factors, which may include low socioeconomic status, living in an urban area, single status, inconsistent use of barrier contraceptives, age under 20 years old, and multiple sex partners. Assess the client for clinical manifestations of gonorrhea, keeping in mind that between 50% and 90% of women infected with gonorrhea are totally symptom-free (Wong, 2015). Because women are so frequently asymptomatic, they are regarded as a major factor in the spread of gonorrhea. If symptoms are present, they might include:

- Abnormal vaginal discharge
- Dysuria
- Cervicitis
- Enlarged lymph glands locally
- Abnormal vaginal bleeding
- Bartholin abscess
- PID
- Neonatal conjunctivitis in newborns
- Mild sore throat (for pharyngeal gonorrhea)
- Rectal infection (itching, soreness, bleeding, discharge)
- Perihepatitis (King et al., 2015)

Sometimes, a local gonorrhea infection is self-limiting (there is no further spread), but usually the organism ascends upward through the endocervical canal to the endometrium of the uterus, further on to the fallopian tubes, and out into the peritoneal cavity. When the peritoneum and the ovaries become involved, the condition is known as PID. The scarring to the fallopian tubes is permanent. This damage is a major cause of infertility and is a possible contributing factor in ectopic pregnancy (Heller, 2015).

If gonorrhea remains untreated, it can enter the bloodstream and produce a disseminated gonococcal infection. This severe form of infection can invade the joints (arthritis), the heart (endocarditis), the brain (meningitis), and the liver (toxic hepatitis). Figure 5.4 shows the typical appearance of gonorrhea.

The CDC recommends screening for all women at risk for gonorrhea. Pregnant women should be screened at the first prenatal visit and again at 36 weeks of gestation. Nucleic acid hybridization tests (GenProbe) are used for diagnosis. Any woman suspected of having gonorrhea should be tested for chlamydia also because coinfection (45%) is extremely common (CDC, 2015f).

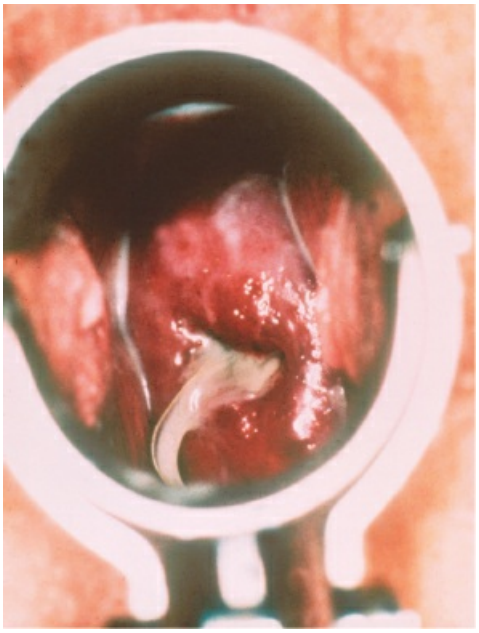

FIGURE 5.4 Gonorrhea. (From Jensen, S. (2015). *Nursing Health Assessment: A Best Practice Approach*, 2nd ed. Philadelphia, PA: Wolters Kluwer.)

Nursing Management of Chlamydia and Gonorrhea

The prevalence of chlamydia and gonorrhea is increasing dramatically, and these infections can have long-term effects on people's lives. Sexual health is an important part of a person's physical and mental health, and nurses have a professional obligation to address it. Be particularly sensitive when addressing STIs because women are often embarrassed or feel guilty. There is still a social stigma attached to STIs, so women need to be reassured about confidentiality.

The nurse's knowledge about chlamydia and gonorrhea should include treatment strategies, referral sources, and preventive measures. It is important to be skilled at client education and counseling and to be comfortable talking with, and advising, women diagnosed with these infections. Provide education about risk factors for these infections. High-risk groups include single women, women younger than 25 years, African American women, women with a history of STIs, those with new or multiple sex partners, those with inconsistent use of barrier contraception, and women living in communities with high infection rates (Wong, 2015). Assessment involves taking a health history that includes a comprehensive sexual history. Ask about the number of sex partners and the use of safer sex techniques. Review previous and current symptoms. Emphasize the importance of seeking treatment and informing sex partners. The four-level P-LI-SS-IT model (Box 5.2) can be used to determine interventions for various women because it can be adapted to the nurse's level of knowledge, skill, and experience. Of utmost importance is the willingness to listen and show interest and respect in a nonjudgmental manner.

BOX 5.2

THE P-LI-SS-IT MODEL

P – Permission—gives the woman permission to talk about her experience

LI – Limited Information—information given to the woman about STIs
- Factual information to dispel myths about STIs
- Specific measures to prevent transmission
- Ways to reveal information to her partners
- Physical consequences if the infections are untreated

SS – Specific Suggestions—an attempt to help women change their behavior to prevent recurrence and prevent further transmission of the STI
IT – Intensive Therapy—involves referring the woman or couple for appropriate treatment elsewhere based on their life circumstances

In addition to meeting the health needs of women with chlamydia and gonorrhea, the nurse is responsible for educating the public about the increasing incidence of these infections. This information should include high-risk behaviors associated with these infections, signs and symptoms, and the treatment modalities available. Stress that both of these STIs can lead to infertility and long-term sequelae. Teach safer sex practices to people in nonmonogamous relationships. Know the physical and psychosocial responses to these STIs to prevent transmission and the disabling consequences. Nurses must also inform their pregnant clients that they should avoid quinolones or tetracyclines to prevent risks associated with malformation of teeth, bones, and joints in the fetus and possible hepatotoxicity and pancreatitis in the mother (King et al. 2015).

Take Note!

If the epidemic of chlamydia and gonorrhea is to be halted, nurses must take a major front-line role now.

INFECTIONS CHARACTERIZED BY GENITAL ULCERS

In the United States, the majority of young, sexually active clients who have genital ulcers have genital herpes, syphilis, or chancroid. The frequency of each condition differs by geographic area and client population; however, genital herpes is the most prevalent of these diseases. More than one of these diseases can be present in a client who has genital ulcers. All three of these diseases have been associated with an increased risk for HIV infection. Not all genital ulcers are caused by STIs.

Genital Herpes Simplex

Genital herpes is a recurrent, lifelong viral infection that has the potential for transmission throughout the lifespan. The CDC estimates that one out of six people 14 to 49 years old have genital herpes simplex (HSV) infection, with 500 million worldwide new cases annually (CDC, 2015e). Two serotypes of HSV have been identified: HSV-1 and HSV-2. Today, a smaller portion of genital herpes infections are thought to be caused by HSV-1 and the bulk of them by HSV-2. HSV-1 mostly causes the familiar fever blisters or cold sores on the lips, eyes, and face. HSV-2 typically invades the mucous membranes of the genital tract and is known as herpes genitalis. Most people infected with HSV-2 have not been diagnosed.

The herpes simplex virus is transmitted by contact of mucous membranes or breaks in the skin with visible or nonvisible lesions. Most genital herpes infections are transmitted by individuals unaware that they have an infection. Many have mild

or unrecognized infections but still shed the herpes virus intermittently. HSV is transmitted primarily by direct contact with an infected individual who is shedding the virus. Kissing, sexual contact, including oral sex, and vaginal birth are means of transmission. The virus replicates at the site of infection, then travels to the dorsal root ganglia and remains latent until stimuli such as fever, stress, ultraviolet radiation, or immunosuppression occurs and reactivates it (Selim et al., 2015).

Having sex with an infected partner places the individual at risk for contracting HSV. After the primary outbreak, the virus remains dormant in the nerve cells for life, resulting in periodic recurrent outbreaks. Recurrent genital herpes outbreaks are triggered by precipitating factors such as emotional stress, menses, and sexual intercourse, but more than half of recurrences occur without a precipitating cause. Immunocompromised women have more frequent and more severe recurrent outbreaks than normal hosts (Silasi et al., 2015).

Living with genital herpes can be difficult due to the erratic, recurrent nature of the infection, the location of the lesions, the unknown causes of the recurrences, and the lack of a cure. Further, the stigma associated with this infection may affect the individual's feelings about herself and her interaction with partners. Potential psychosocial consequences may include emotional distress, isolation, fear of rejection by a partner, fear of transmission of the disease, loss of confidence, and altered interpersonal relationships (Alexander et al., 2014).

Along with the increase in the incidence of genital herpes has been an increase in neonatal herpes simplex viral infections, which are associated with a high incidence of mortality and morbidity. The risk of neonatal infection with a primary maternal outbreak is between 30% and 50%; it is less than 1% with a recurrent maternal infection (CDC, 2015e).

Therapeutic Management

No cure exists, but antiviral drug therapy helps to reduce or suppress symptoms, shedding, and recurrent episodes. Advances in treatment with acyclovir 400 mg orally three times daily for 7 to 10 days, famciclovir 250 mg orally three times daily for 7 to 10 days, and valacyclovir 1 g orally twice daily for 7 to 10 days have resulted in an improved quality of life for those infected with HSV. However, these drugs neither eradicate latent virus nor affect the risk, frequency, or severity of recurrences after the drug is discontinued (CDC, 2015a). Suppressive therapy is recommended for individuals with six or more recurrences per year. The natural course of the disease is for recurrences to be less frequent over time.

The management of genital herpes includes antiviral therapy. The safety of antiviral therapy has not been established during pregnancy. Disclosure of this lifelong viral infection is often a challenge for individuals living with genital herpes. Therapeutic management also includes counseling regarding the natural history of the disease, the risk of sexual and perinatal transmission, and the use of methods to prevent further spread. The following are a few guidelines to delivering information in a time-limited environment: (a) use all available client reading materials; (b) have another knowledgeable staff member in the office who can spend extra time with women who need it; (c) refer clients to good and accurate websites such as the American Social Health Association (www.ashastd.org/hrc); (d) know the phone numbers of herpes support groups in your area; (e) educate the client to abstain

from all sexual activity until HSV lesions resolve; (f) use good hand washing technique to prevent spread; (g) educate that there is no cure, and that practicing safe sex (using condoms) with every sex act is essential to prevent transmission; and (h) encourage all clients to inform their current sex partners that they have genital herpes and to inform future partners before initiating a sexual relationship. Finally, many experts recommend a sympathetic, nonjudgmental approach. The nurse can state in clear terms that having herpes does not change the core of the person or make them less worthwhile (Myers et al., 2015).

Nursing Assessment

Assess the client for clinical manifestations of HSV. Clinical manifestations can be divided into the primary episode and recurrent infections. The first or primary episode is usually the most severe, with a prolonged period of viral shedding. Primary HSV is a systemic disease characterized by multiple painful vesicular lesions, mucopurulent discharge, superinfection with candida, fever, chills, malaise, dysuria, headache, genital irritation, inguinal tenderness, and lymphadenopathy. The lesions in the primary herpes episode are frequently located on the vulva, vagina, and perineal areas. The vesicles will open and weep and finally crust over, dry, and disappear without scar formation (Fig. 5.5). This viral shedding process usually takes up to 2 weeks to complete.

Recurrent infection episodes are usually much milder and shorter in duration than the primary one. Tingling, itching, pain, unilateral genital lesions, and a more rapid resolution of lesions are characteristics of recurrent infections. Recurrent herpes is a localized disease characterized by typical HSV lesions at the site of initial viral entry. Recurrent herpes lesions are fewer in number and less painful and resolve more rapidly (King et al., 2015).

Diagnosis of HSV is often based on clinical signs and symptoms and is confirmed by viral culture of fluid from the vesicle. Papanicolaou (Pap) smears are an insensitive and nonspecific diagnostic test for HSV and should not be relied on for diagnosis. The woman should be tested for all common STIs, especially if she has a new sexual partner. Hopefully, the woman would initiate an open conversation with her sexual partner about the risk of transmission and the need for safer sexual practices.

Syphilis

Syphilis is a chronic, multistage, curable bacterial infection caused by the spirochete *Treponema pallidum* that is typically transmitted sexually with an infected partner or congenitally from an infected mother to her fetus. It is a serious systemic disease that can lead to disability and death if untreated. Rates of syphilis in the United States are increasing. Of primary and secondary syphilis cases, 75% occur in men who have sex with men (CDC, 2015k). It continues to be one of the most important STIs both because of its biologic effect on HIV acquisition and transmission and because of its impact on infant health. Because there is no vaccine to prevent syphilis, control is mainly dependent on the identification and treatment of infected individuals and their contacts with penicillin G, the first-line drug for all stages of syphilis (Stamm, 2015).

The spirochete rapidly penetrates intact mucous membranes or microscopic

lesions in the skin and within hours enters the lymphatic system and bloodstream to produce a systemic infection long before the appearance of a primary lesion. The site of entry may be vaginal, rectal, or oral (Euerle et al., 2014). The syphilis spirochete can cross the placenta at any time during pregnancy. One out of every 10,000 infants born in the United States has congenital syphilis (CDC, 2015c). Maternal infection consequences include spontaneous abortion, low birth weight, fetal growth restriction, prematurity, stillbirth, and multisystem failure of the heart, lungs, spleen, liver, and pancreas, as well as structural bone damage and nervous system involvement and mental retardation (Chen et al., 2015). Most newborns born with congenital syphilis are exposed in utero after the fourth month of pregnancy, although syphilis acquired late in the third trimester can also be transmitted to an infant through exposure to an active genital lesion at the time of birth. If untreated, syphilis is a lifelong infection progressing in orderly staging. The five stages of syphilis infection are: (1) primary, (2) secondary, (3) early latent, (4) late latent, and (5) tertiary. The primary, secondary, and early latent stages are considered the most infectious: the estimated risk of per person transmission is 60% (Queenan, Spong, & Lockwood, 2015).

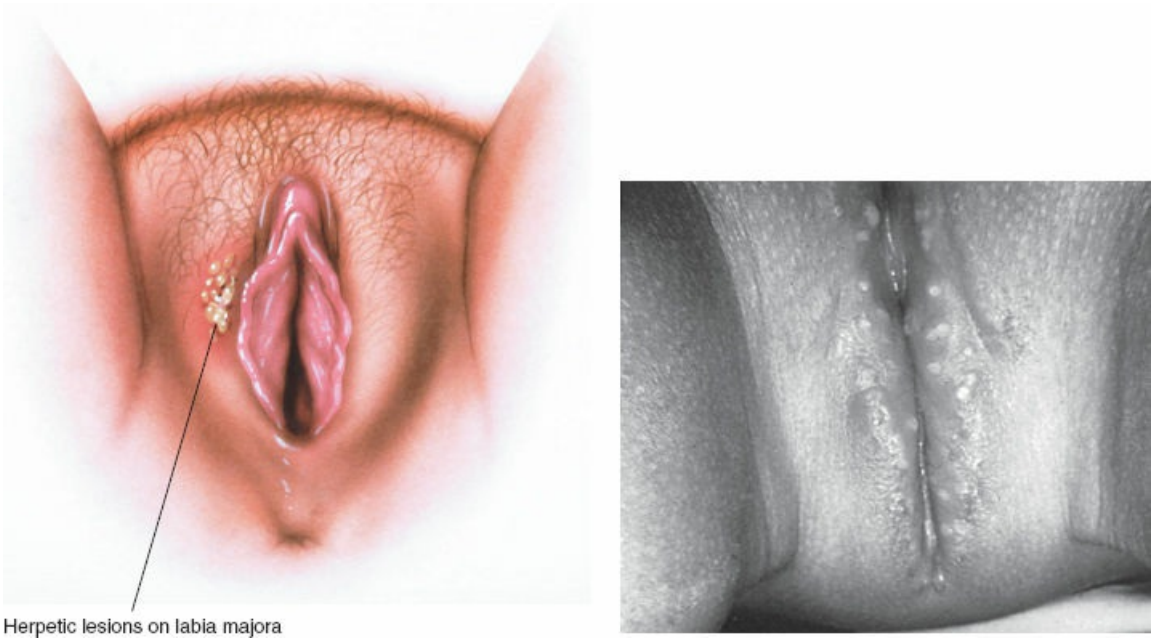

FIGURE 5.5 Genital herpes simplex. (Illustration provided by Anatomical Chart Co. Photograph courtesy of Stephen Ludwig, MD.)

Therapeutic Management

Fortunately, there is effective treatment for syphilis. Benzathine penicillin G, administered by either the IM or intravenous route, is the preferred drug for all stages of syphilis. For pregnant or nonpregnant women with syphilis of less than 1 year's duration, the CDC recommends 2.4 million units of benzathine penicillin G intramuscularly in a single dose. If the syphilis is of longer duration (more than 1 year) or of unknown duration, 2.4 million units of benzathine penicillin G is given intramuscularly once a week for 3 weeks. The preparations used, the dosage, and the length of treatment depend on the stage and clinical manifestations of disease (CDC, 2015a). Other medications, such as doxycycline, are available if the client is

allergic to penicillin.

Women should be re-evaluated at 6 and 12 months after treatment for primary or secondary syphilis with additional serologic testing. Women with latent syphilis should be followed clinically and serologically at 6, 12, and 24 months and also tested for HIV (Lawrence et al., 2015).

Nursing Assessment

Assess the client for clinical manifestations of syphilis. Syphilis is divided into four stages: primary, secondary, latency, and tertiary. Primary syphilis is characterized by a chancre (painless ulcer) at the site of bacterial entry that will disappear within 1 to 6 weeks without intervention (Fig. 5.6). Motile spirochetes are present on dark-field examination of ulcer exudate. In addition, painless bilateral adenopathy is present during this highly infectious period. If left untreated, the infection progresses to the secondary stage. Secondary syphilis appears 2 to 6 months after the initial exposure and is manifested by flu-like symptoms and a maculopapular rash of the trunk, palms, and soles. Alopecia and adenopathy are both common during this stage. In addition to rashes, secondary syphilis may present with symptoms of fever, pharyngitis, weight loss, and fatigue (Euerle et al., 2014). The secondary stage of syphilis lasts about 2 years. Once the secondary stage subsides, the latency period begins. This stage is characterized by the absence of any clinical manifestations of disease, although the serology is positive. This stage can last as long as 20 years. If not treated, tertiary or late syphilis occurs, with life-threatening heart disease and neurologic disease that slowly destroys the heart, eyes, brain, central nervous system, and skin.

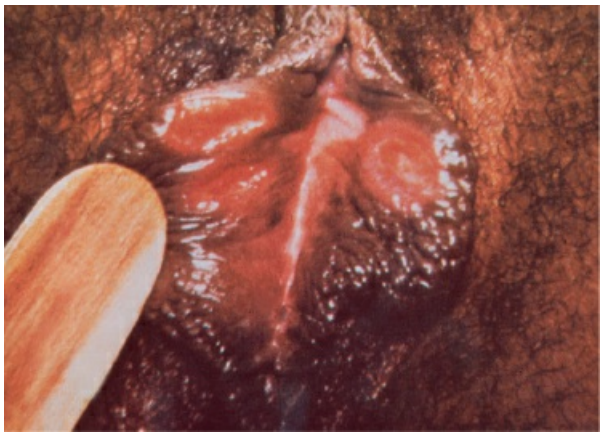

FIGURE 5.6 Chancre of primary syphilis. (From Sweet R. L, Gibbs R. S. (2005). *Atlas of infectious diseases of the female genital tract*. Philadelphia, PA: Lippincott Williams & Wilkins.)

Clients with a diagnosis of HIV or another STI should be screened for syphilis, and all pregnant women should be screened at their first prenatal visit. Dark-field microscopic examinations and direct fluorescent antibody tests of lesion exudate or tissue are the definitive methods for diagnosing early syphilis. A presumptive diagnosis can be made by using two serologic tests:

- Nontreponemal tests (Venereal Disease Research Laboratory [VDRL] and rapid plasma reagin [RPR])
- Treponemal tests (fluorescent treponemal antibody absorbed [FTA-ABS] and *T.*

pallidum particle agglutination [TP-PA]). Dark-field microscopic examinations and direct fluorescent antibody tests of lesion exudate or tissue are the definitive methods for diagnosing early syphilis (CDC, 2015p).

Nursing Management of Herpes and Syphilis

Genital ulcers from either herpes or syphilis can be devastating to women, and the nurse can be instrumental in helping her through this difficult time. Referral to a support group may be helpful. Address the psychosocial aspects of these STIs with women by discussing appropriate coping skills, acceptance of the lifelong nature of the condition (herpes), and options for treatment and rehabilitation. Teaching Guidelines 5.3 highlights appropriate teaching points for the client with genital ulcers.

Teaching Guidelines 5.3
CARING FOR GENITAL ULCERS

- Abstain from intercourse during the prodromal period and when lesions are present.
- Wash hands with soap and water after touching lesions to avoid autoinoculation.
- Use comfort measures such as wearing nonconstricting clothes, wearing cotton underwear, urinating in water if urination is painful, taking lukewarm sitz baths, and air-drying lesions with a hair dryer on low heat.
- Avoid extremes of temperature such as ice packs or hot pads to the genital area as well as application of steroid creams, sprays, or gels.
- Use condoms with all new or noninfected partners.
- Inform health care professionals of your condition.

PELVIC INFLAMMATORY DISEASE

PID is an infection-induced inflammation of the female upper reproductive tract. PID rates remain unacceptably high. PID may involve the uterine lining (endometritis), the connective tissue adjacent to the uterus (parametritis), the Fallopian tubes (salpingitis), or the serous membrane that lines part of the abdominal cavity and viscera (peritonitis), or it may manifest as tubo-ovarian abscess (Brunham, Gottlieb, & Paavonen, 2015). PID results from an ascending polymicrobial infection of the upper female reproductive tract, frequently caused by untreated chlamydia or gonorrhea (Fig. 5.7). An estimated 750,000 women are diagnosed annually, resulting in over 250,000 hospitalizations (CDC, 2015n). Complications include ectopic pregnancy, pelvic abscess, subfertility, recurrent or chronic episodes of the disease, chronic abdominal pain, pelvic adhesions, and depression (Gilbert, 2015). Because most PID cases are secondary to STIs, especially chlamydia, the most effective approach to control it is prevention. Because of the seriousness of the complications of PID, an accurate diagnosis is critical *Healthy People 2020*.

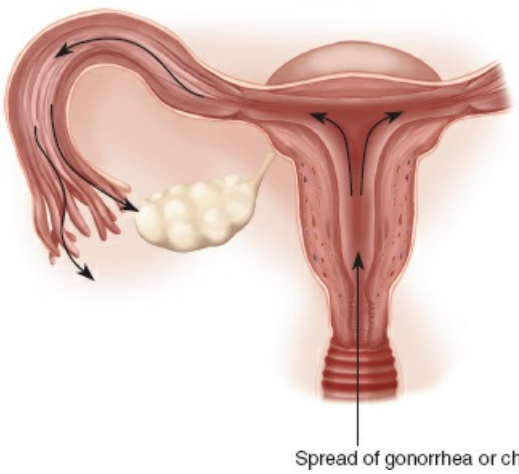

FIGURE 5.7 Pelvic inflammatory disease. Chlamydia or gonorrhea spreads up the vagina into the uterus and then to the fallopian tubes and ovaries.

HEALTHY PEOPLE 2020

STD-5 objective	Significance
Reduce the proportion of females who have ever required treatment for pelvic inflammatory disease (PID)	Educate women that abstinence is the only way to completely avoid contracting sexually transmitted infections
Reduce the proportion of childless females with fertility problems who have had a sexually transmitted disease or who have ever required treatment for PID.	Encourage women always to use condoms if participating in any sexual act Provide an open and confidential environment so women will report symptoms and seek treatment earlier

Therapeutic Management

Broad-spectrum antibiotic therapy is generally required to cover chlamydia, gonorrhea, and/or any anaerobic infection. A parenteral cephalosporin in a single injection with doxycycline 100 mg twice a day for 14 days is the current CDC recommendation (CDC, 2015a). PID in pregnancy is uncommon, but a combination of cefotaxime, azithromycin, and metronidazole for 14 days may be used. The client is treated on an ambulatory basis with a single-dose injectable antibiotic or is hospitalized and given antibiotics intravenously. The decision to hospitalize a woman is based on clinical judgment and the severity of her symptoms (e.g., severely ill with high fever, a tubo-ovarian abscess is suspected, woman is immunocompromised or presents with protracted vomiting). Treatment then includes intravenous antibiotics, increased oral fluids to improve hydration, bed rest, and pain management. Follow-up is needed to validate that the infectious

process is gone to prevent the development of chronic pelvic pain.

Nursing Assessment

Nursing assessment of the woman with PID involves a complete health history and assessment of clinical manifestations, physical examination, and laboratory and diagnostic testing.

Health History and Clinical Manifestations

Explore the client's current and past medical health history for risk factors for PID, which may include:

- Adolescence or young adulthood
- Non-White female
- Having multiple sex partners
- Early onset of sexual activity
- History of PID or STI
- Sexual intercourse at an early age
- Alcohol or drug use
- Having intercourse with a partner who has untreated urethritis
- Recent insertion of an intrauterine contraceptive (IUC)
- Nulliparity
- Cigarette smoking
- Recent termination of pregnancy
- Lack of consistent condom use
- Lack of contraceptive use
- Douching
- Prostitution (Hay et al., 2015)

Assess the client for clinical manifestations of PID, keeping in mind that because of the wide variety of clinical manifestations of PID, clinical diagnosis can be challenging. To reduce the risk of missed diagnosis, the CDC has established criteria to establish the diagnosis of PID. Minimal criteria (all must be present) are lower abdominal tenderness, adnexal tenderness, and cervical motion tenderness. Additional supportive criteria that support a diagnosis of PID are:

- Abnormal cervical or vaginal mucopurulent discharge
- Oral temperature above 101°F
- Cervical motion tenderness
- Elevated erythrocyte sedimentation rate (inflammatory process)
- Elevated C-reactive protein level (inflammatory process)
- *N. gonorrhoeae* or *C. trachomatis* infection documented (causative bacterial organism)
- White blood cells on saline vaginal smear
- Prolonged or increased menstrual bleeding
- Dysmenorrhea
- Dysuria
- Painful sexual intercourse
- Nausea
- Vomiting (CDC, 2015n)

Physical Examination and Laboratory and Diagnostic Tests

Inspect the client for presence of fever (usually over 101˚F) or vaginal discharge. Palpate the abdomen, noting tenderness over the uterus or ovaries. However, the only way to diagnose PID definitively is through an endometrial biopsy, transvaginal ultrasound, or laparoscopic examination.

Nursing Management

If the woman with PID is hospitalized, maintain hydration via intravenous fluids, if necessary and administer analgesics as needed for pain. Semi-Fowler's positioning facilitates pelvic drainage. A key element to treatment of PID is education to prevent recurrence. Depending on the clinical setting (hospital or community clinic) where the nurse encounters the woman diagnosed with PID, a risk assessment should be done to ascertain what interventions are appropriate to prevent a recurrence. To gain the woman's cooperation, explain the various diagnostic tests needed. Discuss the implications of PID and the risk factors for the infection; her sexual partner should be included if possible. Sexual counseling should include practicing safer sex, limiting the number of sexual partners, using barrier contraceptives consistently, avoiding vaginal douching, considering another contraceptive method if she has an intrauterine system (IUS) and has multiple sexual partners, and completing the course of antibiotics prescribed (Shepherd, 2015). Review the serious sequelae that may occur if the condition is not treated or if the woman does not comply with the treatment plan. Ask the woman to have her partner go for evaluation and treatment to prevent a repeat infection. Provide nonjudgmental support while stressing the importance of barrier contraceptive methods and follow-up care. Teaching Guidelines 5.4 gives further information related to PID prevention.

Teaching Guidelines 5.4
PREVENTING PELVIC INFLAMMATORY DISEASE

- Advise sexually active girls and women to insist their partners use condoms.
- Discourage routine vaginal douching, as this may lead to bacterial overgrowth.
- Encourage regular STI screening.
- Emphasize the importance of having each sexual partner receive antibiotic treatment.

VACCINE-PREVENTABLE STIS

Some STIs can be effectively prevented through pre-exposure vaccination. Vaccines are under development or are undergoing clinical trials for certain STIs, including HIV and HSV. However, the only vaccines currently available are for prevention of HAV, HBV, and HPV infection. Vaccination efforts focus largely on integrating the use of these available vaccines into STI prevention and treatment activities (CDC, 2014c).

Human Papillomavirus

HPV is the most common viral infection in the United States (CDC, 2015l). Genital warts or condylomata (Greek for "warts") are caused by HPV. Conservative estimates suggest that in the United States, approximately 80 million people have productive HPV infection, and 14 million Americans acquire it annually (CDC, 2015l). Clinical studies have confirmed that HPV is the cause of essentially all cases of cervical cancer, which is the fourth most common cancer in women in the United States, following lung, breast, and colorectal cancer (American Cancer Society [ACS], 2015). HPV-mediated oncogenesis is responsible for up to 95% of cervical squamous cell carcinomas and nearly all preinvasive cervical neoplasms (Gearhart et al., 2015). More than 30 types of HPV can infect the genital tract. HPV is most prevalent in young women between the ages of 20 and 24 years old, followed closely by the 15- to 19-year-old age group (Callahan, 2016).

Take Note!

Most sexually active men and women will get HPV at some point in their lives. This means everyone is at risk (CDC, 2015l).

Nursing Assessment

Nursing assessment of the woman with HPV involves a complete health history and assessment of clinical manifestations, physical examination, and laboratory and diagnostic testing.

Health History and Clinical Manifestations

Assess the client's health history for risk factors for HPV, which include having multiple sex partners, age 15 to 25 years old, sex with a male who has had multiple sexual partners, and first intercourse at 16 years or younger (Dillner, 2015). Risk factors contributing to the development of cervical cancer include smoking, few or no screenings for cervical cancer, multiple sex partners, immunosuppressed state, nulliparity, long-term contraceptive use (more than 2 years), coinfection with another STI, pregnancy, nutritional deficiencies, and early onset of sexual activity (Coffey et al., 2015).

Assess the client for clinical manifestations of HPV. Most HPV infections are asymptomatic, unrecognized, or subclinical. Visible genital warts are usually caused by HPV types 6 or 11. In addition to the external genitalia, genital warts can occur on the cervix and in the vagina, urethra, anus, and mouth. Depending on the size and location, genital warts can be painful, friable, and pruritic, although most are typically asymptomatic (Fig. 5.8). The strains of HPV associated with genital warts are considered low risk for development of cervical cancer, but other HPV types (16, 18, 31, 33, 45, 52, and 58) have been strongly associated with cervical cancer (CDC, 2015l).

FIGURE 5.8 **Genital warts. (Illustration provided by Anatomical Chart Co. Photograph from Sherwood L. Gorbach, John G. Bartlett, et al. *Infectious Diseases*. Philadelphia: Lippincott Williams & Wilkins, 2004.)**

Physical Examination and Laboratory and Diagnostic Tests

Clinically, visible warts are diagnosed by inspection. The warts are fleshy papules with a warty, granular surface. Lesions can grow very large during pregnancy, affecting urination, defecation, mobility, and descent of the fetus (CDC, 2015l). Large lesions, which may resemble cauliflowers, exist in coalesced clusters and bleed easily.

Serial Pap smears are performed for low-risk women. These regular Pap smears will detect the cellular changes associated with HPV. The FDA has recently approved an HPV test as a follow-up for women who have an ambiguous Pap test. In addition, this HPV test may be a helpful addition to the Pap test for general screening of women aged 30 years and above. The HPV test is a diagnostic test that can determine the specific HPV strain, which is useful in discriminating between low-risk and high-risk HPV types. A specimen for testing can be obtained with a fluid-phase collection system such as Thin Prep. The HPV test can identify 13 of the high-risk types of HPV associated with the development of cervical cancer and can detect high-risk types of HPV even before there are any conclusive visible changes to the cervical cells. If the test is positive for the high-risk types of HPV, the woman should be referred for colposcopy.

Upon physical examination, it is determined that Sandy has genital warts. The nurse finds out that Sandy engaged in high-risk behavior with a stranger she "hooked up" with recently at college. She couldn't imagine that he would give her an STI because "he looked so clean-cut." She wonders how she could possibly have genital warts. What information should be given to Sandy about STIs in general? What specific information about HPV should be stressed?

Therapeutic Management

There is currently no medical treatment or cure for HPV. Instead, therapeutic management focuses heavily on prevention through the use of the HPV vaccine and education and on the treatment of lesions and warts caused by HPV. The FDA has

approved three HPV vaccines to prevent cervical cancer: Cervarix, Gardasil, and Gardasil 9. The CDC's Advisory Committee on Immunization Practices (ACIP) has recommended the vaccine for routine administration to 11- and 12-year-old girls and boys. The ACIP also endorsed the use of a HPV vaccine for girls and boys as young as 9 years and recommended that women between the ages of 13 and 26 years receive the vaccination series, which consists of three injections over 6 months. All three are prophylactic HPV vaccines designed primarily for cervical cancer prevention. Cervarix is effective against HPV-16, 18, 31, 33, and 45, the five most common cancer-causing types, including most causes of adenocarcinoma for which we cannot screen adequately. Gardasil is effective against HPV-16, 18, and 31, three common squamous cell cancer-causing types. In addition, Gardasil is effective against HPV-6 and 11, causes of genital warts and respiratory papillomatosis. The most important determinant of vaccine impact to reduce cervical cancer is its duration of efficacy. Cervarix is used only in females, whereas Gardasil 9 is used for both boys and girls. Gardasil 9 is effective against HPV types 6, 11, 16, 18, 31, 33, 45, 52, and 58. According to the FDA, the new vaccine (Gardasil 9) can potentially prevent about 90% of cervical, vulvar, vaginal, and anal cancers (Gearhart, Higgins, & Randall, 2015). Prophylactic HPV vaccines are safe, well tolerated, and highly efficacious in preventing persistent infections and cervical diseases associated with vaccine-HPV types among young females.

The vaccine is administered intramuscularly in three separate 0.5-mL doses. The first dose may be given to any individual 9 to 26 years old prior to infection with HPV. The second dose is administered 2 months after the first, and the third dose is given 6 months after the initial dose. The deltoid region of the upper arm or anterolateral area of the thigh may be used. The most common vaccine side effects include pain, fainting, redness, and swelling at the injection site; fatigue; headache; muscle and joint aches; and gastrointestinal distress. The vaccine is given in a series of three injections over a 6-month period (CDC, 2015l).

If the woman doesn't receive primary prevention with the vaccine, then secondary prevention would focus on education about the importance of receiving regular Pap smears and, for women over age 30 years, including an HPV test to determine whether the woman has a latent high-risk virus that could lead to precancerous cervical changes. Finally, treatment options for precancerous cervical lesions or genital warts caused by HPV are numerous and may include:

- Topical trichloroacetic acid 80% to 90%
- Liquid nitrogen cryotherapy
- Topical imiquimod 5% cream
- Topical podophyllin 10% to 25%
- Sinecatechins 15% ointment
- Laser carbon dioxide vaporization
- Client-applied podofilox 0.5% solution or gel
- Simple surgical excision
- Loop electrosurgical excisional procedure (LEEP)
- Intralesional interferon therapy (CDC, 2015a)

The goal of treating genital warts is to remove the warts and induce wart-free periods for the client. Treatment of genital warts should be guided by the preference of the client and available resources. No single treatment has been found to be ideal

for all clients, and most treatment modalities appear to have comparable efficacy. Because genital warts can proliferate and become friable during pregnancy, they should be removed using a local agent. A cesarean birth is not indicated solely to prevent transmission of HPV infection to the newborn, unless the pelvic outlet is obstructed by warts (Gearhart et al., 2015).

Nursing Management

An HPV infection has many implications for the woman's health, but most women are unaware of HPV and its role in cervical cancer. The average age of sexual debut is in early adolescence; therefore, it is important to target this population for use of the HPV/cervical cancer vaccine.

Key nursing roles are teaching about prevention of HPV infection and client education and promotion of vaccines and screening tests in order to reduce the morbidity and mortality associated with cervical cancer caused by HPV infection. Teach all women that the only way to prevent HPV is to refrain from any genital contact with another person. Although the effect of condoms in preventing HPV infection is unknown, latex condom use has been associated with a lower rate of cervical cancer. Teach women about the link between HPV and cervical cancer. Explain that, in most cases, there are no signs or symptoms of infection with HPV. Strongly encourage all young women aged between 9 and 26 years to consider getting Gardasil 9, the vaccine against HPV. For all women, promote the importance of obtaining regular Pap smears and, for women over 30 years, suggest an HPV test to rule out the presence of a latent high-risk strain of HPV.

Education and counseling are important aspects of managing women with genital warts. Teach the woman that:

- Even after genital warts are removed, HPV still remains and viral shedding will continue.
- The likelihood of transmission to future partners and the duration of infectivity after treatment for genital warts are unknown.
- The recurrence of genital warts within the first few months after treatment is common and usually indicates recurrence rather than reinfection (CDC, 2015a).

Hepatitis A and B

Hepatitis is an acute, systemic, viral infection that can be transmitted sexually. The viruses associated with hepatitis or inflammation of the liver are hepatitis A, B, C, D, E, and G. Hepatitis A virus (HAV) is spread via the gastrointestinal tract. It can be acquired by drinking polluted water, by eating uncooked shellfish from sewage-contaminated waters or food handled by a hepatitis carrier with poor hygiene, and from oral/anal sexual contact. Approximately 33% of the United States population has serologic evidence of prior hepatitis A infection; the rate increases directly with age (Pyrsopoulos & Reddy, 2015). A person with hepatitis A can easily pass the disease to others within the same household.

Hepatitis B (HBV) is transmitted through saliva, blood serum, semen, menstrual blood, and vaginal secretions. The incubation period from the time of exposure to onset of symptoms is 6 weeks to 6 months (CDC, 2015h). In the early 2000s, transmission among heterosexual partners accounted for 40% of infections, and transmission among men who have sex with men accounted for 20% of infections.

The World Health Organization (WHO) estimates that the prevalence of hepatitis B worldwide is 2 billion people, with about 240 million chronically infected with it. Worldwide, hepatitis B has the highest death rate of any STI except HIV (WHO, 2015b). Risk factors for infection include having multiple sex partners, engaging in unprotected receptive anal intercourse, and having a history of other STIs (CDC, 2015h). The most effective means to prevent the transmission of hepatitis A or B is pre-exposure immunization. Vaccines are available for the prevention of HAV and HBV, both of which can be transmitted sexually. Every person seeking treatment for an STI should be considered a candidate for hepatitis B vaccination, and some individuals (e.g., men who have sex with men, and injection-drug users) should be considered for hepatitis A vaccination (CDC, 2015h).

Therapeutic Management

Unlike other STIs, HBV and HAV are preventable through immunization. HAV is usually self-limiting and does not result in chronic infection. HBV can result in serious, permanent liver damage. Treatment is generally supportive. No specific treatment for acute HBV infection exists.

Nursing Assessment

Assess the client for clinical manifestations of hepatitis A and B. Hepatitis A produces flu-like symptoms with malaise, skin rashes, fatigue, anorexia, nausea, pruritus, fever, and upper right quadrant pain. Symptoms of hepatitis B are similar to those of hepatitis A, but with less fever and skin involvement. The diagnosis of hepatitis A cannot be made based on clinical manifestations alone and requires serologic testing. The presence of IgM antibody to HAV is diagnostic of acute HAV infection. Hepatitis B is detected by a blood test that looks for antibodies and proteins produced by the virus and is positively diagnosed by the presence of hepatitis B surface antibody (HBsAb) (Pyrsopoulos & Reddy, 2015).

Nursing Management

Nurses should encourage all women to be screened for hepatitis when they have their annual Pap smear, or sooner if high-risk behavior is identified. Nurses should also encourage women to undergo HBV screening at their first prenatal visit and repeat screening in the last trimester for women with high-risk behaviors (Lee & Lok, 2015). Nurses can also explain that hepatitis B vaccine is given to all infants after birth in most hospitals. The vaccination consists of a series of three injections given within 6 months. The vaccine has been shown to be safe and well tolerated by most recipients (CDC, 2015a). Hepatitis A vaccine is strongly encouraged for children between 12 and 23 months; persons 1 year of age and older traveling to countries with a high prevalence of hepatitis A, such as Central or South America, Mexico, Asia, Africa, and eastern Europe; men who have sex with men; persons who use street drugs; and persons with chronic liver disease (CDC, 2015g). For others, hepatitis A vaccine series (two doses 6 months apart) may be started whenever a person is at risk of infection.

Hepatitis C

Although HCV is not transmitted sexually, it deserves a brief mention here because injection-drug use by women places them at risk for it. Women at high risk include those with a history of injecting-drug use and those with a history of blood transfusion before 1992 (CDC, 2015i). The prevalence of HCV infection in pregnant women is approximately 1%. The majority of infected women are not aware they have HCV because they are not clinically ill. Perinatal transmission of HCV is relatively rare, except in women who are immunocompromised (HIV/AIDS) (Mattson & Smith, 2015).

ECTOPARASITIC INFECTIONS

Ectoparasites are a common cause of skin rash and pruritus throughout the world, affecting people of all ages, races, and socioeconomic groups. Overcrowding, delayed diagnosis and treatment, and poor public education contribute to the prevalence of ectoparasites in both industrial and nonindustrial nations. Approximately 300 million cases of ectoparasitic cases are reported worldwide each year (CDC, 2015d). These infections include infestations of scabies and pubic lice. Since these parasites are easily passed from one person to another during sexual intimacy, clients should be assessed for them when receiving care for other STIs. Scabies is an intensely pruritic dermatitis caused by a mite. The female mite burrows under the skin and deposits eggs, which hatch. The lesions start as a small papule that reddens, erodes, and sometimes crusts. Diagnosis is based on history and appearance of burrows in the webs of the fingers and the genitalia (Guenther & Maguiness, 2015). Aggressive infestation can occur in immunodeficient, debilitated, or malnourished people, but healthy people do not usually suffer sequelae.

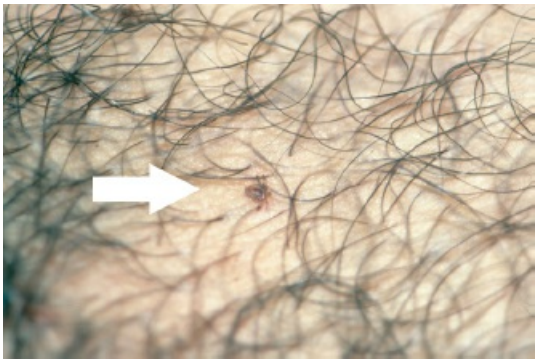

FIGURE 5.9 Pubic lice. A small brown living crab louse is seen at the base of hairs (*arrow*). (From Goodheart, H. (2009). *Goodheart's photoguide of common skin disorders*. Philadelphia, PA: Lippincott Williams & Wilkins.)

Clients with pediculosis pubis (pubic lice) usually seek treatment because of the pruritus, because of a rash brought on by skin irritation from scratching, or because they notice lice or nits in their pubic hair, axillary hair, abdominal and thigh hair, and sometimes in the eyebrows, eyelashes, and beards. Infestation is usually asymptomatic until after a week or so, when bites cause pruritus and secondary infections from scratching (Fig. 5.9). Diagnosis is based on history and the presence of nits (small, shiny, yellow, oval, dewdrop-like eggs) affixed to hair shafts or lice (a yellowish, oval, wingless insect) (Monsel & Chosidow, 2015).

Treatment is directed at the infested area, using permethrin 1% cream rinse and pyrethrin with piperonyl butoxide, which are FDA approved for treating head lice.

Both are available as over-the-counter (OTC) preparations. Repeat treatment in 1 week is advised to eradicate eggs that may have hatched after treatment started (King et al., 2015). Bedding and clothing should be washed in hot water to decontaminate it. Sexual partners should be treated also, as well as family members who live in close contact with the infected person.

Nursing care of a woman infested with lice or scabies involves a three-tiered approach: eradicating the infestation with medication, removing nits, and preventing spread or recurrence by managing the environment. OTC products are safe for use and kill the active lice or mites. Nurses should provide education about these products (Teaching Guidelines 5.5). The nurse can follow these same guidelines to prevent the health care facility from becoming infested.

Teaching Guidelines 5.5

TREATING AND MINIMIZING THE SPREAD OF SCABIES AND PUBIC LICE

- Use the medication according to the manufacturer's instructions.
- Remove nits with a fine-toothed nit comb.
- Do not share any personal items with others or accept items from others.
- Treat objects, clothing, and bedding and wash them in hot water.
- Meticulously vacuum carpets to prevent a recurrence of infestation.

HUMAN IMMUNODEFICIENCY VIRUS (HIV)

An estimated 1 million people in the United States and 34 million globally currently live with HIV and new cases of HIV infection in the United States have remained stable at about 50,000 annually (National Institute of Allergy and Infectious Diseases, 2015). In terms of epidemiology, fatality rate, and its social, legal, ethical, and political aspects, HIV infection became a global public health crisis over 20 years ago and has generated more concern than any other infectious disease in modern medical history (Oyelowo & Johnson, 2016). To date, there is no cure for this fatal viral infection.

The HIV virus is transmitted by intimate sexual contact, by sharing needles for intravenous drug use, from mother to fetus during pregnancy, or by transfusion of infected blood or blood products. Men who have sex with men represent the largest proportion of new infections, followed by men and women infected through heterosexual sex (CDC, 2015k). Approximately one in four people living with HIV infection in the United States are women (CDC, 2015k). About 12,500 new cases of HIV infection among women in the United States occur each year (CDC, 2015k). HIV infection disproportionately affects African American and Hispanic women. Together they represent less than 25% of all US women, yet they account for more than 88% of HIV infection cases (CDC, 2015k).

Women are particularly vulnerable to heterosexual transmission of HIV due to substantial mucosal exposure to seminal fluids. This biologic fact amplifies the risk of HIV transmission when coupled with the high prevalence of nonconsensual sex, sex without condoms, and the unknown and/or high-risk behaviors of their partners

(NIAID, 2015). Therefore, the face of HIV/AIDS is becoming the face of young women. That shift will ultimately exacerbate the incidence of HIV because women spread it not only through sex, but also through nursing and childbirth.

AIDS is a breakdown in the immune function caused by HIV, a retrovirus. The infected person develops opportunistic infections or malignancies that become fatal. Progression from HIV infection to AIDS varies within individuals. HIV affects CD4 cells in two ways: by depleting them and by impairing the remaining ones. This invasion of CD4 cells results in a gradual loss of immune function. If nothing is done to stop this invasion of CD4 cells, HIV can destroy as many as 1 billion CD4 cells daily (King et al., 2015).

Over 30 years (1981) have passed since HIV/AIDS began to affect our society. Since then, 1 million people have been infected by the virus, with AIDS being the fourth leading cause of death globally (CDC, 2015k). The morbidity and mortality of HIV continue to hold the attention of the medical community. While there has been a dramatic improvement in both morbidity and mortality with the use of antiretroviral therapy (ART), the incidence of HIV infection continues to be a public health challenge.

Take Note!

Once the HIV infection has progressed to AIDS, the survival period is usually less than 2 years in untreated clients (Bennett & Gilroy, 2015).

The fetal and neonatal effects of acquiring HIV through perinatal transmission can be devastating. If the HIV-infected infant goes untreated, progression to AIDS and eventual fatality will occur. An infected mother can transmit HIV infection to her newborn before or during birth and through breastfeeding. Current incidence of perinatal transmission is less than 1% if HIV+ mother is taking antiretroviral medication during pregnancy (CDC, 2015k).

HIV and Adolescents

As a typical function of development adolescents may view themselves as invincible, and thus delay seeking health care. They may be embarrassed or lack access to health care or may delay or refuse treatment if a diagnosis of HIV infection is made. Though the rates of HIV infection among adolescents have remained stable since 2006, the effects of HIV infection in this population continue to be of concern (CDC, 2015j). On average, the development of AIDS occurs about 11 years after infection, so most young adults with AIDS were infected during adolescence (Fairlie et al., 2015).

Most HIV-infected adolescents are exposed to the virus through heterosexual or homosexual contact. The majority of HIV-infected adolescent males are infected through sex with other males, while female teenagers are mostly exposed through heterosexual contact. Injected drug use accounts for a small percentage of HIV infection among male and female adolescents. Similar to HIV infection in women, African American and Hispanic adolescents represent a disproportionate percentage of HIV infection among teenagers (CDC, 2015j). More than 2 million adolescents between the ages of 10 and 19 are living with HIV, and many do not receive the care and support they need to stay in good health.

Clinical Manifestations

HIV infection undergoes three distinct phases—acute seroconversion, asymptomatic infection, and then progresses to AIDS. When a person is initially infected with HIV, he or she goes through an acute primary infection period for about 3 weeks. The HIV viral load drops rapidly because the host's immune system works well to fight this initial infection. The onset of the acute primary infection occurs 2 to 6 weeks after exposure. Symptoms include fever, pharyngitis, rash, and myalgia. Most people do not associate this flu-like condition with HIV infection. After initial exposure, there is a period of 3 to 12 months before seroconversion. The person is considered infectious during this time.

After the acute phase, the infected person becomes asymptomatic, but the HIV virus begins to replicate. Even though there are no symptoms, the immune system runs down. A normal person has a CD4 T-cell count of 450 to 1,200 cells per μL. When the CD4 T-cell count reaches 200 or less, the person has reached the stage of AIDS. The immune system begins a constant battle to fight this viral invasion, but over time it falls behind. A viral reservoir occurs in T cells that can store various stages of the virus. The onset and severity of the disease correlate directly with the viral load: the more HIV virus that is present, the worse the person will feel.

As profound immunosuppression begins to occur, an opportunistic infection will occur, qualifying the person for the diagnosis of AIDS. The diagnosis is finally confirmed when the CD4 count is below 200. As of now, AIDS will eventually develop in everyone who is HIV-positive.

World Health Organization (2015a) now recommends earlier initiation of ART for adults and adolescents, the delivery of more client-friendly antiretroviral (ARV) drugs, and prolonged use of ARVs to reduce the risk of mother-to-child transmission of HIV. ART should be started when the CD4 count reaches the 350 to 500 range. Also, WHO (2015a) recommends that HIV-positive mothers or their infants take ARVs while breastfeeding to prevent HIV transmission for up to 12 months after birth.

Diagnosis

HIV testing is regarded as the gateway to prevention and treatment. Several types of tests are approved to detect antigens, antibodies, or RNA. Screening for HIV infection is paramount, since infected individuals may remain asymptomatic for years while the infection progresses. Currently, there are two categories of screening methods: rapid HIV tests and confirmatory tests. The rapid tests allow for screening at the point of care and offer quick results. Five rapid HIV tests that are FDA approved are OraQuick Advance HIV tests (whole blood used); Uni-Gold Recombigen HIV test (whole blood used); Reveal G-3 Rapid HIV Antibody test (serum or plasma used); Multispot (serum or plasma used); and Clearview Stat-Pak (whole blood used). A positive result is followed up with one of two confirmatory tests: Western blot (WB) test or immunofluorescence assay (IFA) (Bennett & Gilroy, 2015).

Quick tests for HIV produce results in 10 to 20 minutes and also lower the health care worker's risk of occupational exposure by eliminating the need to draw blood. The CDC's Advancing HIV Prevention initiative, launched in 2003, has made increased testing a national priority. The initiative calls for testing to be

incorporated into all routine medical care and to be delivered in more nontraditional settings.

Fewer than half of adults between the ages of 18 and 64 have ever had an HIV test, according to the CDC. The agency estimates that one fourth of the 1 million HIV-infected people in the United States do not know they are infected. This means they are not receiving treatment that can prolong their lives, and they may be unknowingly infecting others. In addition, even when people do get tested, one in three failed to return to the testing site to learn their results when there was a 2-week wait. The CDC hopes that the new "one-stop" approach to HIV testing changes that pattern. About 50,000 new HIV cases are reported each year in the United States, and that number has held steady for the past few years despite massive efforts in prevention education (CDC, 2015k).

People who are infected with HIV but not aware of it are not able to take advantage of the therapies that can keep them healthy and extend their lives, nor do they have the knowledge to protect their sex or drug-use partners from becoming infected. Knowing whether one is positive or negative for HIV confers great benefits in healthy decision making.

Rapid point of service HIV tests are becoming powerful screening tools in various health care settings because they offer the opportunity to not only screen for HIV, but also to educate the person regarding risk factors, and discuss their test results—all in one clinical visit. Most use a finger stick drop of blood or a swab of saliva taken from the mouth. Results are typically ready within 10 to 20 minutes. The CDC has specific protocols for confirmation of positive screening test results—confirmation tests include the WB test or IFA. Home HIV testing kits are available, accurate, and being used by many with the potential to increase testing, diagnosis, and ultimately reduce HIV prevalence (Dore, 2015).

If the confirmation test (WB or IFA) is positive, the person is infected with HIV and is capable of transmitting the virus to others. HIV antibody is detectable in at least 95% of people within 3 months after infection (CDC, 2015k).

Therapeutic Management

The goals of HIV drug therapy are to:
- Decrease the HIV viral load below the level of detection
- Restore the body's ability to fight off pathogens
- Improve the client's quality of life
- Reduce HIV morbidity and mortality (King et al., 2015)

Highly active antiretroviral therapy (HAART), which combines at least three ARV drugs, has dramatically improved the prognosis of HIV/AIDS. Treatment with HAART should begin for any person with an AIDS-defining illness or with a history of a CD4 count less than 350 cells/mm (WHO, 2016). The current HAART standard is a triple combination therapy, but some clients may be given a fourth or fifth agent.

Current therapy to prevent the transmission of HIV to the newborn includes a three-part regimen of having the mother take an oral ARV agent at 14 to 34 weeks of gestation; it is continued throughout pregnancy. During labor, an ARV agent is administered intravenously until delivery. An ARV syrup is administered to the infant within 12 hours after birth.

Dramatic new treatment advances with ARV medications have turned a disease that used to be a death sentence into a chronic, manageable one for individuals who live in countries where ART is available. Despite these advances in treatment, however, only a minority of HIV-positive people in the United States who take ARV medications are receiving the full benefits because they are not adhering to the prescribed regimen. Successful ART requires nearly perfect adherence to a complex medication regimen; less-than-perfect adherence leads to drug resistance (King et al., 2015).

Adherence is difficult because of the complexity of the regimen and the lifelong duration of treatment. A typical ARV regimen may consist of three or more medications taken twice daily. Adherence is made even more difficult because of the unpleasant side effects, such as nausea and diarrhea. Women in early pregnancy already experience these, and the ARV medication only exacerbates them.

Nursing Management

Nurses can play a major role in caring for the HIV-positive woman by helping her accept the possibility of a shortened life span, cope with others' reactions to a stigmatizing illness, and develop strategies to maintain her physical and emotional health. Educate the woman about changes she can make in her behavior to prevent spreading HIV to others, and refer her to appropriate community resources such as HIV medical care services, substance abuse, mental health services, and social services. See Nursing Care Plan 5.1: Overview for the Woman With HIV (at the end of the chapter).

Providing Education About Drug Therapy

The goal of ART is to suppress viral replication so that the viral load becomes undetectable by diagnostic tests. This is done to preserve immune function and delay disease progression but is a challenge because of the side effects of nausea and vomiting, diarrhea, altered taste, anorexia, flatulence, constipation, headaches, anemia, and fatigue. Although not everyone experiences all of the side effects, the majority do have some of them. Current research hasn't documented the long-term safety of exposure of the fetus to ARV agents during pregnancy, but collection of data is ongoing.

Help to reduce the development of drug resistance and thus treatment failure by identifying the barriers to adherence; identifying these barriers can help the woman to overcome them. Some of the common barriers exist because the woman:

- Does not understand the link between drug resistance and nonadherence
- Fears revealing her HIV status by being seen taking medication
- Hasn't adjusted emotionally to the HIV diagnosis
- Doesn't understand the dosing regimen or schedule
- Experiences unpleasant side effects frequently
- Feels anxious or depressed (Abdurakhmanov & Zandman-Goddard, 2015)

Educate the woman about the prescribed drug therapy and stress that it is very important to take the regimen as prescribed. Offer suggestions about how to cope with anorexia, nausea, and vomiting by:

- Separating the intake of food and fluids
- Eating dry crackers upon arising

- Eating six small meals daily
- Using high-protein supplements (Boost, Ensure) to provide quick and easy protein and calories
- Eating "comfort foods," which may appeal when other foods don't

Promoting Compliance

Remaining compliant with drug therapy is a huge challenge for many HIV-infected people. Compliance becomes difficult when the same pills that are supposed to thwart the disease are making the person sick. Nausea and diarrhea are just two of the possible side effects. It is often difficult to increase the client's quality of life when so much oral medication is required. The combination medication therapy is challenging for many people, and staying compliant over a period of years is extremely difficult. Stress the importance of taking the prescribed ARV drug therapies by explaining that they help prevent replication of the retroviruses and subsequent progression of the disease, as well as decreasing the risk of perinatal transmission of HIV. In addition, provide written materials describing diet, exercise, medications, and signs and symptoms of complications and opportunistic infections. Reinforce this information at each visit.

Preventing HIV Infection

The lack of information about HIV infection and AIDS causes great anxiety and fear of the unknown. It is vital to take a leadership role in educating the public about risky behaviors in the fight to control this disease. The core of HIV prevention is to abstain from sex until marriage, to be faithful, and to use condoms. This is all good advice for many women, but some simply do not have the economic and social power or choices or control over their lives to put that advice into practice. Recognize that fact, and address the factors that will give women more control over their lives by providing anticipatory guidance, giving ample opportunities to practice negotiation techniques and refusal skills in a safe environment, and encouraging the use of female condoms to protect against this deadly virus. Prevention is the key to reversing the current infection trends.

Providing Care During Pregnancy and Childbirth

Voluntary counseling and HIV testing should be offered to all pregnant women as early in the pregnancy as possible to identify HIV-infected women so that treatment can be initiated early. Once a pregnant woman is identified as being HIV-positive, she should be informed about the risk for perinatal infection. The risk of perinatal transmission of HIV from an infected mother to her newborn is about 25%. This risk falls to less than 1% if the mother receives ART during pregnancy (Adam, 2015). HIV can be spread to the infant through breastfeeding so that when acceptable alternative infant formulas are readily available, HIV-infected mothers should be counseled to avoid breastfeeding and use formula instead. WHO (2015a) recommendations indicate that transmission of HIV via breast milk is decreased when the mother is undergoing ART.

In addition, the woman needs instructions on ways to enhance her immune system by following these guidelines during pregnancy:

- Getting adequate sleep each night (7 to 9 hours)

• Avoiding infections (e.g., staying away from crowds, handwashing)
• Decreasing stress in her life
• Consuming adequate protein and vitamins
• Increasing her fluid intake to 2 L daily to stay hydrated
• Planning rest periods throughout the day to prevent fatigue

Despite the dramatic reduction in perinatal transmission, hundreds of infants will be born infected with HIV. The birth of each infected infant is a missed prevention opportunity. To minimize perinatal HIV transmission, identify HIV infection in women, preferably before pregnancy; provide information about disease prevention; and encourage HIV-infected women to follow the prescribed drug therapy.

Providing Appropriate Referrals

The HIV-infected woman may have difficulty coping with the normal activities of daily living because she has less energy and decreased physical endurance. She may be overwhelmed by the financial burdens of medical and drug therapies and the emotional responses to a life-threatening condition, as well as concern about her infant's future, if she is pregnant. A case management approach is needed to deal with the complexity of her needs during this time. Be an empathetic listener and make appropriate referrals for nutritional services, counseling, homemaker services, spiritual care, and local support groups. Many community-based organizations have developed programs to address the numerous issues regarding HIV/AIDS. The national AIDS hotline (1–800–342-AIDS) is a good resource. Table 5.4 provides a summary of perinatal effects of STIs during pregnancy.

PREVENTING SEXUALLY TRANSMITTED INFECTIONS

Education about safer sex practices—and the resulting increase in the use of condoms—can play a vital role in reducing STI rates all over the world. Clearly, knowledge and prevention are the best defenses against STIs. The prevention and control of STIs is based on the following concepts (CDC, 2014c).

1. Education and counseling of people at risk about safer sexual behavior
2. Identification of asymptomatic infected people and of symptomatic people unlikely to seek diagnosis and treatment
3. Effective diagnosis and treatment of infected people
4. Evaluation, treatment, and counseling of sex partners of people who are infected with an STI
5. Pre-exposure vaccination of people at risk for vaccine-preventable STIs

Nurses play an integral role in identifying and preventing STIs. They have a unique opportunity to educate the public about this serious public health issue by communicating the methods of transmission and symptoms associated with each condition, tracking the updated CDC treatment guidelines, and offering clients strategic preventive measures to reduce the spread of STIs.

It is not easy to discuss STI prevention when globally we are failing at it. Knowledge exists on how to prevent every single route of transmission, but the incidence continues to climb. Challenges to prevention of STIs include lack of resources and difficulty in changing the behaviors that contribute to their spread.

Regardless of the challenging factors involved, nurses must continue to educate and meet the needs of all women to promote their sexual health. Successful treatment and prevention of STIs is impossible without education. Successful teaching approaches include giving clear, accurate messages that are age-appropriate and culturally sensitive.

Primary prevention strategies include education of all women, especially adolescents, regarding the risk of early sexual activity, the number of sexual partners, and STIs. Sexual abstinence is ideal but often not practiced; therefore, the use of barrier contraception (condoms) should be encouraged (see Teaching Guidelines 5.1).

Secondary prevention involves the need for annual pelvic examinations with Pap smears for all sexually active women, regardless of age. Many women with STIs are asymptomatic, so regular screening examinations are paramount for early detection. Understanding the relationship between poor socioeconomic conditions and poor patterns of sexual and reproductive self-care is significant in disease prevention and health promotion strategies.

Consider This

I was thinking of my carefree college days, when the most important thing was having an active sorority life and meeting guys. I had been raised by very strict parents and was never allowed to date under their watch. Since I attended an out-of-state college, I figured that my parents' outdated advice and rules no longer applied. Abruptly, my thoughts of the past were interrupted by the HIV counselor asking about my feelings concerning my positive diagnosis. What was there to say at this point? I had a lot of fun but never dreamed it would haunt me for the rest of my life, which was going to be shortened considerably now. I only wish I could turn back the hands of time and listen to my parents' advice, which somehow doesn't seem so outdated now.

Thoughts: All of us have thought back on our lives to better times and wondered how our lives would have changed if we had made better choices or gone down another path. It is a pity that we have only one chance to make good, sound decisions at times. What would you have changed in your life if given a second chance? Can you still make a change for the better now?

TABLE 5.4 MATERNAL AND FETAL EFFECTS FROM STIS

STI	Maternal Effects	Fetal Effects
Candidiasis	Resistant to treatment during pregnancy Uncomfortable localized genital itching and discharge	Can acquire thrush in the mouth during birthing process if mother infected
Trichomoniasis	Has been implicated to cause PROM and preterm births	Risk of prematurity
Bacterial vaginosis	Increases risk for spontaneous abortion, PROM, chorioamnionitis, postpartum endometritis, and preterm labor	Risk of neonatal sepsis
Chlamydia	Postpartum endometritis, PROM, and preterm birth	Conjunctivitis, which can lead to blindness Low birth weight; and pneumonitis
Gonorrhea	Chorioamnionitis, preterm birth, PROM, fetal growth restriction, postpartum sepsis	Eye infection *gonococcal ophthalmia* which can cause blindness
Genital herpes	Spontaneous abortion, intrauterine infection, preterm labor, PROM, fetal growth restriction	Birth anomalies; transplacental infection
Syphilis	Spontaneous abortion, preterm birth, stillbirth	Congenital syphilis: multisystem organ failure, structural damage; mental retardation
Human papillomavirus (HPV)	May cause dystocia if large lesions	None known
Hepatitis B	May cause preterm birth; can be transmitted to fetus if active in last trimester	Can become chronic carrier of hepatitis B which may lead to liver cancer or cirrhosis
HIV	Fatigue, nausea, weight loss	Transmission can occur transplacentally, during childbirth or through breast milk

Every successful form of prevention requires a change in behavior. The nursing role in teaching and rendering quality health care is invaluable evidence that the key to reducing the spread of STIs is through behavioral change. Nurses working in these specialty areas have a responsibility to educate themselves, their clients, their families, and the community about STIs, and to provide compassionate and supportive care to clients. Some strategies nurses can use to prevent the spread of STIs are detailed in Box 5.3.

Behavior Modification

Research validates that changing behaviors does result in a decrease in new STIs, but it must encompass all levels—governments, community organizations, schools, churches, parents, and individuals. Nurses can advocate for the development and implementation of educational initiatives to increase awareness of STIs (Alexander et al., 2015). Education must address ways to prevent becoming infected, ways to prevent transmitting infection, symptoms of STIs, and treatment. At this point in the STI epidemic, nurses do not have time to debate the relative merits of prevention versus treatment: both are underused and underfunded, and one leads to the other. But being serious about prevention and focusing on the strategies outlined above will bring about a positive change on everyone's part.

Contraception

The spread of STIs could be prevented by access to safe, efficient, appropriate, modern contraception for everyone who wants it. Nurses can play an important role in helping women to identify their risk of STIs and to adopt preventive measures through the dual protection that contraceptives offer. Traditionally, family planning and STI services have been separate entities. Family planning services have addressed a woman's need for contraception without considering her or her partner's risk of STI; meanwhile, STI services have been heavily slanted toward men, ignoring the contraceptive needs of men and their partners.

BOX 5.3

SELECTED NURSING STRATEGIES TO PREVENT THE SPREAD OF STIS

- Provide basic information about STI transmission.
- Outline safer sexual behaviors for people at risk for STIs.
- Refer clients to appropriate community resources to reduce risk.
- Screen asymptomatic persons with STIs.
- Identify barriers to STI testing and remove them.
- Offer pre-exposure immunizations for vaccine-preventable STIs.
- Respond honestly about testing results and options available.
- Counsel and treat sexual partners of persons with STIs.
- Educate school administrators, parents, and teens about STIs.
- Support youth development activities to reduce sexual risk-taking.
- Promote the use of barrier methods (condoms, diaphragms) to prevent the spread of STIs.
- Assist clients to gain skills in negotiating safer sex.
- Discuss reducing the number of sexual partners to reduce risk.

Many women are at significant risk for unintended pregnancy and STIs, yet with this separation of services, there is limited evaluation of whether they need dual protection—that is, concurrent protection from STIs and unintended pregnancy. This lack of integration of services represents a missed opportunity to identify many at-risk women and to offer them counseling on dual protection (Zapata et al., 2015).

Nurses can expand their scopes in either setting by discussing dual protection by use of a male or female condom alone or by use of a condom along with a nonbarrier contraceptive. Because barrier methods are not the most effective means of fertility control, they have not been typically recommended as a method alone for dual protection. Unfortunately, the most effective pregnancy prevention methods—sterilization, hormonal methods, and intrauterine devices—do not protect against STIs. Dual-method use protects against STIs and pregnancy.

NURSING CARE PLAN 5.1

Overview of the Woman Who is HIV-Positive

Annie, a 28-year-old African American woman, is HIV-positive. She acquired HIV through unprotected sexual contact. She has been inconsistent in taking her antiretroviral medications and presents today stating she is tired and doesn't feel well.

NURSING DIAGNOSIS: Ineffective protection related to risk of infection secondary to inadequate immune system as manifested by client stating she has been inconsistent in taking her antiretroviral therapy medications.

Outcome Identification and Evaluation

Client will remain free of opportunistic infections as evidenced by temperature within acceptable parameters and absence of signs and symptoms of opportunistic infections.

Interventions: ***Minimizing the Risk of Opportunistic Infections***

- Assess CD4 count and viral loads *to determine disease progression* (CD4 counts 500/L and viral loads >10,000 copies/L = increased risk for opportunistic infections).
- Assess complete blood count *to identify presence of infection* (>10,000 cells/mm^3 may indicate infection).
- Assess oral cavity and mucous membranes for painful white patches in mouth *to evaluate for possible fungal infection.*
- Teach client to monitor for general signs and symptoms of infections, such as fever, weakness, and fatigue, *to ensure early identification.*
- Provide information explaining the importance of avoiding people with infections when possible *to minimize risk of exposure to infections.*
- Teach importance of keeping appointments so her CD4 count and viral load can be monitored *to alert the health care provider about her immune system status.*
- Instruct her to reduce her exposure to infections via:
  - Meticulous handwashing
  - Thorough cooking of meats, eggs, and vegetables
  - Wearing shoes at all times, especially when outdoors
- Encourage a balance of rest with activity throughout the day *to prevent overexertion.*
- Stress importance of maintaining prescribed antiretroviral drug therapies *to prevent disease progression and resistance.*
- If necessary, refer Annie to a nutritionist to help her understand what constitutes a well-balanced diet with supplements *to promote health and ward off infection.*

NURSING DIAGNOSIS: Knowledge deficit related to HIV infection and possible complications.

Outcome Identification and Evaluation

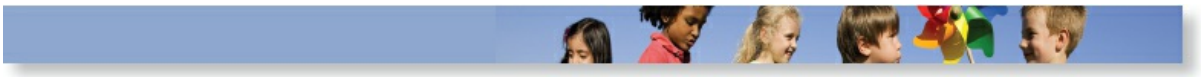
Client will demonstrate increased understanding of HIV infection as evidenced by verbalizing appropriate health care practices and adhering to measures to comply with therapy and reduce her risk of further exposure and reduce risk of disease progression.

Interventions: ***Providing Client Education***

- Assess her understanding of HIV and its treatment *to provide a baseline for teaching.*
- Establish trust and be honest with Annie; encourage her to talk about her fears and the impact of the disease *to provide an outlet for her concerns.* Encourage her to discuss reasons for her noncompliance.
- Provide a nonjudgmental, accessible, confidential, and culturally sensitive approach *to promote Annie's self-esteem and allow her to feel that she is a priority.*
- Explain measures, including safer sex practices and birth control options, to prevent disease transmission; determine her willingness to practice safer sex to protect others *to determine further teaching needs.*
- Discuss the signs and symptoms of disease progression and potential opportunistic infections *to promote early*

detection for prompt intervention.

- Outline with the client the availability of community resources and make appropriate referrals as needed *to provide additional education and support.*
- Encourage Annie to keep scheduled appointments *to ensure follow-up and allow early detection of potential problems.*



KEY CONCEPTS

- Avoiding risky sexual behaviors may preserve fertility and prevent chronic conditions later in life.
- An estimated 65 million people live with an incurable STI, and another 20 million are infected each year.
- The most reliable way to avoid transmission of STIs is to abstain from sexual intercourse (i.e., oral, vaginal, or anal sex) or to be in a long-term, mutually monogamous relationship with an uninfected partner.
- Barrier methods of contraception are recommended because they increase protection from contact with urethral discharge, mucosal secretions, and lesions of the cervix or penis.
- The high rate of asymptomatic transmission of STIs calls for teaching high-risk women the nature of transmission and how to recognize infections.
- The CDC and ACOG recommend that all women be offered group B streptococcal screening by rectovaginal culture at 35 to 37 weeks of gestation, and that colonized women be treated with intravenous antibiotics at the time of labor or ruptured membranes.
- Nurses should practice good handwashing techniques and follow standard precautions to protect themselves and their clients from STIs.
- Nurses are in an important position to promote the sexual health of all women. Nurses should make their clients and the community aware of the perinatal implications and lifelong sequelae of STIs.

CHAPTER WORKSHEET

MULTIPLE CHOICE QUESTIONS

1. Which of the following contraceptive methods offers protection against sexually transmitted infections (STIs)?
   a. Oral contraceptives
   b. Withdrawal
   c. Latex condom
   d. Intrauterine system
2. When teaching about HIV transmission, which of the following does the nurse explain that the virus cannot be transmitted by?
   a. Shaking hands
   b. Sharing drug needles
   c. Sexual intercourse
   d. Breastfeeding
3. A woman with HPV is likely to present with which nursing assessment finding?
   a. Profuse, pus-filled vaginal discharge
   b. Clusters of genital warts
   c. Single painless ulcer
   d. Multiple vesicles on genitalia
4. The nurse's discharge teaching plan for the woman with PID should reinforce which of the following potentially life-threatening complications?
   a. Involuntary infertility
   b. Chronic pelvic pain
   c. Depression
   d. Ectopic pregnancy
5. To confirm a finding of primary syphilis, the nurse would observe which of the following on the external genitalia?
   a. A highly variable skin rash
   b. A yellow-green vaginal discharge
   c. A nontender, indurated ulcer
   d. A localized gumma formation
6. A sexually active 19-year-old presents to the clinic with postcoital bleeding, dysuria, and a yellow discharge. Her cervix upon exam is red and friable. What might the nurse suspect?
   a. Cervical cancer
   b. A tampon injury
   c. Primary syphilis
   d. Chlamydia

The correct response is “D” because these clinical manifestations are typical of a chlamydia infection (postcoital bleeding, dysuria, frequency, vaginal discharge, cervical tenderness with easily induced bleeding). Response “A” is incorrect because it would be rare to have cervical cancer at such a young age and the symptoms presented are not suggestive of this diagnosis. Response “B” is incorrect because the presenting symptoms are not suggestive of a cervical injury. Response “C” is incorrect because primary syphilis would present with a chancre lesion at the site where the bacteria entered the body, typically the vulva.

CRITICAL THINKING EXERCISE

1. Sally, age 17, comes to the teen clinic saying that she is in pain and has some “crud” between her legs. The nurse takes her into the examining room and questions her about her symptoms. Sally states she had numerous genital bumps that had been filled with fluid, then ruptured and turned into ulcers with crusts. In addition, she has pain on urination and overall body pain. Sally says she had unprotected sex with several men when she was drunk at a party a few weeks back, but she thought they were “clean.”
   a. Which STI would the nurse suspect?
   b. The nurse should give immediate consideration to which of Sally’s complaints?
   c. What should be the goal of the nurse in teaching Sally about STIs?

STUDY ACTIVITIES

1. Select a website at the end of the chapter to explore. Educate yourself about one specific STI thoroughly and share your expertise with your clinical group.
2. Contact your local health department and request current statistics regarding three STIs. Ask them to compare the current number of cases reported to last year’s. Are they less or more? What may be some of the reasons for the change in the number of cases reported?
3. Request permission to attend a local STI clinic to shadow a nurse for a few hours. Describe the nurse’s counseling role with clients and what specific information is emphasized to clients.
4. Two common STIs that appear together and commonly are treated together regardless of identification of the secondary one are _____ and _____.
5. Genital warts can be treated with which of the following? Select all that apply.
   a. Penicillin
   b. Podophyllin
   c. Imiquimod
   d. Cryotherapy
   e. Antiretroviral therapy
   f. Acyclovir

BRINGING IT ALL TOGETHER: A CASE STUDY

Charlotte, a 22 year old, has presented at the local clinic with concerns of having contracted a sexually transmitted infection (STI). During the nursing interview Charlotte identifies that she has been sexually active since the age of 15 and has had

“at least 5 different sex partners”. The health assessment confirms that Charlotte has been infected with pediculosis pubis (pubic lice) and treatment has been prescribed.

Go to thePoint to find questions to consider about this case.

6

Disorders of the Breasts

WOW

Words of Wisdom

Focus on reducing fear, anxiety, pain, and aloneness in all women diagnosed with a breast disorder..

KEY TERMS

benign breast disorder
breast augmentation
breast cancer
breast-conserving surgery
breast implants
breast self-examination (BSE)
carcinoma
chemotherapy
duct ectasia
endocrine therapy
fibroadenomas
fibrocystic breast changes
mammography

mastitis
modified radical mastectomy
simple mastectomy

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Identify the incidence, risk factors, screening methods, and treatment modalities for benign breast conditions.
2. Appraise reasons behind breast augmentation including the potential benefits and risks.
3. Outline preventive strategies for breast cancer through lifestyle changes and health screening.
4. Analyze the incidence, risk factors, treatment modalities, and nursing considerations related to breast cancer.
5. Develop an educational plan to teach BSE to a group of high-risk women.

***Nancy* hasn't been able to sleep well since she felt the lump in her left breast over a month ago, just after her 60th birthday. She knows she is at high risk because her mother died of breast cancer, but she can't bring herself to have it checked out.**

INTRODUCTION

The breasts are modified sweat glands, lying over the pectoralis major muscles of the chest wall. Physiologically, the breast is an organ specialized for milk formation to nourish their offspring. Each breast extends approximately from the second to the sixth rib. The female breasts are closely linked to womanhood in American culture. Women's breasts act as physical markers for transitions from one stage of life to another, and although the primary function of the breasts is lactation, they are perceived as a symbol of beauty and sexuality.

This chapter discusses assessments, screening procedures, and management of specific benign and malignant breast disorders. Nurses play a key role in helping women maintain breast health by providing education and screening. A good working knowledge of early detection techniques, diagnosis, and treatment options is essential.

BENIGN BREAST DISORDERS

A benign breast disorder is any noncancerous breast abnormality. Though not life-threatening, benign disorders can cause pain and discomfort, and they account for a large number of visits to primary care providers. Fully understanding benign breast disorders should enable the nurse to appropriately evaluate symptoms, determine which breast lesions require treatment, and identify women who are at increased risk for breast cancer.

Depending on the type of benign breast disorder, treatment might or might not be

necessary. Although these disorders are benign, the emotional trauma women experience is phenomenal. Fear, anxiety, disbelief, helplessness, and depression are just a few of the reactions that a woman may have when she discovers a lump in her breast. Many women believe that all lumps are cancerous, but actually more than 80% of the lumps discovered are benign and need no treatment (Alexander et al., 2014). Patience, support, and education are essential components of nursing care.

The most commonly encountered benign breast disorders in women include fibrocystic changes of the breasts, **fibroadenomas**, and **mastitis**. Although these breast disorders are considered benign, fibrocystic changes of the breasts carry a cancer risk, with prolific masses and hyperplastic changes occurring within the breasts. Generally speaking, fibroadenomas and mastitis carry little cancer risk (Seetharam & Rodrigues, 2015). Table 6.1 summarizes benign breast conditions.

Fibrocystic Breast Changes

Fibrocystic breast changes, also known as *benign breast disease* (BBD), represent a variety of changes in the glandular and structural tissues of the breast. Because this condition affects 50% to 60% of all women at some point, it is more accurately defined as a "change" rather than a "disease." Fibrocystic changes are caused by an overgrowth of fibrous tissues in the connective tissues supporting the breasts. This is frequently accompanied by the presence of fluid-filled cysts, which contribute to the lumpy feeling experienced by women. In contrast to malignant breast lesions, the cysts that develop move freely when palpated and symptoms decline after menopause when levels of estrogen and progesterone drop (Sabel, 2015). Fibrocystic changes do not increase the risk of breast cancer for most women except when the breast biopsy shows "atypia" or abnormal breast cells. The cause for concern for many women with fibrocystic changes is that breast examinations and **mammography** become more difficult to interpret with multiple cysts present, and early cancerous lesions may occasionally be overlooked (American Cancer Society [ACS], 2015a).

TABLE 6.1 SUMMARY OF BENIGN BREAST DISORDERS

Breast Condition	Nipple Discharge	Site	Characteristics/ Age of Client	Tenderness	Diagnosis & Treatment
Fibrocystic breast changes	+ or –	Bilateral; upper outer quadrant	Round, smooth Several lesions Cyclic, palpable 30–50 yrs old	+	Aspiration and biopsy Limit caffeine; ibuprofen; supportive bra
Fibroadenomas	–	Unilateral; nipple area or upper outer quadrant	Round, firm, movable Palpable, rubbery Well delineated Single lesion 15–30 yrs old	–	Mammogram "Watchful waiting" Aspiration and biopsy Surgical excision
Mastitis	–	Unilateral; outer quadrant	Wedge shaped Warmth, redness Swelling Nipple cracked Breast engorged	+	Antibiotics Warm shower Supportive bra Breast-feeding Increase fluids

Adapted from Alexander, L. L., LaRosa, J. H., Bader, H., & Garfield, S. (2014). *New dimensions in women's health* (6th ed.). Sudbury, MA: Jones & Bartlett; American Cancer Society (ACS). (2015a). *Non-cancerous breast conditions.* Retrieved from http://www.cancer.org/Healthy/FindCancerEarly/WomensHealth/Non-CancerousBreastConditions/non-cancerous-breast-conditions-fibrocystic-changes; and Bope, E. T., & Kellerman, R. D. (2015). *Conn's current therapy 2015*. Philadelphia, PA: Saunders Elsevier.

Fibrocystic breast changes are most common in women between the ages of 20 and 50. The condition is rare in postmenopausal women not taking hormone replacement therapy (HRT). According to the ACS (2015a), fibrocystic breast changes affect at least half of all women at some point in their lives and are the most common breast disorder today.

Therapeutic Management

Management of the symptoms of fibrocystic breast changes begins with self-care. For some women, diet and lifestyle changes help to reduce discomfort. Other options include wearing a supportive bra, taking over-the-counter pain relievers, and limiting salt consumption which can cause fluid retention (Files, Allen, & Pruthi, 2015). In severe cases drugs, including bromocriptine, tamoxifen, or danazol, can be used to reduce the influence of estrogen on breast tissue. However, several undesirable side effects, including masculinization, have been documented. Aspiration or surgical removal of breast lumps will reduce pain and swelling by removing the space-occupying mass.

Nursing Assessment

Nursing assessment consists of a health history, physical examination, and laboratory and diagnostic tests.

HEALTH HISTORY

Ask the woman about common clinical manifestations, which include lumpy, tender breasts, particularly during the week before menses. Changes in breast tissue produce pain by nerve irritation from edema in connective tissue and by fibrosis from nerve pinching. The pain is cyclic and frequently dissipates after the onset of menses. The pain is described as a dull, aching feeling of fullness. Masses or nodularities usually appear in both breasts and are often found in the upper outer quadrants. Some women also experience spontaneous clear to yellow nipple discharge when the breast is squeezed or manipulated.

PHYSICAL EXAMINATION

It is best to examine a woman's breast a week after menses, when swelling has subsided. The breast examination is performed using the Triple Touch Method in which the health care provider uses the pads of the middle three fingers and makes dime-sized overlapping circles to feel the breast tissue with three levels of pressure: light, medium, and firm (Jarvis, 2015). Observe the breasts for fibrosis, or thickening of the normal breast tissues, which occurs in the early stages. Cysts form in the later stages and feel like multiple, smooth, well-delineated tiny pebbles or bumpy oatmeal under the skin (Fig. 6.1). On physical examination of the breasts, a few characteristics might be helpful in differentiating a cyst from a cancerous lesion. Cancerous lesions typically are fixed and painless and may cause skin retraction (pulling). Cysts tend to be mobile and tender and do not cause skin retraction in the surrounding tissue.

LABORATORY AND DIAGNOSTIC TESTS

Mammography can be helpful in distinguishing fibrocystic changes from breast cancer. Ultrasound is a useful adjunct to mammography for breast evaluation because it helps to differentiate a cystic mass from a solid one (Dixon & Macaskill, 2015). Ultrasound produces images of the breasts by sending sound waves through a gel applied to the breasts. Fine-needle aspiration biopsy can also be done to differentiate a solid tumor, cyst, or malignancy. A fine-needle aspiration biopsy uses a thin needle guided by ultrasound to the mass. In a method called stereotactic needle biopsy, a computer maps the exact location of the mass using mammograms taken from two angles, and the map is used to guide the needle.

Nursing Management

A nurse caring for a woman with fibrocystic breast changes can teach her about the condition, provide tips for self-care (Teaching Guidelines 6.1), suggest lifestyle changes, and demonstrate how to perform monthly **breast self-examination (BSE)** after her menses to monitor the changes. Nursing Care Plan 6.1 (at the end of the chapter) presents a plan of care for a woman with fibrocystic breast changes.

Teaching Guidelines 6.1
RELIEVING SYMPTOMS OF FIBROCYSTIC BREAST CHANGES

- Wear an extra-supportive bra to prevent undue strain on the ligaments of the breasts to reduce discomfort.
- Take oral contraceptives, as recommended by a health care practitioner, to stabilize the monthly hormonal levels.
- Eat a low-fat diet rich in fruits, vegetables, and grains to maintain a healthy nutritional lifestyle and ideal weight.
- Apply heat to the breasts to help reduce pain via vasodilation of vessels.
- Take diuretics, as recommended by a health care practitioner, to counteract fluid retention and swelling of the breasts.
- Reduce salt intake to reduce fluid retention and swelling in the breasts.
- Take over-the-counter medications, such as acetylsalicylic acid (Aspirin) or

ibuprofen (Motrin, Advil, Nuprin), to reduce inflammation and discomfort.
- Use thiamine and vitamin E therapy. This has been found helpful for some women, but research has failed to demonstrate a direct benefit from either therapy.
- Take medications as prescribed (e.g., bromocriptine, tamoxifen, or danazol).
- Discuss the possibility of aspiration or surgical removal of breast lumps with a health care practitioner.
- Avoid caffeinated drinks (coffee, tea, soda) which tend to trigger breast discomfort.

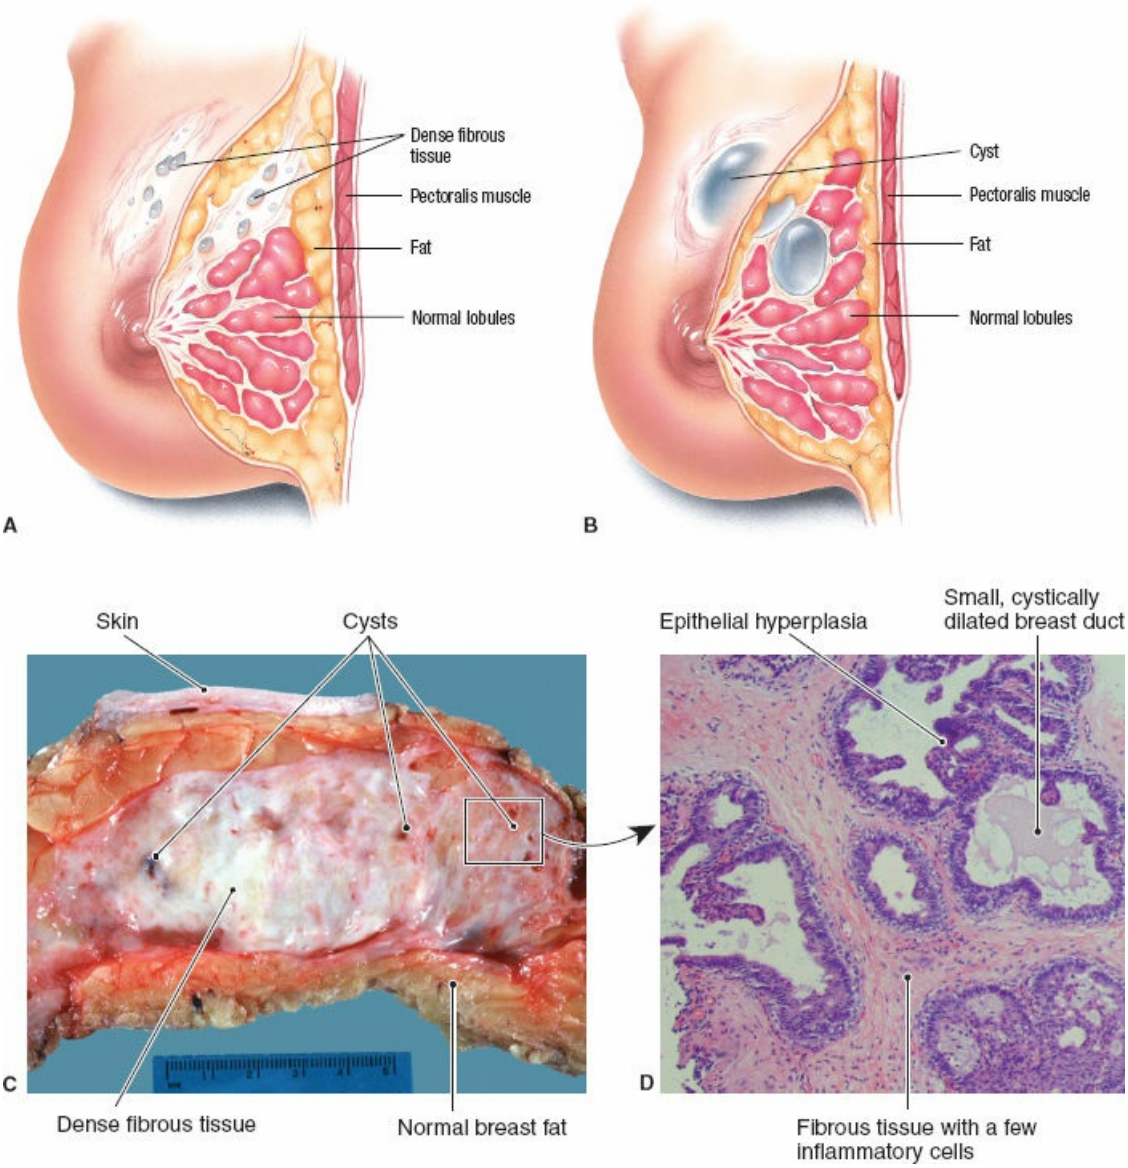

FIGURE 6.1 A. Fibrocystic breast changes. B. Breast cysts. C. This gross study shows that most of the abnormal tissue is fibrous. Cysts are relatively inconspicuous in this example. D. The microscopic study shows dense fibrous tissue containing dilated ducts lined by hyperplastic epithelium. (Images A & B are from The Anatomical Chart Company. (2006). *Atlas of pathophysiology*. Springhouse, PA: Springhouse Corporation. Images C & D courtesy of McConnell, T. H. (2014). *The nature of disease pathology for the health professions* (2nd ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Fibroadenomas

Fibroadenomas are common benign solid breast tumors that occur in about 25% of all women and account for up to half of all breast biopsies. They are the most common mass in women aged 15 to 25 years (Seetharam & Rodrigues, 2015). They are considered hyperplastic lesions associated with an aberration of normal development and involution rather than a neoplasm. Fibroadenomas can be stimulated by external estrogen, progesterone, lactation, and pregnancy (Schuiling & Likis, 2016). They are composed of both fibrous and glandular tissue that feels round or oval, firm, rubbery and smooth, and is mobile and may be tender. They are usually unilateral, but may present in both breasts (Alexander et al., 2014). Giant fibroadenomas account for approximately 4% of cases. These masses are frequently larger than 5 cm and occur most often in pregnant or lactating women. These large lesions may regress in size once hormonal stimulation subsides (Janardhan, Venkateshwar, & Rao, 2015). Fibroadenomas are rarely associated with cancer.

Therapeutic Management

Treatment may include a period of "watchful waiting" because many fibroadenomas stop growing or shrink on their own without any treatment. Other growths may need to be surgically removed if they do not regress or if they remain unchanged. Cryoablation, an alternative to surgery, can also be used to remove a tumor. In this procedure, extremely cold gas is piped into the tumor using ultrasound guidance. The tumor freezes and dies. The current trend is toward a more conservative approach to treatment after careful evaluation and continued monitoring.

Nursing Assessment

Ask the woman about clinical manifestations of fibroadenomas. These lumps are felt as firm, rubbery, well-circumscribed, freely mobile nodules that might or might not be tender when palpated.

Breast fibroadenomas are usually detected incidentally during clinical or self-examinations and are usually located in the upper outer quadrant of the breast; more than one may be present (Fig. 6.2). Several other breast lesions have similar characteristics, so every woman with a breast mass should be evaluated to exclude cancer. A clinical breast examination (CBE) by a health care provider is critical. In addition, diagnostic studies include imaging studies (mammography, ultrasound, or both) and some form of biopsy, most often a fine-needle aspiration, core needle biopsy, or stereotactic needle biopsy. The core needle biopsy removes a small cylinder of tissue from the breast mass, more than the fine-needle aspiration biopsy. If additional tissue needs to be evaluated, the advanced breast biopsy instrument (ABBI) is used. This instrument removes a larger cylinder of tissue for examination by using a rotating circular knife. The ABBI procedure removes more tissue than any of the other methods except a surgical biopsy (ACS, 2015a).

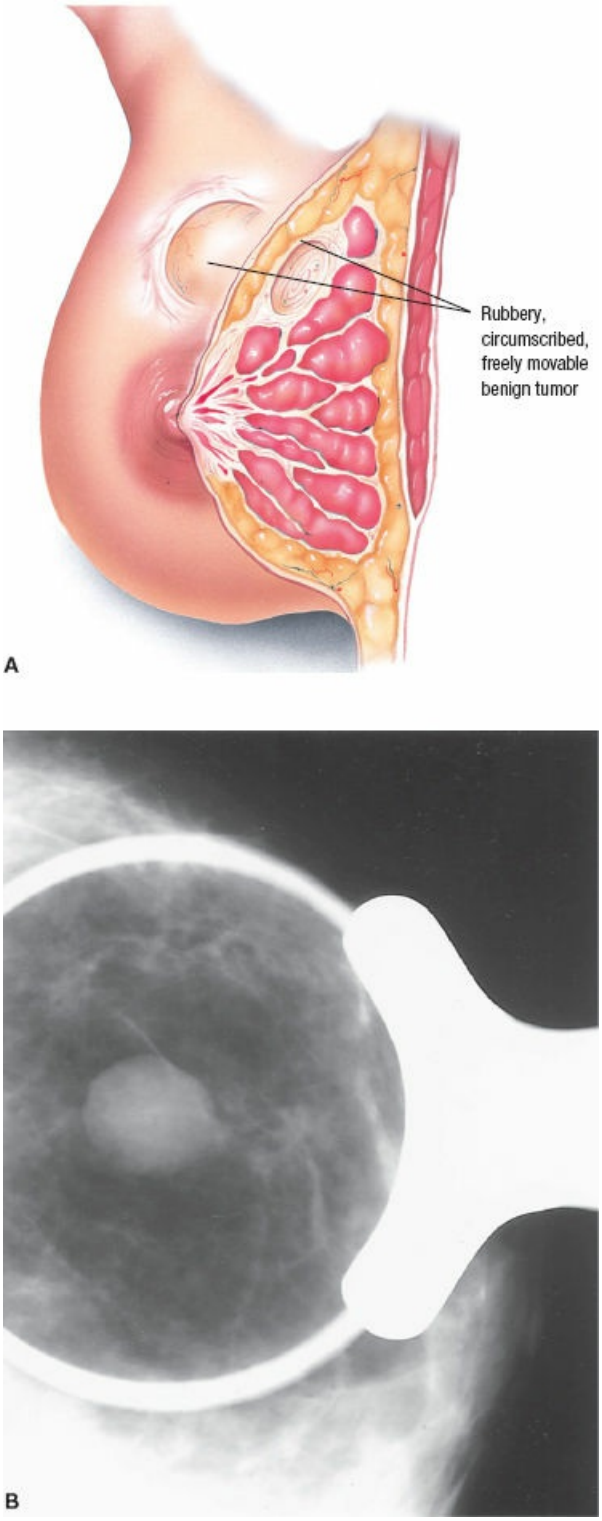

FIGURE 6.2 A. Fibroadenoma. (Asset provided by Anatomical Chart Co.) B. Spot compression view of a smoothly marinated mass proven to represent a fibroadenoma. Ultrasonography demonstrated a solid mass.

Nursing Management

The nurse should urge the client to return for reevaluation in 6 months, perform monthly BSEs, and return annually for a CBE. Recent studies suggest that women with high breast density and proliferative BBD are at very high risk for future breast cancer. Women with low breast density are at low risk, regardless of their benign

pathologic diagnosis (Slanetz, Freer, & Birdwell, 2015). This is all the more reason for women to have close monitoring over time.

Mastitis

Mastitis is an infection or inflammation of the connective tissue in the breast that occurs primarily in lactating or engorged women. The prevalence of it in breast-feeding women may be as high as 33% (Faguy, 2015). Mastitis is divided into lactational or nonlactational types. The usual causative organisms for lactational mastitis are *Staphylococcus aureus, Haemophilus influenzae,* and haemophilus and streptococcus species, the source of which is the baby's flora. Lactating mastitis typically occurs in the first 2 to 3 weeks of lactation, but can occur at any stage of lactation. One or more of the ducts drain poorly or become blocked, resulting in bacterial growth in the retained milk (Pluchinotta, 2015). The only evidence-based predisposing factor that may lead to mastitis is the development of milk stasis. However, other associated factors include damaged or cracked nipples, especially those colonized with *S. aureus;* irregular or missed feedings; failing to allow the infant to empty one breast completely before moving on to the next breast; poor latch and transfer of milk; illness of mother or infant; oversupply; a tight bra; blocked nipple pore or duct; being primiparous women; and maternal stress and fatigue (Miller & Kennedy, 2015).

Nonlactational mastitis can be caused by **duct ectasia**, which occurs when the milk ducts become congested with secretions and debris, resulting in periductal inflammation. It may be divided into central (periareolar) and peripheral breast lesions. Periareolar infections consist of active inflammation around nondilated subareolar breast ducts—a condition termed periductal mastitis. Peripheral nonlactating breast abscesses are less common than periareolar abscesses and are often associated with an underlying condition, such as diabetes, rheumatoid arthritis, steroid treatment, granulomatous lobular mastitis, and trauma (Faguy, 2015). Women with these types of abscesses present with greenish nipple discharge, nipple retraction, and noncyclical pain.

Therapeutic Management

Effective milk removal, pain medication, and antibiotic therapy have been the mainstays of treatment. Management of both types of mastitis involves the use of oral antibiotics (usually a penicillinase-resistant penicillin or cephalosporin), warm compresses to the inflamed area of the breast, continued breast-feeding, and acetaminophen (Tylenol) for pain and fever (King et al., 2015).

Nursing Assessment

Assess the client's health history for risk factors for mastitis, which include poor hand hygiene ductal abnormalities, nipple cracks and fissures, lowered maternal defenses due to fatigue, tight clothing, poor support of pendulous breasts, failure to empty the breasts properly while breast-feeding, or missing breast-feedings.

The diagnosis of mastitis is made clinically on the basis of a localized, unilateral area of erythema with associated fever. Assess the client for clinical manifestations of mastitis, which include flu-like symptoms of malaise, nausea, headache, leukocytosis, fever, fatigue, and chills. Physical examination of the breasts reveals

increased warmth, swollen area of one breast, redness, tenderness, and swelling. The nipple is usually cracked or abraded and the breast is distended with milk (Fig. 6.3). In a lactating woman, severe engorgement can be differentiated from mastitis because engorgement is bilateral with general involvement of the whole breast. Ultrasound scans can be undertaken to differentiate between the types of mastitis or abscesses, but typically the diagnosis is made based on history and examination.

Nursing Management

Teach the woman about the etiology of mastitis and encourage her to continue to breast-feed, emphasizing that it is safe for her infant to do so. Stress to all breast-feeding mothers to check for medication safety before taking it. Drugs administered to mothers can accumulate in the bodies of their infants and can alter infant's bowel flora, causing diarrhea. Mothers should be warned about this to reduce their anxiety. Once it has been declared safe to do so, the nurse should urge them to take the medication as prescribed until completed. Continued emptying of the breast or pumping improves the outcome, decreases the duration of symptoms, and decreases the incidence of breast abscess. Thus, continued breast-feeding is recommended in the presence of mastitis (King et al., 2015).

FIGURE 6.3 Mastitis. (From Sweet, R. L., & Gibbs, R. S. (2009). *Infectious diseases of the female genital tract*. Philadelphia, PA: Lippincott Williams & Wilkins.)

Although 80% of breast biopsy results prove to be benign, increased surveillance is necessary because of the risk of cancer development. The recommended follow-up schedule is imaging (mammography or ultrasound) and a CBE by a surgeon at 6, 12, and 24 months after a benign breast biopsy finding (Tharpe, Farley, & Jordan, 2016). Instructions for the woman with mastitis are detailed in Teaching Guidelines 6.2.

Teaching Guidelines 6.2
CARING FOR MASTITIS

- Take medications as prescribed to reduce inflammation and infection.
- Continue breast-feeding, as tolerated to keep the milk flowing.
- Begin feeding on most affected breast to allow it to be emptied first.
- Massage the breasts before and during breast-feeding to encourage milk

extraction.
- Wear a supportive bra 24 hours a day to support the breasts for comfort.
- Increase fluid intake to stay hydrated.
- Gentle massage toward nipple several times daily.
- Vary the infants breast-feeding position-–cradle, side-lying, football, & belly to belly.
- Make sure infant is positioned correctly on the nipple to prevent discomfort.
- Practice good hand hygiene techniques to reduce risk of bacterial transfer.
- Apply warm compresses to the affected breast or take a warm shower before breast-feeding.
- Frequently change positions while nursing to improve milk flow.
- Get adequate rest and nutrition to support or improve the immune system.
- Instruct to contact their health care provider if fever returns, chills, or worsening symptoms.

MALIGNANT BREAST DISORDER

Breast cancer is a neoplastic disease in which normal body cells are transformed into malignant ones (National Cancer Institute [NCI], 2015a). It is the most common cancer in women and the second leading cause of cancer deaths (lung cancer is first) among American women. Breast cancer accounts for one of every three cancers diagnosed in the United States (ACS, 2015a). A new case is discovered every 2 minutes. It is estimated that one out of every eight women will develop the disease at some time during her life, and the mortality rate of those with breast cancer is 1 in 36 (NCI, 2015a).

Over 200,000 cases of invasive breast cancer are diagnosed in the United States each year (ACS, 2015a). Breast cancer can also affect men, but only 1% of all individuals diagnosed with breast cancer annually are men. About 2,000 men are diagnosed with breast cancer annually, with about a one in four mortality rate (Khan, Allerton, & Pettit, 2015). Because men are not routinely screened for breast cancer, the diagnosis is often delayed. The most common clinical manifestation of male breast cancer is a painless, firm, subareolar breast mass. Any suspicious breast mass in a male should undergo diagnostic biopsy. If a malignancy is diagnosed, typical treatment is mastectomy with assessment of the axillary nodes.

The cause of breast cancer, while not well understood, is thought to be a complex interaction between environmental, genetic, and hormonal factors. Breast cancer is a progressive rather than a systemic disease, meaning that most cancers grow from small size with low metastatic potential to larger size and greater metastatic potential. Tumor stage, size, and lymph node involvement are major predictors of metastatic potential (Arora et al., 2015).

Consider This

It was pouring down rain and I was driving alone along dark wet streets to my 8 AM appointment for a breast ultrasound. I recently had my annual mammogram and the radiologist thought he saw something suspicious on my right breast. I was on my way to confirm or refute his suspicions, and I couldn't keep focused on the road ahead. For the past few days I had been a basket case, fearing the worst. I was playing in my mind, what I would do if…? What changes would I make in my life and how would I react when told? I have been through such personal turmoil since that doctor announced he wanted "more tests."

Thoughts: This woman is worrying and is emotionally devastated before she even has a conclusive diagnosis. Is this a typical reaction to a breast disorder? Why do women fear the worst? Many women use denial to mask their feelings and hope against hope the doctor made a mistake or misread their mammogram. How would you react if you or your sister, girlfriend, or mother were confronted with a breast disorder?

Pathophysiology

Cancer is not just one disease, but rather a group of diseases that result from unregulated cell growth. Without regulation, cells divide and grow uncontrollably until they eventually form a tumor. Extensive research has determined that all cancer is the result of changes in DNA or chromosome structure that cause the mutation of specific genes. Most genetic mutations that cause cancer are acquired sporadically, which means they occur by chance and are not necessarily due to inherited mutations (Shannon & Chittenden, 2015). Cancer development is thought to be clonal in nature, which means that each cell is derived from another cell. If one cell develops a mutation, any daughter cell derived from that cell will have that same mutation, and this process continues until a malignant tumor forms.

Breast cancer starts in the epithelial cells that line the mammary ducts within the breast. The growth rate depends on hormonal influences, mainly estrogen and progesterone. The two major categories of breast cancer are noninvasive and invasive. Noninvasive, or in situ, breast cancers are those that have not extended beyond their duct, lobule, or point of origin into the surrounding breast tissue. Conversely, invasive (infiltrating) breast cancers have extended into the surrounding breast tissue, with the potential to metastasize. Many researchers believe that most invasive cancers probably originate as noninvasive cancers (Cuzick & Thorat, 2015).

Breast cancer is considered to be a highly variable disease. While the process of metastasis is a complex and poorly understood phenomenon, there is evidence to suggest that new vascularization of the tumor plays an important role in the biologic aggressiveness of breast cancer (Toi et al., 2015). Breast cancer metastasizes widely and to almost all organs of the body, but primarily to the bone, lungs, lymph nodes, liver, and brain. The first sites of metastases are usually local or regional, involving the chest wall or axillary supraclavicular lymph nodes or bone (ACS, 2015a).

Invasive Ductal Carcinoma

By far the most common breast cancer is invasive ductal **carcinoma**, which represents 85% of all cases (ACS, 2015c). Carcinoma is a malignant tumor that occurs in epithelial tissue; it tends to infiltrate and give rise to metastases. The incidence of this cancer peaks in the sixth decade of life (>60 years old). It spreads

rapidly to axillary and other lymph nodes, even while small. Infiltrating ductal carcinoma may take various histologic forms—well differentiated and slow growing, poorly differentiated and infiltrating, or highly malignant and undifferentiated with numerous metastases. This common type of breast cancer starts in the ducts, breaks through the duct wall, and invades the fatty breast tissue. This type of cancer accounts for 75% of all breast cancers (Stopeck, Chalasani, & Thompson, 2015).

Invasive Lobular Carcinoma

Invasive lobular carcinomas, which originate in the terminal lobular units of breast ducts, account for 10% of all cases of breast cancer. The peak incidence is in women aged 40 to 50 years old. It presents as an area of ill-defined thickening rather than a palpable mass. The tumor is frequently located in the upper outer quadrant of the breast, and by the time it is discovered the prognosis is usually poor (Selvi, 2015).

Other Invasive Carcinomas

Other invasive types of cancer include tubular carcinoma (29%), which is fairly uncommon and typically occurs in women aged 55 and older. Colloid carcinoma (2% to 4%) occurs in women 60 to 70 years of age and is characterized by the presence of large pools of mucus interspersed with small islands of tumor cells. Medullary carcinoma accounts for 5% to 7% of malignant breast tumors; it occurs frequently in younger women (<50 years of age) and grows into large tumor masses. Inflammatory breast cancer (<4%) often presents with skin edema, redness, and warmth and is associated with a poor prognosis. Paget disease (2% to 4%) originates in the nipple and typically occurs with invasive ductal carcinoma (Bope & Kellerman, 2015).

Staging of Breast Cancer

Breast cancers are classified into three stages based on:

1. Tumor size
2. Extent of lymph node involvement
3. Evidence of metastasis

The purposes of tumor staging are to determine the probability that the tumor has metastasized, to decide on an appropriate course of therapy, and to assess the client's prognosis. Table 6.2 gives details and characteristics of each stage (also Fig. 6.4). The overall 10-year survival rate for a woman with stage I breast cancer is 80% to 90%; for a woman with stage II, it is about 50%. The outlook is not as good for women with stage III or IV disease (Alexander et al., 2014).

There is no completely accurate way to know whether the cancer has micrometastasized to distant organs, but certain tests can help determine if the cancer has spread. A bone scan can be performed to assess the bones. Magnetic resonance imaging (MRI) can be used to detect metastases to the liver, abdominal cavity, lungs, or brain.

TABLE 6.2 STAGING OF BREAST CANCER

Stage	Characteristics
0	In situ, early type of breast cancer
I	Localized tumor <1 in in diameter
II	Tumor 1–2 in in diameter; spread to axillary lymph nodes
III	Tumor 2 in or larger; spread to other lymph nodes and tissues
IV	Cancer has metastasized to other body organs

Adapted from American Cancer Society (ACS). (2015h). *How is breast cancer staged?* Retrieved from http://www.cancer.org/Cancer/BreastCancer/DetailedGuide/breast-cancer-staging.

Risk Factors

An estimated 80% of women in whom breast cancer develops have no documented risk factors (Bope & Kellerman, 2015). Breast cancer is thought to develop in response to a number of related factors: aging; gender (99% of cases occur in women, delayed childbearing or never bearing children, genetic influences); BRCA1 and BRCA2 genetic mutations; history of receiving ionizing radiation; high breast density; postmenopausal obesity; family history of cancer; hormonal factors such as early menarche <12 years, late menopause >50 years, first term pregnancy >30 to 35 years of age; HRT with estrogen plus progestin; and ingestion of two drinks or more alcohol each day (ACS, 2015b). Other factors might contribute to breast cancer but have not been scientifically proven.

In 1970, the lifetime risk for developing breast cancer was 1 in 10; since then, the risk has gradually risen (NCI, 2015b). This slight increase in incidence might be explained in a variety of ways: better detection and screening tools are available, which have identified more cases; women are living to an older age, when their risk increases; and lifestyle changes in American women (having their first pregnancy at an older age, having fewer children, and using hormonal therapy to treat the symptoms of menopause) might have produced the higher numbers. Age is a significant risk factor. Because rates of breast cancer increase with age, estimates of risk at specific ages are more meaningful than estimates of lifetime risk. The estimated chances of a woman being diagnosed with breast cancer between the ages of 30 and 70 are detailed in Table 6.3.

TABLE 6.3 ESTIMATED RISK OF BREAST CANCER AT SPECIFIC AGES

Ages 30–39	1 out of 233
Ages 40–49	1 out of 69
Ages 50–59	1 out of 42
Ages 60–69	1 out of 29

Adapted from American Cancer Society (ACS). (2015l) *How many women get breast cancer?* Retrieved from http://www.cancer.org/cancer/breastcancer/overviewguide/breast-cancer-overview-key-statistics

Risk factors for breast cancer can be divided into those that cannot be changed (nonmodifiable risk factors) and those that can be changed (modifiable risk factors). Nonmodifiable risk factors (ACS, 2015b) are:

- Gender (female)
- Aging (>50 years old)
- Genetic mutations (BRCA1 and BRCA2 genes)
- Personal history of ovarian or colon cancer
- Increased breast density increases the risk three-to-fivefold
- Family history of breast cancer
- Personal history of breast cancer (three- to fourfold increase in risk for recurrence)
- Race/ethnicity (higher in White women, but African-American women are more likely to die of it)
- Previous abnormal breast biopsy (atypical hyperplasia)
- Exposure to chest radiation (radiation damages DNA)
- Previous breast radiation (12 times normal risk)
- Early menarche (<12 years old) or late onset of menopause (>55 years old), which represents increased estrogen exposure over the lifetime

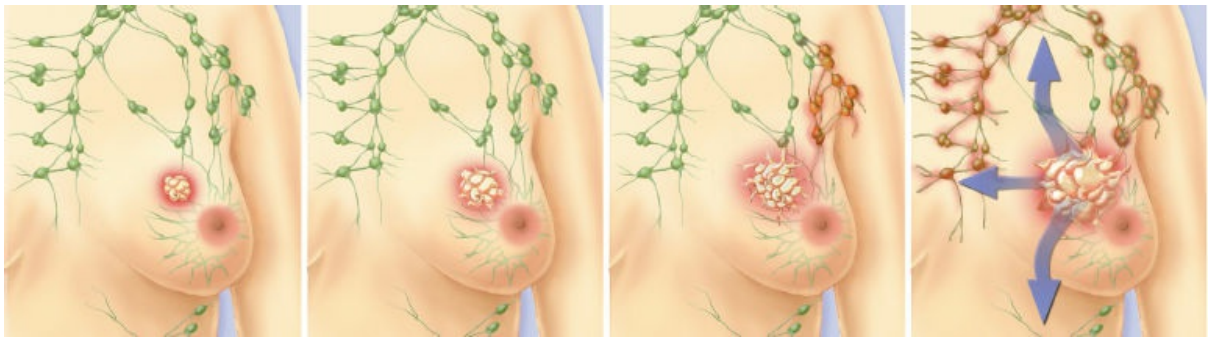

FIGURE 6.4 Stages I to IV of breast cancer.

Modifiable risk factors related to lifestyle choices (ACS, 2015b) include:

- Not having children at all or not having children until after age 30—this increases the risk of breast cancer by not reducing the number of menstrual cycles
- Postmenopausal use of estrogens and progestins—the Women's Health Initiative study (2002) reported increased risks with long-term (>5 years) use of HRT
- Failing to breast-feed for up to a year after pregnancy—increases the risk of breast cancer because it does not reduce the total number of lifetime menstrual cycles
- Alcohol consumption—boosts the level of estrogen in the bloodstream

- Smoking—exposure to carcinogenic agents found in cigarettes
- Obesity and consumption of high-fat diet—fat cells produce and store estrogen, so more fat cells create higher estrogen levels
- Sedentary lifestyle and lack of physical exercise—increases body fat, which houses estrogen

Breast cancer incidence rates are higher in non-Hispanic White women compared with African-American women for most age groups. However, African-American women have a higher incidence rate before 40 years of age and are more likely to die from breast cancer at every age (ACS, 2015b). Some of that gap is because of social factors such as poverty and restricted access to health care. Some studies have also found genetic differences in the type of breast cancer that develops in African American and White women. Little is known, however, about whether other risk factors have a different impact in women of different races. A new study's findings suggest that the risk factors are similar in both races (ACS, 2015b).

The presence of risk factors, especially several of them, calls for careful ongoing monitoring and evaluation to promote early detection. Even though risk factors are important considerations, many women with newly diagnosed breast cancer have no known risk factors. Although routine mammography and self-examination are prudent for high-risk women, these precautions may become lifesavers for early detection of cancerous lesions.

Consuming a low-fat diet with plenty of fruits, vegetables, legumes, and whole grains can provide all the vitamins and nutrients our bodies need and has been shown to significantly reduce the risk of developing many types of cancer. A plant-based diet can also reduce cancer recurrence: high-fiber, low-fat diets rich in fruits and vegetables, avoiding sugared beverages and calorie dense foods, and processed meats reduce breast cancer recurrence, according to Catsburg et al., (2015). They studied the effectiveness of a high-vegetable, low-fat diet, aimed at markedly raising circulating carotenoid concentrations from food sources, in reducing additional breast cancer events and early death in women with early-stage invasive breast cancer. It is a prescription for cancer prevention that has only positive side effects—lower cholesterol, weight loss, and a lower risk of heart disease. Adherence to a plant-based diet that limits red meat intake may be associated with reduced risk of breast cancer, particularly in postmenopausal women (Catsburg et al., 2015).

Screening for breast cancer begins with a routine history and physical examination. Nurses should take every opportunity to educate and emphasize the goal of breast cancer screening: early detection reduces mortality. Screening also includes a BSE, CBE, and mammography.

Diagnosis

Many studies can be performed to make an accurate diagnosis of a malignant breast lump. Diagnostic tests include:

- Diagnostic mammography or digital mammography
- Magnetic resonance mammography (MRM)
- Fine-needle aspiration
- Stereotactic needle-guided biopsy
- Sentinel lymph node biopsy
- Hormone receptor status

• Infrared thermal imaging
• DNA ploidy status
• Cell proliferative indices
• HER-2/neu genetic marker (Han et al., 2015)

Mammography

Mammography has become an accepted screening procedure that is sanctioned by most cancer organizations and is paid for annually by most health insurance agencies. Mammography serves a twofold purpose: to screen and to diagnose. Mammography involves taking x-ray pictures of a bare breast while it is compressed between two plastic plates. This procedure is a screening tool used to identify and characterize a breast mass and to detect an early malignancy. It remains the gold standard screening method for women at average risk for breast cancer. It is relatively inexpensive, requires only a low dose of radiation, and reliably identifies malignant tumors, especially those that are too small to feel. It can also be used to investigate breast lumps and other symptoms. A screening mammogram typically consists of four views, two per breast (Fig. 6.5). It can detect lesions as small as 0.5 cm (the average size of a tumor detected by a woman practicing occasional BSE is approximately 2.5 cm) (Rifkin & Lazris, 2015).

FIGURE 6.5 **Mammography. A. A top-to-bottom view of the breast. B. A side view of the breast.**

A diagnostic mammogram is performed when a woman has suspicious clinical findings on a breast examination or an abnormality has been found on a screening mammogram. A diagnostic mammogram uses additional views of the affected breast as well as magnification views. Diagnostic mammography provides the radiologist

with additional detail to render a more specific diagnosis. Currently, digital mammography is being used to diagnose breast lesions.

Most women find the 10-minute mammography procedure uncomfortable but not painful. Teaching Guidelines 6.3 offers tips for a client to follow before she undergoes this procedure.

Teaching Guidelines 6.3
PREPARING FOR A SCREENING MAMMOGRAM

- Schedule the procedure just after menses, when breasts are less tender.
- Do not use deodorant or powder on the day of the procedure, because they can appear on the x-ray film as calcium spots.
- Acetaminophen (Tylenol) or acetylsalicylic acid (aspirin) can relieve any discomfort after the procedure.
- Remove all jewelry from around your neck, because the metal can cause distortions on the film image.
- Select a facility that is accredited by the American College of Radiology to ensure appropriate credentialed staff.

The U.S. Preventive Services Task Force (USPSTF) changed its recommendations for breast cancer screening in 2009, resulting in considerable controversy. The USPSTF now recommends biennial screening mammography for women aged 50 to 74 years. Previously, women 40 years and older were advised to start screening mammography. They stated that the decision to start regular, biennial screening mammography before the age of 50 years should be an individual one and take client context into account, including the client's values regarding specific benefits and harms. In addition, the USPSTF concluded that the current evidence is insufficient to assess the additional benefits and harms of screening mammography in women 75 years or older. Finally, the USPSTF recommended against teaching BSE because scientific evidence does not support this practice as a valid screening method for women since its sensitivity ranges from 12% to 41%, lower than that of the CBE done by a health care provider and mammography, and it is age dependent. The USPSTF is currently updating their breast cancer screening recommendation guidelines and may return to every 1 to 2 years for women age 40 or older for diagnostic mammograms (U.S. Preventive Services Task Force [USPSTF], 2015).

The American Cancer Society has different guidelines for women with no symptoms or family history of breast cancer than the USPSTF. They still recommend annual mammograms and CBEs for women starting at age 40 and do not recommend stopping them at any age. They also recommend a CBE about every 3 years for women in their 20s and 30s and every year for women >40. BSE is an option for women starting in their 20s (ACS, 2015d).

The American Congress of Obstetricians and Gynecologists (ACOG) recommends that mammography screening be offered annually to women beginning at age 40. Previous ACOG guidelines recommended mammograms every 1 to 2 years starting at age 40 and annually beginning at age 50. ACOG continues to recommend annual

CBEs for women aged 40 and older, and every 1 to 3 years for women aged 20 to 39. Additionally, it encourages breast self-awareness for women ages 20 and older (American Congress of Obstetricians and Gynecologists [ACOG], 2015).

This conflicting information can be confusing to women trying to make decisions about breast cancer screening. Nurses can present the latest evidence-based research to help women make informed decisions based on their age, overall health status, and family history of cancer. (See Table 6.4 for a helpful outline.) There really isn't any clear direction given to women by the authoritative agencies; they in essence leave the decision up to the woman and her health care provider. The associated risk is delay in detecting a breast lesion early when it could be treated and her life saved.

Magnetic Resonance Mammography

MRM is a relatively new procedure that might allow for earlier detection because it can detect smaller lesions and provide finer detail. MRM is a highly accurate (>90% sensitivity for invasive carcinoma) but costly tool. Contrast infusion is used to evaluate the rate at which the dye initially enters the breast tissue. The basis of the high sensitivity of MRM is the tumor angiogenesis (vessel growth) that accompanies a majority of breast cancers, even early ones. Malignant lesions tend to exhibit increased enhancement within the first 2 minutes (Bhatti et al., 2015). Currently MRM is used as a complement to mammography and CBE because it is expensive, but recent research findings report that it is more accurate than mammography for size assessment of breast lesions (Poulos, 2015).

Fine-Needle Aspiration Biopsy or Core Biopsy

Fine-needle aspiration biopsy is done to identify a solid tumor, cyst, or malignancy. It is a simple office procedure that can be performed with or without anesthesia. A small (23- to 27-gauge) needle connected to a 10-mL or larger syringe is inserted into the breast mass and suction is applied to withdraw the contents. The aspirate is then sent to the cytology laboratory to be evaluated for abnormal cells.

A core needle biopsy is much like a fine-needle biopsy except that a larger needle is used to withdraw small cylinders or cores of tissue from the abnormal area of the breast. It takes longer than the fine-needle biopsy, but more tissue is sampled to be tested.

TABLE 6.4 SCREENING RECOMMENDATIONS FROM USPSTF, ACS, AND ACOG

The U.S. Preventive Services Task Force	In 2009, the USPSTF changed its recommendations for breast cancer screening for women with no symptoms or no family history of breast cancer. Previously they advised screening mammography for women ages 40 yrs and older. Updated recommendations include biennial screening mammography for women ages 50–74 yrs, and no breast self-examination (BSE) since scientific evidence does not support this practice as a valid screening method for women because its sensitivity ranges from 12–41%, which is lower than that of the clinical breast examination done by a health professional and mammography, and it is age dependent. The previous recommendations are now under review (2015). The USPSTF states that a woman's decision to start regular, biennial screening mammography before the age of 50 yrs should be an individual one and take client context into account, including the client's values regarding specific benefits and harms. The USPSTF also reports that current evidence is insufficient to assess the additional benefits and harmful aspects of screening mammography in women 75 yrs or older (USPSTF, 2015).
The American Cancer Society	Guidelines from the ACS differ from those of the USPSTF for women with no symptoms or no family history of breast cancer. The ACS still recommends annual mammograms and clinical breast examinations for women starting at age 40 and do not recommend stopping them at any age. They suggest that BSEs can be optional for women from age 20 onward (ACS, 2015d).
The American Congress of Obstetricians and Gynecologists	The ACOG recommends screening mammograms be offered annually to women beginning at age 40. Previous guidelines recommended a mammogram every 1–2 yrs starting at age 40 and annually beginning at age 50. Clinical breast examinations are still recommended every year, but BSEs are optional and not strongly recommended (ACOG, 2015).

Stereotactic Needle-Guided Biopsy

This diagnostic tool is used to target and identify mammographically detected nonpalpable lesions in the breast. This procedure is less expensive than an excisional biopsy. The procedure takes place in a specially equipped room and generally takes about an hour. Women are required to lie prone and must be able to remain still for approximately 20 minutes while the biopsy is taken. When proper placement of the breast mass is confirmed by digital mammograms, the breast is locally anesthetized and a spring-loaded biopsy gun is used to obtain two or three core biopsy tissue samples. After the procedure is finished, the biopsy area is cleaned and a sterile dressing is applied.

Sentinel Lymph Node Biopsy

The status of the axillary lymph nodes is an important prognostic indicator in early-stage breast cancer. The presence or absence of malignant cells in lymph nodes is highly significant: the more lymph nodes involved and the more aggressive the cancer, the more powerful **chemotherapy** will have to be, both in terms of the toxicity of drugs and the duration of treatment (Tsujimoto, 2015). With a sentinel lymph node biopsy, the clinician can determine whether breast cancer has spread to the axillary lymph nodes without having to do a traditional axillary lymph node dissection. Experience has shown that the lymph ducts of the breast typically drain to one lymph node first before draining through the rest of the lymph nodes under the arm. The first lymph node is called the sentinel lymph node.

This procedure can be performed under local anesthesia. A radioactive blue dye is injected 2 hours before the biopsy to identify the afferent sentinel lymph node. The surgeon usually removes one to three nodes and sends them to the pathologist to determine whether cancer cells are present. The sentinel lymph node biopsy is usually performed before a lumpectomy to make sure the cancer has not spread. Removing only the sentinel lymph node can allow women with breast cancer to avoid many of the side effects (lymphedema) associated with a traditional axillary

lymph node dissection. This procedure is associated with less morbidity compared to the axillary lymph node dissection, which results in more accurate staging, better axillary tumor control and improved survival. It is considered a standard of care for initial evaluation of metastatic spread to the axillary lymph node chain (Chatterjee, Serniak, & Czerniecki, 2015).

Hormone Receptor Status

Normal breast epithelium has hormone receptors and responds specifically to the stimulatory effects of estrogen and progesterone. Most breast cancers retain estrogen receptors, and for those tumors estrogen will retain proliferative control over the malignant cells. It is therefore useful to know the hormone receptor status of the cancer to predict which women will respond to hormone manipulation. Hormone receptor status reveals whether the tumor is stimulated to grow by estrogen and progesterone. Postmenopausal women tend to be ER+; premenopausal women tend to be ER− (Kalinsky et al., 2015). To determine hormone receptor status, a sample of breast cancer tissue obtained during a biopsy or a tumor removed surgically during a lumpectomy or mastectomy is examined by a cytologist.

Therapeutic Management

Women diagnosed with breast cancer have many treatments available to them. Generally, treatments fall into two categories: local and systemic. Local treatments are surgery and radiation therapy. Effective systemic treatments include chemotherapy, hormonal therapy, and immunotherapy (Evidence-Based Practice 6.1).

Treatment plans are based on multiple factors, with the primary factors being whether the cancer is invasive or noninvasive, the tumor's size and grade, the number of cancerous axillary lymph nodes, the hormone receptor status, and the ability to obtain clear surgical margins (ACS, 2015e). A combination of surgical options and adjunctive therapy is often recommended.

Another consideration in making decisions about a treatment plan is genetic testing for BRCA1 and BRCA2 genetic mutations. This genetic testing became available in 1995 and can pinpoint women who have a significantly increased risk for breast, ovarian cancer and contralateral breast cancer: individuals with BRCA1 and BRCA2 mutations have a 75% lifetime risk of breast cancer and a 30% lifetime risk of ovarian cancer. Most cases of breast and ovarian cancer are sporadic in nature, but approximately 10% of breast and ovarian cancers are thought to result from genetic inheritance (Li et al., 2015). DNA (from a blood or saliva sample) is needed for mutation testing. The sample is sent to a laboratory for analysis. It usually takes about a month to get the results back. Testing positive for a BRCA1 or BRCA2 mutation can significantly alter health care decisions. In some cases, before genetic testing was available, lumpectomy with radiation or mastectomy was the treatment most often recommended. However, if the woman is found to have a BRCA1 mutation, she is most likely to be offered the option of bilateral prophylactic mastectomy and possible bilateral oophorectomy. A recent study found that current evidence does not support worse breast cancer survival of BRCA1/2 mutation carriers in the adjuvant setting; differences if any are likely to be small when compared to non-BRCA1/2 mutation carriers (van den Broek et al., 2015).

EVIDENCE-BASED PRACTICE 6.1

COMBINATION (SEVERAL DRUGS AT A TIME) VERSES SEQUENTIAL CHEMOTHERAPY (SAME DRUG GIVEN ONE AFTER THE OTHER) FOR METASTATIC BREAST CANCER

STUDY

Combination chemotherapy can cause greater tumor cell kill if the drug dose is not compromised, while sequential single agent chemotherapy may allow for greater dose intensity and treatment time, potentially meaning greater benefit from each single agent. In addition, sequentially using single agents might cause less toxicity and impairment of quality of life, but it is not known whether this might compromise survival time. The purpose of this study was to assess the effect of combination chemotherapy compared to the same drugs given sequentially in women with metastatic breast cancer.

Findings

Randomized controlled trials of combination chemotherapy compared to the same drugs used sequentially in women with metastatic breast cancer in the first-, second- or third-line setting were selected. Twelve trials reporting on nine treatment comparisons (2,317 patients randomized) were identified. The findings concluded that sequential single agent chemotherapy has a positive effect on progression-free survival, whereas combination chemotherapy has a higher response rate and a higher risk of febrile neutropenia in metastatic breast cancer. There was no difference in overall survival time between these treatment strategies, but when drugs were given one at a time, there was more time before the tumors grew back again. However, combination chemotherapy caused tumors to shrink more. Generally this study supports the recommendations by international guidelines to use sequential monotherapy unless there is rapid disease progression.

Nursing Implications

Although not entirely conclusive in its findings, nurses need to be aware of this study's findings to be able to counsel women when both therapies are being considered. This study suggests that accurate information about both therapies is needed for all women with metastatic breast cancer, for them to make an informed decision. Nurses need to remember that metastatic breast cancer is not currently curable, but can be effectively treated with chemotherapy. Average survival is about 2 years, but many women live much longer. The type of therapy chosen should take into consideration optimizing survival, minimizing side effects, and quality of life.

Adapted from Dear, R. F., McGeechan, K, Jenkins, M. C., Barratt, A., Tattersall, M. H. N, & Wilcken, N. (2015). Combination versus sequential single agent chemotherapy for metastatic breast cancer. *Cochrane Database of Systematic Reviews* 2013, *3*:CD008792. doi: 10.1002/14651858.CD008792.pub2.

Discovery of mutations in the breast and ovarian cancer susceptibility genes BRCA1 and BRCA2 can have emotional consequences for both the tested individual and his or her relatives.

Severe psychological distress can occur as a result of genetic testing. Their distress relates to family cancer history, relationships, coping strategies, communication patterns, and mutation status (Wevers et al., 2015). Nurses might find it useful to

explore these issues in order to prepare clients before BRCA1/BRCA2 testing and to support them through shifts in family dynamics after disclosure of results. Also, many women perceive their breasts as intrinsic to their femininity, self-esteem, and sexuality, and the risk of losing a breast can provoke extreme anxiety (Alexander et al., 2014). Nurses need to address the physical, emotional, and spiritual needs of the women they care for, as well as their families, since this mutation is inherited in an autosomal dominant fashion. Nurses should identify the woman's personal coping style which has an impact on her likelihood of experiencing distress after her diagnosis. Women who are emotionally expressive and/or have a "fighting spirit" usually experience lower levels of emotional distress. Based on Mendelian genetics, women with BRCA1 and BRCA2 mutations have a 5- to 20-fold increased risk of developing breast and ovarian cancer (Caple & Schub, 2015).

Surgical Options

Generally, the first treatment option for a woman diagnosed with breast cancer is surgery. A few women with tumors larger than 5 cm or inflammatory breast cancer may undergo neoadjuvant chemotherapy or radiotherapy to shrink the tumor before surgical removal is attempted (Debled et al., 2015). The surgical options depend on the type and extent of cancer. The choices are typically either **breast-conserving surgery** (lumpectomy with radiation) or mastectomy with or without reconstruction. The overall survival rate with lumpectomy and radiation is about the same as that with **modified radical mastectomy** (ACS, 2015f). Research has shown that the survival rates in women who have had mastectomies versus those who have undergone breast-conserving surgery followed by radiation are the same. However, lumpectomy may not be an option for some women, including those:

- Who have two or more cancer sites that cannot be removed through one incision
- Whose surgery will not result in a clean margin of tissue
- Who have active connective tissue conditions (lupus or scleroderma) that make body tissues especially sensitive to the side effects of radiation
- Who have had previous radiation to the affected breast
- Whose tumors are larger than 5 cm (2 in) (National Comprehensive Cancer Network [NCCN], 2015).

These decisions are made jointly between the woman and her surgeon. If mastectomy is chosen, because of either tumor characteristics or client preference, then discussion needs to include breast reconstruction and regional lymph node biopsy versus sentinel lymph node biopsy. The mastectomy techniques are a **simple mastectomy** with sentinel node biopsy or a radical mastectomy with regional node biopsy. Removal of numerous lymph nodes places the client at high risk for lymphedema.

BREAST-CONSERVING SURGERY

Breast-conserving surgery, the least invasive procedure, is the wide local excision (or lumpectomy) of the tumor along with a 1-cm margin of normal tissue. A lumpectomy is often used for early-stage localized tumors. The goal of breast-conserving surgery is to remove the suspicious mass along with tissue free of malignant cells to prevent recurrence. The results are less drastic and emotionally less scarring than having a mastectomy to the woman. Women undergoing breast-

conserving therapy receive radiation after lumpectomy with the goal of eradicating residual microscopic cancer cells to limit locoregional recurrence. In women who do not require adjuvant chemotherapy, radiation therapy typically begins 2 to 4 weeks after surgery to allow healing of the lumpectomy incision site. Radiation is administered to the entire breast at daily doses over a period of several weeks (Corradini et al., 2015).

A sentinel lymph node biopsy may also be performed since the lymph nodes draining the breast are located primarily in the axilla. Theoretically, if breast cancer is to metastasize to other parts of the body, it will probably do so via the lymphatic system. If malignant cells are found in the nodes, more aggressive systemic treatment may be needed.

MASTECTOMY

A simple mastectomy is the removal of all breast tissue, the nipple, and the areola. The axillary nodes and pectoral muscles are spared. This procedure would be used for a large tumor or multiple tumors that have not metastasized to adjacent structures or the lymph system.

A modified radical mastectomy is another surgical option, conducive to breast reconstruction and results in greater mobility and less lymphedema (Alexander et al., 2014). This procedure involves removal of breast tissue, and a few positive axillary nodes. Breast-conserving surgeries do not increase the future risk of death from recurrent disease when compared with mastectomy (Schuiling & Likis, 2016).

In conjunction with the mastectomy, lymph node surgery (removal of underarm nodes) may need to be done to reduce the risk of distant metastasis and improve a woman's chance of long-term survival. For women with a positive sentinel node biopsy, 10 to 20 underarm lymph nodes may need to be removed. Complications associated with axillary lymph node surgery include nerve damage during surgery, causing temporary numbness down the upper aspect of the arm; seroma formation (fluid build-up) followed by wound infection; restrictions in arm mobility (some women need physiotherapy); and lymphedema (swelling related to the lymph glands). In many women lymphedema can be avoided by:

- Avoiding using the affected arm for drawing blood, inserting intravenous lines, or measuring blood pressure (can cause trauma and possible infection)
- Seeking medical care immediately if the affected arm swells
- Wearing gloves when engaging in activities such as gardening that might cause injury
- Wearing a well-fitted compression sleeve to promote drainage return

Women having mastectomies must decide whether to have further surgery to reconstruct the breast. If the woman decides to have reconstructive surgery, it ideally is performed immediately after the mastectomy. The woman must also determine whether she wants the surgeon to use saline implants or natural tissue from her abdomen (TRAM flap method) or back (LAT flap method).

If reconstructive surgery is desired, the ultimate decision regarding the method will be determined by the woman's anatomy (e.g., is there sufficient fat and muscle to permit natural reconstruction?) and her overall health status. Both procedures require a prolonged recovery period.

Some women opt for no reconstruction, and many of them choose to wear breast

prostheses. Some prostheses are worn in the bra cup and others fit against the skin or into special pockets created into clothing.

Whether to have reconstructive surgery is an individual and very complex decision. Each woman must be presented with all of the options and then allowed to decide. The nurse can play an important role here by presenting the facts to the woman so that she can make an intelligent decision to meet her unique situation. Breast reconstruction surgery can help restore the look and feel of the breast after a mastectomy. Performed by a plastic surgeon, breast reconstruction can be done immediately after the mastectomy or at a later date. Breast reconstruction can be done with **breast implants** (filled with saline or silicone); natural tissue flaps (using skin fat and muscle from your own body); or a combination of both. Side effects or complications include risk of rupture, hardening of the tissues around the implant, infection, and pain. Nurses need to educate the woman about these potential problems and make sure they understand before consenting to breast reconstruction. See Figure 6.6 for examples of a postmastectomy (A) and reconstruction breast Augmentation (B).

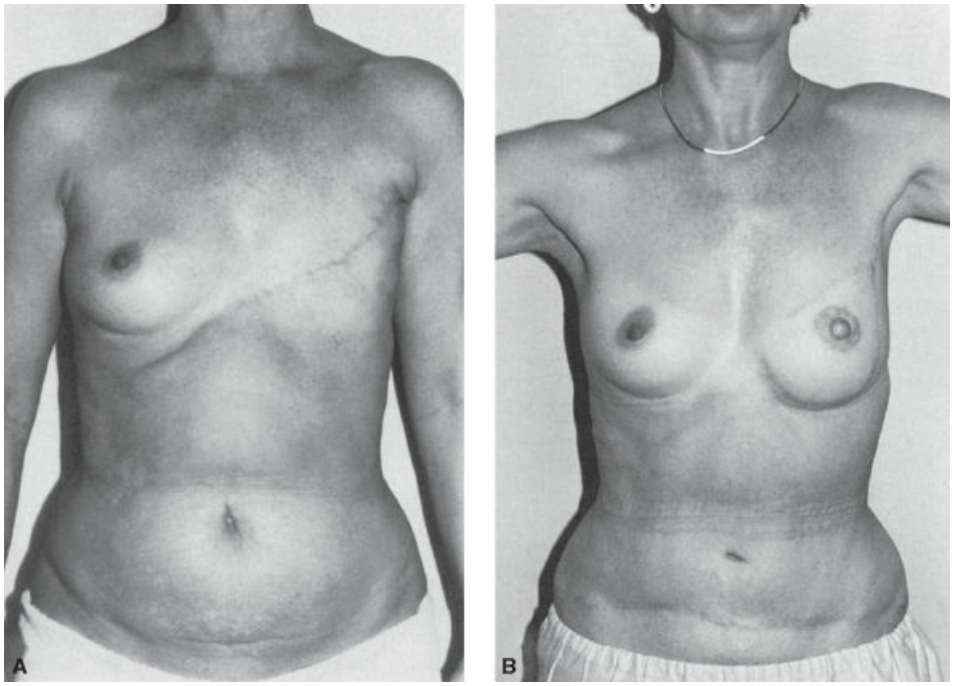

FIGURE 6.6 Before and after photos of postmastectomy and reconstruction.

BREAST AUGMENTATION

Breast augmentation is a common surgical procedure with women undergoing it with implants for a variety of reasons ranging from aesthetic to reconstructive surgery following a mastectomy. Saline-filled or silicone-filled implants are used in cosmetic enhancement and reconstructive surgeries. The exact anatomical placement of breast implants can vary, but the location typically is subglandular (over the pectoral muscle) or subpectoral (under the muscle). Breast implants are not lifetime devices, but most are guaranteed for approximately 10 years in case of rupture. Breast augmentation with implants is not without risks. Potential complications include capsular contracture, rippling, implant rupture, infection, or hematoma. Capsular contraction occurs when scar tissue forms, contracts, and

hardens around the implant. Rippling most often occurs when wrinkles form in the implant or as a complication of contracture (Mugea, 2015).

Breast examination in women with reconstructive surgery is done exactly the same way as for natural breasts. Breasts with implants in place usually feel firmer than normal breast tissue on palpation due to the formation of a fibrotic band or capsule around the implant. If implants are used, press firmly inward at the edges of the implant to feel the ribs beneath.

Adjunctive Therapy

Adjunctive therapy is supportive or additional therapy that is recommended after surgery. Adjunctive therapies include local therapy such as radiation therapy and systemic therapies using chemotherapy, hormonal therapy, and immunotherapy.

RADIATION THERAPY

Radiation therapy (also called radiotherapy) uses high-energy rays to destroy cancer cells that might have been left behind in the breast, chest wall, or underarm area after a tumor has been removed surgically. Usually serial radiation doses are given 5 days a week to the tumor site for 6 to 8 weeks postoperatively. Each treatment takes only a few minutes, but the dose is cumulative. Women undergoing breast-conserving therapy receive radiation to the entire breast after lumpectomy with the goal of eradicating residual microscopic cancer cells to reduce the chance of recurrence (Chu et al., 2015).

Side Effects. Side effects of traditional radiation therapy include inflammation, local edema, anorexia, swelling, and heaviness in the breast; sunburn-like skin changes in the treated area; and fatigue. Changes to the breast tissue and skin usually resolve in about a year in most women (Lara et al., 2015). This type of therapy can be given several ways: external beam radiation, which delivers a carefully focused dose of radiation from a machine outside the body, or internal radiation, in which tiny pellets that contain radioactive material are placed into the tumor.

Several advances have taken place in the field of radiation oncology for the treatment of women with early-stage breast cancer that assist in reducing the side effects. The treatment position for external radiation has changed from supine to prone, with the arm on the affected side raised above the head, so that the treated breast hangs dependently through the opening of the treatment board. Treatment in the prone position improves dose distribution within the breast and allows for a decrease in the dose delivered to the heart, lung, chest wall, and other breast (NCCN, 2015).

High-dose brachytherapy is another advance that is an alternative to traditional radiation treatment. A balloon catheter is used to insert radioactive seeds into the breast after the tumor has been removed surgically. The seeds deliver a concentrated dose directly to the operative site; this is important because most cancer recurrences in the breast occur at or near the lumpectomy site (Chang et al., 2015). This allows a high dose of radiation to be delivered to a small target volume with a minimal dose to the surrounding normal tissue. This procedure takes 4 to 5 days as opposed to the 4 to 6 weeks that traditional radiation therapy takes; it also eliminates the need to delay radiation therapy to allow for wound healing.

Brachytherapy is now used as a primary radiation treatment after breast-conserving surgery in selected women as an alternative to whole breast irradiation (Guinot et al., 2015). Side effects of brachytherapy include redness or discharge around catheters, fever, and infection. Daily cleansing of the catheter insertion site with a mild soap and application of an antibiotic ointment will minimize the risk of infection.

Intensity-modulated radiation therapy (IMRT) offers still another new approach to the delivery of treatment to reduce the dose within the target area while sparing surrounding normal structures. A computed tomography scan is used to create a three-dimensional model of the breast. Based on this model, a series of intensity-modulated beams is produced to the desired dose distribution to reduce radiation exposure to underlying structures. Acute toxicity is thus minimized (Muralidhar, Soubhagya, & Ahmed, 2015). Research is ongoing to evaluate the impact of all of these advances in radiation therapy.

CHEMOTHERAPY

Chemotherapy refers to the use of drugs that are toxic to all cells and interfere with a cell's ability to reproduce. They are particularly effective against malignant cells but affect all rapidly dividing cells, especially those of the skin, the hair follicles, the mouth, the gastrointestinal tract, and the bone marrow. Breast cancer is a systemic disease in which micrometastases are already present in other organs by the time the breast cancer is diagnosed. Chemotherapeutic agents perform a systemic "sweep" of the body to reduce the chances that distant tumors will start growing.

Chemotherapy may be indicated for women with tumors larger than 1 cm, positive lymph nodes, or cancer of an aggressive type. Chemotherapy is prescribed in cycles, with each period of treatment followed by a rest period. Treatment typically lasts 3 to 6 months, depending on the dose used and the woman's health status.

Different classes of drugs affect different aspects of cell division and are used in combinations or "cocktails." The most active and commonly used chemotherapeutic agents for breast cancer include alkylating agents, anthracyclines, antimetabolites, and vinca alkaloids. Fifty or more chemotherapeutic agents can be used to treat breast cancer; however, a combination drug approach appears to be more effective than a single drug treatment (ACS, 2015g). Refer to Evidence-Based Practice 6.1.

Side Effects. Side effects of chemotherapy depend on the agents used, the intensity of dosage, the dosage schedule, the type and extent of cancer, and the client's physical and emotional status. Nurses need to remain current in order to accommodate new treatments and the side effect profiles. This knowledge is vital to providing evidence-based care for breast cancer women receiving these treatments (Bourdeanu & Lui, 2015). However, typical side effects include nausea and vomiting, diarrhea or constipation, hair loss, weight loss, stomatitis, fatigue, and immunosuppression. The most serious is bone marrow suppression (myelosuppression). This causes an increased risk of infection, bleeding, and a reduced red blood cell count, which can lead to anemia. Treatment of the side effects can generally be addressed through appropriate support medications such as antinausea drugs. In addition, growth-stimulating factors, such as epoetin alfa (Procrit) and filgrastim (Neupogen), help keep blood counts from dropping too low.

Counts that are too low would stop or delay the use of chemotherapy.

An aggressive systemic option, when other treatments have failed or when there is a strong possibility of relapse or metastatic disease, is high-dose chemotherapy with bone marrow and/or stem cell transplant. This therapy involves the withdrawal of bone marrow before the administration of toxic levels of chemotherapeutic agents. The marrow is frozen and then returned to the client after the high-dose chemotherapy is finished. Clinical trials are still researching this experimental therapy (King et al., 2015).

HORMONAL THERAPY

One of estrogen's normal functions is to stimulate the growth and division of healthy cells in the breasts. However, in some women with breast cancer, this normal function contributes to the growth and division of cancer cells.

The objective of **endocrine therapy** is to block or counter the effect of estrogen. Estrogen plays a central role in the pathogenesis of cancer, and treatment with estrogen deprivation has proven to be effective. Approximately two thirds of women diagnosed with early-stage breast cancer have hormone-sensitive disease (estrogen receptor positive and/or progesterone receptor positive), and adjuvant hormone therapy plays an essential role in reducing the risk of recurrence and improving survival (Gradishar, 2015). Several different drug classes are used to interfere or block estrogen receptors. They include selective estrogen receptor modulators (SERMs), estrogen receptor downregulators, aromatase inhibitors, luteinizing hormone–releasing hormone, progestin, and biologic response modifiers (King et al., 2015). Current recommendations for most women with ER+ breast cancer are to take a hormone-like medication—known as a SERM antiestrogenic agent—daily for up to 5 years after initial treatment. Certain areas in the female body (breasts, uterus, ovaries, skin, vagina, and brain) contain specialized cells called hormone receptors that allow estrogen to enter the cell and stimulate it to divide. SERMs enter these same receptors and act like keys, turning off the signal for growth inside the cell (King et al., 2015). The best-known SERM is tamoxifen (Nolvadex, 20 mg daily for 5 years). Although it works well in preventing further spread of cancer, it is also associated with an increased incidence of endometrial cancer, pulmonary embolus, deep vein thrombosis, hot flashes, vaginal discharge and bleeding, stroke, and cataract formation (Jager et al., 2015).

Another SERM is the antiosteoporosis drug raloxifene (Evista), which has shown promising results. It has antiestrogen effects on the breast and uterus. In recent studies involving postmenopausal women at high risk for breast cancer, raloxifene worked as well as tamoxifen in preventing breast cancer, but with fewer serious adverse effects. Both drugs cut the cancer risk in half (Bevers, 2015). It was originally marketed solely for the prevention and treatment of osteoporosis but is now used as adjunctive breast cancer therapy.

Another class of endocrine agents, aromatase inhibitors, works by inhibiting the conversion of androgens to estrogens. Aromatase inhibitors include letrozole (Femara, 2.5 mg daily), exemestane (Aromasin, 25 mg daily), and anastrozole (Arimidex, 1 mg daily for 5 years), all of which are taken orally. These are usually given to women with advanced breast cancer. In recent clinical studies in postmenopausal women with breast cancer, third-generation aromatase inhibitors were shown to be superior to tamoxifen for the treatment of metastatic disease

(Bevers, 2015).

Side Effects. The side effects associated with these endocrine therapies include hot flashes, bone pain, bone thinning, insomnia, weight gain, depression, fatigue, nausea, cough, dyspnea, and headache (Breast Cancer Organization, 2015). Women with hormone-sensitive cancers can live for long periods without any intervention other than hormonal manipulation, but quality-of-life issues need to be addressed in the balance between treatment and side effects.

IMMUNOTHERAPY

Immunotherapy, used as an adjunct to surgery, represents an attempt to stimulate the body's natural defenses to recognize and attack cancer cells. Trastuzumab (Herceptin, 2 to 4 mg/kg intravenous infusion) is the first monoclonal antibody approved for breast cancer (NCCN, 2015). Some tumors produce excessive amounts of HER-2/neu protein, which regulates cancer cell growth. Breast cancers that overexpress the HER-2/neu protein are associated with a more aggressive form of disease and a poorer prognosis. Trastuzumab blocks the effect of this protein to inhibit the growth of cancer cells. It can be used alone or in combination with other chemotherapy to treat clients with metastatic breast disease. Although immunotherapy has shown some promise against the fight against cancer, recent data suggests that greater success will be achieved by combining it with other therapies, such as radiation (Leavy, 2015).

Concept Mastery Alert

Tamoxifen Versus Trastuzumab in Breast Cancer Treatment

Tamoxifen is a selective estrogen receptor modulator used to prevent further spread of breast cancer in women with ER-positive breast cancer. Trastuzumab is a monoclonal antibody used in the treatment of breast cancer and is considered immunotherapy.

Side Effects. Adverse effects of trastuzumab include cardiac toxicity, vascular thrombosis, hepatic failure, fever, chills, nausea, vomiting, and pain with first infusion (Skidmore-Roth, 2015).

NURSING PROCESS FOR THE CLIENT WITH BREAST CANCER

When a woman is diagnosed with breast cancer, she faces treatment that may alter her body shape, may make her feel unwell, and may not carry a certainty of cure. Nurses can support women from the time of diagnosis, through the treatments, and through follow-up after the surgical and adjunctive treatments have been completed. Allowing clients time to ask questions and to discuss any necessary preparations for treatment is critical. As our understanding of breast disorders keeps improving, treatments continue to change.

Although the goal of treatment remains improved survival, increasing emphasis is being focused on prevention. Breast cancer prevention measures focus on

evaluating and reducing risk factors. Approaches for reducing breast cancer risk include lifestyle modifications (diet and physical exercise), chemoprevention (SERMs & AIs), and prophylactic surgery (bilateral salpingo-oophorectomy & bilateral prophylactic mastectomy) (Euhus & Diaz, 2015). Nurses can have an impact on early detection of breast disorders, treatment, and symptom management. Women with a cancer diagnosis often experience negative emotions and nurses' empathic response can help alleviate their distress (Alexander et al., 2014). A nurse who is involved in the woman's treatment plan from the beginning can effectively offer support throughout the whole experience.

Teamwork is important in breast screening and caring for women with breast disorders. Treatment is often fragmented between the hospital and community treatment centers, which can be emotionally traumatic for the woman and her family. The advances being made in the diagnosis and treatment of breast disorders mean that guidelines are constantly changing, requiring all health care providers to keep up to date. Informed nurses can provide support and information and, most importantly, continuity of care for the woman undergoing treatment for a breast problem.

The nurse plays a particularly important role in providing psychological support and self-care teaching to clients with breast cancer. Nurses can influence both physical and emotional recovery, which are both important aspects of care that help in improving the woman's quality of life and the ability to survive. The nurse's role should extend beyond helping clients; spreading the word in the community about screening and prevention is a big part in the ongoing fight against cancer. The community should see nurses as both educators and valued sources of credible information. This role will help improve clinical outcomes while achieving high levels of client satisfaction.

Despite the new guidelines issued by various governmental agencies regarding BSEs, a CBE done by a professional health care provider is essential for good breast health for all women. See Box 6.1 for additional information.

Remember Nancy from the chapter opener? Is her response typical of many women upon discovering a lump in their breast? Nancy confides her discovery of the lump and her worries to you. What advice would you give her?

Assessment

Early breast cancer has no symptoms. The earliest sign of breast cancer is often an abnormality seen on a screening mammogram before the woman or the health care provider feels it. A healthy, asymptomatic presentation is typical. However, symptoms may include a lump in the breast that is usually nontender, fixed, and hard with irregular borders. In the woman presenting with a breast disorder, take a thorough history of the problem and explore the woman's risk factors for breast cancer. Assess the woman for clinical manifestations of breast cancer, such as changes in breast appearance and contour, which become apparent with advancing breast cancer (ACS, 2015d). These changes include:

- Continued and persistent changes in the breast
- A lump or thickening in one breast

• Persistent nipple irritation
• Unusual breast swelling or asymmetry
• A lump or swelling in the axilla
• Changes in skin color or texture
• Nipple retraction, tenderness, or discharge

Complete a breast examination to validate the clinical manifestations and findings of the health history and risk factor assessment. The CBE involves both inspection and palpation (Box 6.1). Helpful characteristics in evaluating palpable breast masses are described in Table 6.5. If a lump can be palpated, the cancer has been there for quite some time.

Be cognizant of the impact that breast cancer has on a woman's emotional state, coping ability, and quality of life. Women may experience sadness, vulnerability, loss of control, alteration of body image and integrity, anger, the illness's impact on relationships, fear of mortality, the need to reprioritize her life, and guilt as a result of having breast cancer. However, despite potential negative outcomes, many women have a positive outlook for their future and adapt to treatment modalities with a good quality of life (Kleban & Glaser, 2015). Closely monitor clients for their psychosocial adjustment to diagnosis and treatment and be able to identify those who need further psychological intervention. By giving practical advice, the nurse can help the woman adjust to her altered body image and to accept the changes in her life.

Because family members play a significant role in supporting women through breast cancer diagnosis and treatment, assess the emotional distress of both partners during the course of treatment and, if needed, make a referral for psychological counseling. By identifying interpersonal strains, negative psychosocial side effects of cancer treatment can be minimized.

BOX 6.1

CLINICAL BREAST EXAMINATION BY HEALTH CARE PROVIDER

If the woman is deemed high risk, the nurse would then teach the woman to perform a BSE to enhance breast awareness.

Purpose: To Assess Breasts For Abnormal Findings

1. Inspect the breast for size, symmetry, and skin texture and color. It is common for the left breast to be slightly larger than the right. Inspect the nipples and areola. Ask the client to sit at the edge of the examination table, with her arms resting at her sides.

2. Inspect the breast for masses, retraction, dimpling, or ecchymosis.
   • The client places her hands on her hips.

   • She then raises her arms over her head so the axillae can also be inspected.

   • The client then stands, places her hands on her hips, and leans forward.

3. Palpate the breasts using the pads of your first three fingers and make a rotary motion on the breast. Assist the client into a supine position with her arms above her head. Place a pillow or towel under the client's head to help spread the breasts. Three patterns might be used to palpate the breasts:

• Spiral

• Pie-shaped wedges

• Vertical strip

4. Compress the nipple gently between the thumb and index finger to evaluate for masses and squeeze to check for any discharge.

5. Palpate the axillary area for any tenderness or lymph node enlargement. Have the client sit up and move to the edge of the examination table. While supporting the client's arm, palpate downward from the armpit, palpating toward the ribs just below the breast.

Adapted from Ball, J. W., Dains, J. E., Flynn, J. A., Soloman, B. S., & Stewart, R. W. (2015). *Seidel's guide to physical examination* (8th ed.). St. Louis, MO: Elsevier Saunders.

TABLE 6.5 CHARACTERISTICS OF BENIGN VERSUS MALIGNANT BREAST MASSES

Benign Breast Masses Are Described As	Malignant Breast Masses Are Described As
• Frequently painful • Firm, rubbery mass • Bilateral masses • Induced nipple discharge • Regular margins (clearly delineated) • No skin dimpling • No nipple retraction • Mobile, not affixed to the chest wall • No bloody discharge	• Hard to palpation • Painless • Irregularly shaped (poorly delineated) • Immobile, fixed to the chest wall • Skin dimpling • Nipple retraction • Unilateral mass • Bloody, serosanguineous, or serous nipple discharge • Spontaneous nipple discharge

Nursing Diagnosis

Appropriate nursing diagnoses for a woman with a diagnosis of breast cancer might include:

- Disturbed body image related to:
  - Loss of body part (breast)
  - Loss of femininity
  - Loss of hair due to chemotherapy
- Fear related to:
  - Diagnosis of cancer

- Prognosis of disease

- Deficient knowledge related to:
  - Cancer treatment options
  - Reconstructive surgery decisions
  - Breast self-examination

Nursing Interventions

Offer information, support, and perioperative care to women diagnosed with breast cancer who are undergoing treatment. Implement health promotion and disease prevention strategies to minimize the risk for developing breast cancer and to promote optimal outcomes.

Remember Nancy, who discovered a breast lump? You offer to go with her to the doctor. After a full examination and several diagnostic tests, the results come back positive for breast cancer. What treatment options does Nancy have, and what factors need to be considered in selecting those options?

Providing Client Education

Help the woman and her partner to prioritize the voluminous amount of information given to them so that they can make informed decisions. Explain all treatment options in detail so the client and her family understand them. By preparing an individualized packet of information and reviewing it with the woman and her partner (if applicable), the nurse can help the woman understand her specific type of cancer, the diagnostic studies and treatment options she may choose, and the goals of treatment. For example, nurses play an important role in educating women about the use of endocrine therapies, observing women's experiences with treatment, and communicating those observations to their primary health care providers to make dosage adjustments, in addition to contributing to the knowledge base of endocrine therapy in the treatment of breast cancer.

Providing information is a central role of the nurse in caring for the woman with a diagnosis of breast cancer. This information can be given via telephone counseling, one-to-one contact, and pamphlets. Telephone counseling with women and their partners may be an effective method to improve symptom management and quality of life. Educate women on living with risk, maintaining quality of life, and participating in support groups (Strayer & Schub, 2014).

PROVIDING EMOTIONAL SUPPORT

The diagnosis of cancer affects all aspects of life for a woman and her family. The threatening nature of the disease and feelings of uncertainty about the future can lead to anxiety and stress. Address the woman's need for:

- Information about diagnosis and treatment
- Physical care while undergoing treatments
- Contact with supportive people
- Education about disease, options, and prevention measures

• Discussion and support by a caring, competent nurse

Reassure the client and her family that the diagnosis of breast cancer does not necessarily mean imminent death, a decrease in attractiveness, or diminished sexuality. Encourage the woman to express her fears and worries. Be available to listen and address the woman's concerns in an open manner to help her toward recovery. All aspects of care must include sensitivity to the client's personal efforts to cope and heal. Some women will become involved in organizations or charities that support cancer research; they may participate in breast cancer walks to raise awareness or become a *Reach to Recovery* volunteer to help others. Each woman copes in her own personal manner, and all of these efforts can be positive motivators for her own healing.

To help women cope with the diagnosis of breast cancer, the ACS launched *Reach to Recovery* more than 30 years ago. Specially trained breast cancer survivors give women and their families' opportunities to express their feelings, verbalize their fears, and get answers. Recovery volunteers can also, when appropriate, provide a temporary breast form and give information on types of permanent prostheses, as well as lists of where those items are available in the community. Most importantly, *Reach to Recovery* volunteers offer understanding, support, and hope through face-to-face visits or by telephone; they are proof that people can survive breast cancer and live productive lives. National contact information is 1-800-ACS-2345.

Providing Postoperative Care

For the woman who has had surgery to remove a malignant breast lump or an entire breast, excellent postoperative nursing care is crucial. Tell the woman what to expect in terms of symptoms and when they usually occur during treatment and after surgery. This allows women to anticipate these symptoms and proactively employ management strategies to improve their cancer experience. Postoperative care includes immediate postoperative care, pain management, care of the affected arm, wound care, mobility care, respiratory care, emotional care, referrals, and educational needs.

IMMEDIATE POSTOPERATIVE CARE

Assess the client's respiratory status by auscultating the lungs and observing the breathing pattern. Assess circulation; note vital signs, skin color, and skin temperature. Observe the client's neurologic status by evaluating the level of alertness and orientation. Monitor the wound for amount and color of drainage. Monitor the intravenous lines for patency, correct fluid, and rate. Assess the drainage tube for amount, color, and consistency of drainage.

PAIN MANAGEMENT

Provide analgesics as needed. Reassure the woman that her pain will be controlled. Teach the woman how to communicate her pain intensity on a scale of 0 to 10, with 10 being the worst pain imaginable. Assess the client's pain level frequently and anticipate pain before assisting the woman to ambulate.

AFFECTED ARM CARE

Elevate the affected arm on a pillow to promote lymph drainage. Make sure that no treatments are performed on the affected arm, including laboratory draws, intravenous lines, blood pressures, and so on. Place a sign above the bed to warn others not to touch the affected arm.

WOUND CARE

Observe the wound often and empty drainage reservoirs as needed. Tell the client to report any evidence of infection early, such as fever, chills, or any area of redness or inflammation along the incision line. Also tell the client to report any increase in drainage, foul odor, or separation at the incision site.

MOBILITY CARE

Perform active range-of-motion and arm exercises as ordered. Encourage self-care activities for successful rehabilitation. Perform dressing and drainage care; explain the care during the procedure.

RESPIRATORY CARE

Assist with turning, coughing, and deep breathing every 2 hours. Explain that this helps to expand collapsed alveoli in the lungs, promotes faster clearance of inhalation agents from the body, and prevents postoperative pneumonia and atelectasis.

EMOTIONAL CARE AND REFERRALS

Encourage the client to participate in her care. Assess her coping strategies preoperatively. Explain possible body image concerns after discharge. Promote the ACS web sites, which provide the latest cancer therapy news. Encourage the client to attend local support groups for breast cancer survivors, such as *Reach to Recovery*.

EDUCATIONAL NEEDS

Provide follow-up information about adjunctive therapy. Explain that radiation therapy may start within weeks postoperatively. Discuss chemotherapy, its side effects and cycles, home care during treatment, and future monitoring strategies. Explain hormonal therapy, including antiestrogens or aromatase inhibitors. Teach progressive arm exercises to minimize lymphedema. Explain that ongoing surveillance is needed to detect recurrence of cancer or a new primary site and that the client will typically see the health care provider every 6 months.

***Nancy* underwent a mastectomy with radiation and chemotherapy. What follow-up care is needed? How can the nurse assist Nancy to cope with her uncertain future? What community resources might help her?**

Implementing Health Promotion and Disease Prevention Strategies

In the past, most women assumed that there was little they could do to reduce their risk of developing breast cancer, but since the 1970s significant advances have been made in the diagnosis and treatment of breast cancer. Mortality rates have decreased since 1990, particularly in women <50 years old. The declining

incidence of breast cancer and lower mortality rates have been attributed to early detection, improved treatment, and research (Sestak & Cuzick, 2015). However, research has found that the choices women make concerning breast cancer screening, diet, exercise, and other health practices have a profound impact on cancer risk. In the fight against cancer, nurses often assume a variety of roles, such as educator, counselor, advocate, and role model. Nurses can offer education about the following:

- Prevention
- Early detection
- Screening
- Dispelling myths and fears
- Self-examination techniques if needed
- Individual risk status and strategies for risk reduction

It is important to be knowledgeable about the most current evidence-based practices and cognizant of how the media presents this information. Offer prevention strategies within the context of a woman's life. Factors such as lifestyle choices, economic status, and multiple roles need to be taken into consideration when counseling women. Advocate for healthy lifestyles and making sound choices to prevent cancer. Nurses, like all health care providers, should offer guidance from a comprehensive perspective that acknowledges the unique needs of each individual. Nurses need to not only be proficient in the postoperative physical care of clients who undergo mastectomy but also demonstrate advanced skills related to the educational needs of clients and their families and to ensure care is delivered in a manner that is client-centered and individualized. Nurses require advanced skills to meet the social and psychological care needs of the woman and her family during this major life event (Fallowfield & Jenkins, 2015).

Breast cancer is a frightening experience for all women but is particularly burdensome on African American women, ranking second among the cause of cancer deaths in them. Although the incidence of breast cancer is highest in White women, African American women have a higher breast cancer mortality rate at every age and a lower survival rate than any other racial or ethnic group. Statistics indicate that the gap is widening (ACS, 2015e).

Like a black cloud hanging over their heads, with little regard for any victim, breast cancer stalks women everywhere they go. Many women are left with new health risks and lingering effects associated with treatment (e.g., limited mobility, memory problems, low social activity and support). Many have a close friend or relative who is battling the disease; many have watched their mothers and sisters die of this dreaded disease. Those with risk factors live with even greater anxiety and fear. No woman wants to hear those chilling words: "The biopsy is positive. You have breast cancer." Provide women with information about detection and risk factors, inform them about the new ACS screening guidelines, instruct them on BSE, and outline dietary changes that might reduce their risk of breast cancer.

Awareness is the first step toward a change in habits. Raising the level of awareness about breast cancer is of paramount importance, and nurses can play an important role in health promotion, disease prevention, and education.

Breast Cancer Screening

The three components of early detection are BSE, CBE, and mammography. The ACS (2015d) has issued breast cancer screening guidelines that, for the first time, offer specific guidance for the women and greater clarification of the role of breast examinations (Table 6.4). ACS screening guidelines are revised about every 5 years to include new scientific findings and developments.

Women are exposed to multiple sources of cancer prevention information, and much of it may not be sound. Discuss the benefits, risks, and potential limitations of BSE, CBE, and mammography with each woman and tailor the information to her specific risk factors (ACS, 2015b). Based on the new guidelines, make clinical judgments as to the appropriateness of recommending BSE, and reevaluate the need to teach the procedure to all women. The focus might instead be on encouraging regular mammograms (depending, of course, on the woman's individual risk factors).

Breast Self-Examination

BSE is a technique that enables a woman to detect any changes in her breasts. BSEs, once thought essential for early breast cancer detection, are now considered optional. Instead, breast awareness is stressed. Breast awareness refers to a woman being familiar with the normal consistency of both breasts and the underlying tissue. This emphasis is now on awareness of breast changes, not just discovery of cancer. Research has shown that BSE plays a small role in detecting breast cancer compared with self-awareness. However, doing BSE is one way for a woman to know how her breasts normally feel so that she can notice any changes that do occur (ACS, 2015d).

If appropriate, there are two steps to conducting a BSE: visual inspection and tactile palpation. The visual part should be done in three separate positions: with the arms up behind the head, with the arms down at the sides, and bending forward. Instruct the woman to look for:

- Changes in shape, size, contour, or symmetry
- Skin discoloration or dimpling, bumps/lumps
- Sores or scaly skin
- Discharge or puckering of the nipple

In the second part, the tactile examination, the health care provider feels the woman's breasts in one of three specific patterns: spiral, pie-shaped wedges, or a vertical strip (up and down). When using any of the three patterns, the woman should use a circular rubbing motion (in dime-sized circles) without lifting the fingers. The examiner checks not only the breasts but also between the breast and the axilla, the axilla itself, and the area above the breast up to the clavicle and across the shoulder. The pads of the three middle fingers on the right hand are used to assess the left breast; the pads of the three middle fingers on the left hand are used to assess the right breast. Instruct the woman to use three different degrees of pressure:

- Light (move the skin without moving the tissue underneath)
- Medium (midway into the tissue)
- Hard (down to the ribs)

Nutrition

Nutrition plays a critical role in health promotion and disease prevention. Cancer is considered to be a chronic disease that may be influenced at many stages by nutrition. These factors may affect prevention, progression, and treatment of the disease (Shrivastava, Shrivastava, & Ramasamy, 2015). Being overweight or obese is a risk factor for breast cancer in postmenopausal women. Excess body weight has been linked to an increased risk of postmenopausal breast cancer, and growing evidence also suggests that obesity is associated with poor prognosis in women diagnosed with early-stage breast cancer. Dozens of studies demonstrate that women who are overweight or obese at the time of breast cancer diagnosis are at increased risk of cancer recurrence and death compared with leaner women, and some evidence suggests that women who gain weight after breast cancer diagnosis may also be at increased risk of poor outcomes (Wright et al., 2015). *Healthy People 2020* identified being overweight or obese as one of the 10 leading health indicators and a major health concern (U.S. Department of Health and Human Services, 2010). Almost 65% of women over the age of 20 years are overweight; of these, 33.4% are obese (Carlson, 2015). A Mediterranean diet high in fruits, vegetables, and high-fiber carbohydrates and low in animal fats seems to offer protection against breast cancer as well as weight control. Women who followed these dietary guidelines decreased their risk of breast cancer. In addition, substantial evidence has shown that obesity, as measured by body mass index (BMI) is linked to breast cancer outcomes and greater mortality risks (Chan & Norat, 2015).

The Women's Health Initiative Dietary Modification Trial (Brasky et al., 2015) was designed to study a low-fat diet, a nutritional approach to prevention of chronic diseases. It found a marginally statistically significant reduction in breast cancer incidence among women in the low-fat dietary pattern group, and also disproved that "heart healthy eating" prevented future cardiac events in women.

The American Institute for Cancer Research, which conducts extensive research, made the following recommendations to reduce a woman's risk for developing breast cancer:

- Engaging in daily moderate exercise and weekly vigorous physical activity
- Consuming at least five servings of fruits and vegetables daily
- Not smoking or using any tobacco products
- Keeping a maximum BMI of 25 and limiting weight gain to no more than 11 lb since age 18
- Consuming seven or more daily portions of complex carbohydrates, such as whole grains and cereals
- Limiting intake of processed foods and refined sugar
- Limiting consumption of energy-dense foods and sugary drinks
- Avoiding use of dietary supplements which are unlikely to improve prognosis
- Restricting red meat intake to approximately 3 oz daily
- Limiting intake of fatty foods, particularly those of animal origin
- Restricting intake of salted foods and use of salt in cooking (Swisher et al., 2015).

The medical community is also starting to study the role of phytochemicals in health. The unique geographic variability of breast cancer around the world and the low rate of breast cancer in Asian countries compared with Western countries prompted this interest. This area of research appears hopeful for women seeking to

prevent breast cancer as well as those recovering from it. Although the mechanism is not clear, certain foods demonstrate anticancer properties and boost the immune system. Phytochemical-rich foods include:

- Green tea and herbal teas
- Garlic
- Whole grains and legumes
- Onions and leeks
- Soybeans and soy products
- Tomato products (cooked tomatoes)
- Fruits (citrus, apricots, pumpkin, berries)
- Green leafy vegetables (spinach, collards, romaine)
- Colorful vegetables (carrots, squash, tomatoes)
- Cruciferous vegetables (broccoli, cabbage, cauliflower)
- Flax seeds (Bahadoran, Karimi, & Abedini, 2015).

Adopt a holistic approach when addressing the nutritional needs of women with breast cancer. Incorporate nutritional assessment into the general overall assessment of all women. Culturally sensitive nutritional assessment tools need to be developed and used to enhance this process. Providing examples of appropriate foods associated with the woman's current dietary habits, relating current health status to nutritional intake, and placing proposed modifications within a realistic personal framework may increase a woman's willingness to incorporate needed changes in her nutritional behavior. Be able to interpret research results and stay up to date on nutritional influences so that you can transmit this key information to the public.

NURSING CARE PLAN 6.1

Overview of the Woman with Fibrocystic Breast Changes

Sheree Rollins is a 37-year-old woman who comes to the clinic for her routine checkup. During the examination, she says, "Sometimes my breasts feel so heavy and they ache a lot. I noticed a couple of lumpy areas in my breast last week just before I got my period. Is this normal? Now they feel like they're almost gone. Should I be worried?" Clinical breast examination reveals two small (pea-sized), mobile, slightly tender nodules in each breast bilaterally. No skin retraction noted. Previous mammogram revealed fibrocystic breast changes.

NURSING DIAGNOSIS: Pain related to changes in breast tissue

Outcome Identification and Evaluation

The client will demonstrate a decrease in breast pain as evidenced by a pain rating of 1 or 2 on a pain rating scale of 0 to 10 with statements made that her pain is lessened.

Interventions: *Relieving Pain*

- Ask client to rate her pain using a numeric pain rating scale to establish a baseline.
- Discuss with client any measures used to relieve pain to determine effectiveness of the measures.
- Encourage use of a supportive bra to aid in reducing discomfort.
- Instruct client in use of over-the-counter analgesics to promote pain relief.
- Advise the client to apply warm compresses or allow warm water from the shower to flow over her breasts to promote vasodilation and subsequent pain relief.

• Tell client to reduce her intake of salt to reduce risk of fluid retention and swelling leading to increased pain.

NURSING DIAGNOSIS: Deficient knowledge related to fibrocystic breast changes and appropriate care measures

Outcome Identification and Evaluation

The client will verbalize understanding of condition as evidenced by statements about the cause of breast changes and appropriate choices for lifestyle changes, and demonstration of self-care measures.

Interventions: ***Providing Client Education***

• Assess client's knowledge of fibrocystic breast changes to establish a baseline for teaching.
• Explain the role of monthly hormonal level changes and describe the signs and symptoms to promote understanding of this condition.
• Teach the client how to perform breast self-examination after her menstrual period to monitor for changes.
• Encourage client to report any changes promptly to ensure early detection of problems.
• Suggest client speak with her primary care provider about the use of oral contraceptives to help stabilize monthly hormonal levels.
• Review lifestyle choices, such as eating a low-fat diet rich in fruits, vegetables, and grains, and adhering to screening recommendations to promote health.
• Discuss measures for pain relief to minimize discomfort associated with breast changes.

KEY CONCEPTS

- Many women believe that all lumps are cancerous, but actually more than 80% of the lumps discovered are benign and need no treatment (Alexander et al., 2014).
- The most commonly encountered benign breast disorders in women include fibrocystic breasts, fibroadenomas, and mastitis (Bope & Kellerman, 2015).
- Current research suggests that women with fibrocystic breast disease or other benign breast conditions are more likely to develop breast cancer later only if a breast biopsy shows "atypia" or abnormal breast cells (ACS, 2015a).
- Fibroadenomas are common benign solid breast tumors that can be stimulated by external estrogen, progesterone, lactation, and pregnancy.
- Mastitis is an infection of the connective tissue in the breast that occurs primarily in lactating or engorged women; it is divided into lactational or nonlactational types.
- Management of both types of mastitis involves the use of oral antibiotics (usually a penicillinase-resistant penicillin or cephalosporin) and acetaminophen (Tylenol) for pain and fever (Miller & Kennedy, 2015).
- Breast cancer is the most common cancer in women and the second leading cause of cancer deaths (lung cancer is first) among American women (ACS,

2015a).

- Breast cancer metastasizes widely and to almost all organs of the body, but primarily to the bone, lungs, lymph nodes, liver, and brain.
- The etiology of breast cancer is unknown, but the disease is thought to develop in response to a number of related factors: aging, delayed childbearing or never bearing children, high breast density, family history of cancer, late menopause, obesity, and hormonal factors.
- Breast cancer treatments fall into two categories: local and systemic. Local treatments are surgery and radiation therapy. Effective systemic treatments include chemotherapy, hormonal therapy, and immunotherapy.
- Women commonly perceive their breasts as intrinsic to their femininity, self-esteem, and sexuality, and the risk of losing a breast can provoke extreme anxiety.
- Nurses can influence both physical and emotional recovery, which are both important aspects of care that help in improving the woman's quality of life and the ability to survive.
- Providing up-to-date information and emotional support are central roles of the nurse in caring for the woman with a diagnosis of breast cancer.

CHAPTER WORKSHEET

MULTIPLE-CHOICE QUESTIONS

1. Breast self-examinations involve both touching of breast tissue and:
   a. Palpation of cervical lymph nodes
   b. Firm squeezing of both breast nipples
   c. Visualizing both breasts for any change
   d. A mammogram to evaluate breast tissue

2. Which of the following is the strongest risk factor for breast cancer?
   a. Advancing age and being female
   b. High number of children
   c. Genetic mutations in BRCA1 and BRCA2 genes
   d. Family history of colon cancer

3. A biopsy procedure that traces radioisotopes and blue dye from the tumor site through the lymphatic system into the axillary nodes is:
   a. Stereotactic biopsy
   b. Sentinel node biopsy
   c. Axillary dissection biopsy
   d. Advanced breast biopsy

4. The most serious potential adverse reaction from chemotherapy is:
   a. Thrombocytopenia
   b. Deep vein thrombosis
   c. Alopecia
   d. Myelosuppression

5. What suggestion would be helpful for the client experiencing painful fibrocystic breast changes?
   a. Increase her caffeine intake.
   b. Take a mild analgesic when needed.
   c. Reduce her intake of leafy vegetables.
   d. Wear a bra bigger than she needs.

6. A postoperative mastectomy client should be referred to which of the following organizations for assistance upon discharge from the hospital?
   a. National Organization for Women (NOW)
   b. Food and Drug Administration (FDA)
   c. March of Dimes Foundation (MDF)
   d. Reach to Recovery (RTR)

7. Breast cancer that is localized is referred to as:
   a. Primary
   b. In situ

c. Metastasized
d. Localized

8. A 25-year-old woman presents with an asymptomatic breast mass. Which of the following is true concerning her diagnosis and treatment?
   a. All breast masses should be considered premalignant
   b. The breast mass should be surgically removed immediately
   c. Ultrasound is typically used to determine the diagnosis
   d. Since it is asymptomatic, just reassurance is needed now

CRITICAL THINKING EXERCISES

1. Mrs. Gordon, 48, presents to the women's community clinic where you work as a nurse. She is very upset and crying. She tells you that she found lumps in her breast: "I know that it's cancer and I will die." When you ask her about her problem, she says she does not check her breasts monthly and hasn't had a mammogram for years because "they're too expensive." She also describes the intermittent pain she experiences.
   a. What specific questions would you ask this client to get a clearer picture?
   b. What education is needed for this client regarding breast health?
   c. What community referrals are needed to meet this client's future needs?
2. Ruth Davis, 51, stops in at the urgent care facility with an anxious look on her face. She tells the nurse practitioner that she has green discharge coming from her right breast and discomfort intermittently. She can't understand how this would happen since she hasn't previously had any nipple discharge or pain.
   a. What benign breast condition might the nurse practitioner suspect based on her description?
   b. What specific information should the nurse practitioner give Mrs. Davis about duct ectasia?
   c. The typical treatment of this benign breast condition would include what?

STUDY ACTIVITIES

1. Discuss with a group of women what their breasts symbolize to them and to society. Do they symbolize something different to each one?
2. When a woman experiences a breast disorder, what feelings might she be experiencing and how can a nurse help her sort them out?
3. Interview a woman who has fibrocystic breast changes and find out how she manages this condition.
4. An infection of the breast connective tissue that frequently occurs in the lactating woman is _____.

BRINGING IT ALL TOGETHER: A CASE STUDY

A 67-year-old obese woman presented to her internist after a several year absence complaining of back pain that has persisted despite taking a nonsteroidal anti-inflammatory drug (NSAID) for several weeks. She also has recently noticed a 10-lb weight loss over the past 6 months and occasional right upper quadrant discomfort. She also states that she has been feeling tired over the last several months, but

rationalized it as “old age” catching up with her.

ASSESSMENT

She has a family history of breast and colon cancer in her immediate family and both of her parents died from these (mother from breast cancer and father from colon cancer). Her aunt also had breast cancer, but is in remission now after treatment. She can’t remember when the last time she had a pap smear or mammogram. She admits that she doesn’t keep up with her health checkups, since she babysits for her grandchildren and has difficulty scheduling them. She confesses that her diet hasn’t been what it should be, since her grandchildren prefer fast food and sodas for meals, rather than home-cooked ones. Thus, she gives into them and eats what they want.

1. Based on her chief complaint, what might be a reason for her current back pain?
2. What is concerning about her family health history that might have a bearing on her present symptoms?
3. How does her poor dietary intake and weight status impact her overall health status?

Breast cancer does metastasize to the bone and this could be the reason for her back pain that doesn’t response to anti-inflammatory medications. Since she has first-degree relatives that had cancer, she is at high risk for it herself. Research in nutrition and obesity and its link to cancer suggests that high consumption of processed foods (fast foods) and low consumption of fruits and vegetables in addition to being obese places people at risk for cancer.

PLAN

1. What diagnostic tests might be ordered to determine her diagnosis?
2. What treatment modalities are available to her if metastatic cancer is found?
3. What health promotion instructions are needed for this client?
4. How can the nurse provide an open forum for this woman to discuss her feelings?

An MRI and a bone scan might be ordered to identify any “hot spots” or cancerous lesions on her bones as well as her liver, which are common areas cancer might have spread to. Depending on the extent of the metastasis, chemotherapy and radiation might be treatment modalities. Nutrition counseling and lifestyle changes to lose weight to promote better health are both health promotion areas that need to be addressed with this client. A thorough explanation of the treatments, their side effects and prognosis need to also be discussed to make sure she understands. Fear and anxiety are common feelings felt by anyone with a cancer diagnosis, so the nurse needs to be open and supportive to her and allow time for her to express her fears.

7

Benign Disorders of the Female Reproductive Tract

WOW

Words of Wisdom

Women can influence their aging process by making wise lifestyle choices early on.

KEY TERMS

cystocele
enterocele
ovarian cyst
pelvic floor muscle exercises (Kegel exercises)
pelvic organ prolapse (POP)
pessary
polycystic ovary syndrome (PCOS)
polyps
rectocele
urinary incontinence (UI)
uterine fibroids

uterine prolapse

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Characterize the major pelvic relaxation disorders in terms of etiology, management, and nursing interventions.
2. Outline the nursing management needed for the most common benign reproductive disorders in women.
3. Evaluate urinary incontinence in terms of pathology, clinical manifestations, treatment options, and effect on quality of life.
4. Compare the various benign growths in terms of their symptoms and management.
5. Analyze the emotional impact of polycystic ovarian syndrome and the nurse's role as a counselor, educator, and advocate.

***Liz*, a 26-year-old, overweight woman, presented to the clinic with hirsutism and facial acne and told the nurse she was concerned about her irregular menstrual periods. She also said that recently the hair on top of her head seemed to be falling out. What diagnostic tests might the nurse anticipate with this client? How can the nurse prepare Liz for them?**

INTRODUCTION

The incidence of several benign pelvic disorders increases as women age. For instance, women may experience pelvic floor disorders related to pelvic relaxation or urinary incontinence (UI). These disorders generally develop after years of wear and tear on the muscles and tissues that support the pelvic floor—such as that which occurs with childbearing, chronic coughing, straining, surgery, or simply aging. In addition to pelvic floor disorders, woman may also experience various benign neoplasms of the reproductive tract, such as cervical polyps, uterine leiomyomas (fibroids), ovarian cysts, genital fistulas, and Bartholin cysts. This chapter provides an overview of various pelvic floor disorders and benign neoplasms, discussing the assessment, treatment, and prevention strategies for each. It also addresses female genital cutting in the context of it being a harmful practice that affects girls' and women's health.

PELVIC FLOOR DISORDERS

Pelvic floor disorders such as pelvic organ prolapse (POP) or genital prolapse and urinary and fecal incontinence are common in aging women. Researchers funded by the National Institutes of Health (NIH) (2015a) reported that more than one third of women in the United States have a pelvic floor disorder, and nearly one quarter of women in the United States have one or more pelvic floor disorders that cause symptoms. The study reported that the frequency of pelvic floor disorders increases with age, affecting more than 40% of women from 60 to 79 years of age, and about

50% of women 80 years and older. The NIH analysis is the first to document in a nationally representative sample the extent of pelvic floor disorders, a cluster of health problems that causes physical discomfort and limits activity.

Pelvic floor disorders cause significant physical and psychological morbidity and can diminish women's social interactions, emotional well-being, and overall quality of life. Because these disorders increase with age, the problem will grow worse as our population ages. The term "pelvic floor" refers to the group of muscles that form a sling or hammock across the pelvis. Together with their surrounding tissues, these muscles hold the pelvic organs (uterus, bladder, & bowel), in place so that they can function correctly. These disorders occur as a result of weakness of the connective tissue and muscular support of pelvic organs due to a number of factors: pregnancy, vaginal childbirth, obesity, lifting, chronic cough from smoking, straining at defecation secondary to constipation, radiation to the pelvis for cancer, and estrogen deficiency (American College of Obstetricians and Gynecologists [ACOG], 2015a). The female anatomy is susceptible to the development of pelvic floor disorders because of its vertical structures placement. The bony pelvis has an exaggerated lumbar spinal curve and downward tilt to it. The bladder rests on the symphysis and the posterior organs rest on the sacrum and coccyx. The pelvis holds the organs, but a woman's erect posture causes a funneling effect and constant downward pressure.

Pelvic Organ Prolapse

Pelvic organ prolapse (POP) (from the Latin *prolapsus,* "a slipping forth") refers to the abnormal descent or herniation of the pelvic organs from their original attachment sites or their normal position in the pelvis. POP occurs when structures of the pelvis shift and protrude into or outside of the vaginal canal. This disorder affects a woman's micturition, defecation, and sexual activity. The Egyptians were the first to describe prolapse of the genital organs. Hippocrates in 400 BC made reference to placing a pomegranate half into the vagina to treat organ prolapse. A disorder exclusive to women, POP rarely results in severe morbidity or mortality but can affect a woman's daily activities and quality of life (Brown, 2015). It is difficult to determine the incidence of POP, because the disorder is often asymptomatic and many women do not seek treatment. It has been estimated, however, that up to 75% of all women who have had a vaginal birth have POP (ACOG, 2015a). Each year, over 250,000 women undergo surgery to repair the prolapse at a cost of over $1 billion for hospitalization and physician or nurse practitioner fees alone (Maher & Haya, 2015). As the older adult population is expected to double in number by 2030, POP and its associated symptoms will become more prevalent (Mukwege, et al., 2015).

Obesity is associated with a high prevalence of pelvic floor disorders. Obesity can also aggravate symptoms of POP, fecal incontinence, sexual dysfunction, stress UI and increase the risk of endometrial polyps and symptomatic fibroids. Weight reduction enhances reproductive outcomes, diminishes symptoms of UI, improves sexual dysfunction, and reduces morbidity following gynecologic surgery. Sustained and substantial weight loss, however, is difficult to achieve for many women with their current lifestyle and dietary choices (Ramalingam & Monga, 2015).

The treatment and diagnosis of POP is challenging and problematic.

Types of Pelvic Organ Prolapse

The four most common types of pelvic or genital prolapse are cystocele, rectocele, enterocele, and uterine prolapse (Fig. 7.1):

- **Cystocele** occurs when the posterior bladder wall protrudes downward through the anterior vaginal wall.
- **Rectocele** occurs when the rectum sags and pushes against or into the posterior vaginal wall.
- **Enterocele** occurs when the small intestine bulges through the posterior vaginal wall (especially common when straining).
- **Uterine prolapse** occurs when the uterus descends through the pelvic floor and into the vaginal canal. Multiparous women are at particular risk for uterine prolapse. The extent of uterine prolapse is classified in terms of stages:
  - *Stage 0:* No descent of pelvic structure during straining.
  - *Stage I:* The prolapsed descending organ is >1 cm above the hymenal ring.
  - *Stage II:* The prolapsed organ extends ~1 cm below the hymenal ring.
  - *Stage III:* The prolapsed organ extends 2 to 3 cm below the hymenal ring.
  - *Stage IV:* The vagina is completely everted or the prolapsed organ is >3 cm below the hymenal ring (Riss & Koch, 2015).

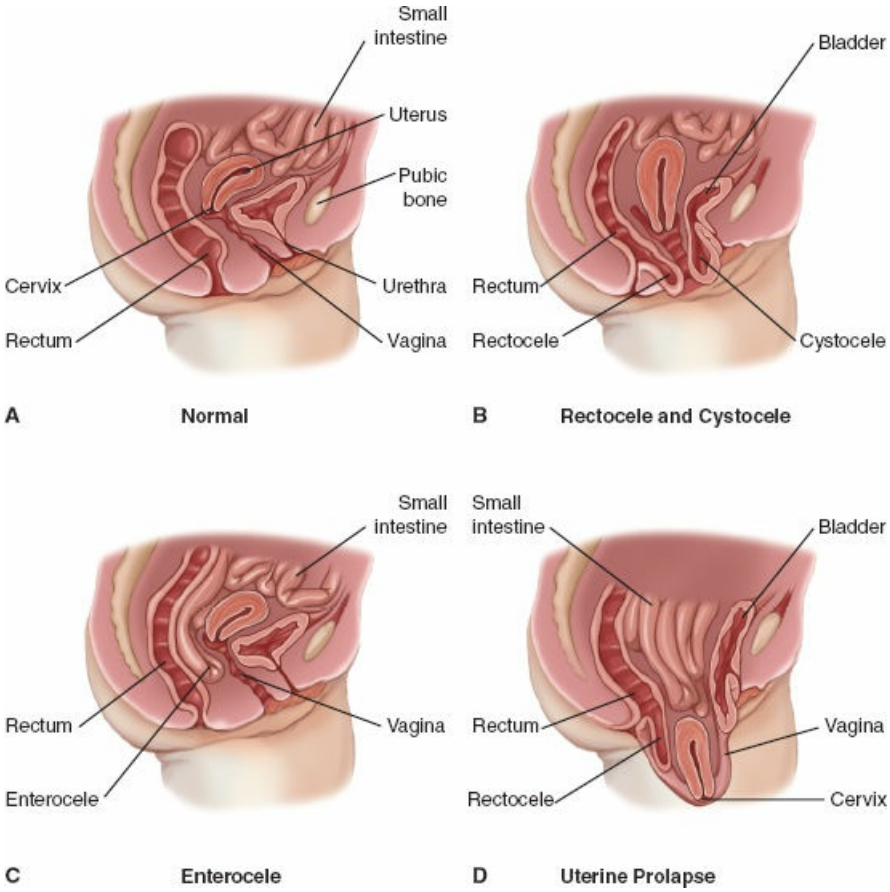

FIGURE 7.1 Types of pelvic prolapses. A. Normal. B. Rectocele and cystocele. C. Enterocele. D. Uterine prolapse.

Etiology

Anatomic support of the pelvic organs is mainly provided by the levator ani muscle complex and the connective tissue attachments of the pelvic organ fascia.

Dysfunction of one or both of these components can lead to loss of support and eventually POP. Weakened pelvic floor muscles also prevent complete closure of the urethra, resulting in urine leakage during physical stress. This problem is not limited to older women: UI has been documented in women of varying ages, including young (<25 years old) women (Walters, 2015).

Many risk factors for POP have been suggested, but the true cause is likely to be multifactorial. Causes might include:

- Constant downward gravity because of erect human posture
- Atrophy of supporting tissues with aging and decline of estrogen levels
- Weakening of pelvic support related to childbirth trauma
- Reproductive surgery, including hysterectomy
- Instrumental childbirth
- Multiparity
- Uncontrolled rapid birth
- Family history of POP
- Young age at first birth
- Connective tissue disorders
- Infant birth weight of more than 4,500 g
- Pelvic radiation
- Increased abdominal pressure secondary to:
  - Lifting of children or heavy objects
  - Straining due to chronic constipation
  - Respiratory problems or chronic coughing
- Obesity (Rodriguez-Mias et al., 2015)

Therapeutic Management

Treatment options for POP depend on the symptoms and their effect on the woman's quality of life. Important considerations when deciding on nonsurgical or surgical options include the severity of symptoms, the woman's preferences, the woman's health status, age, and suitability for surgery, and the presence of other pelvic conditions (urinary or fecal incontinence).

Conservative measures such as pelvic floor muscle exercises (PFMEs) or Kegel exercises supplemented by lifestyle interventions such as weight loss, avoidance of straining (reducing lifting heavy weights, treatment of chronic cough and constipation) are recommended as first-line management. PFME is aimed to increase the strength and endurance of the pelvic floor supports, prevent or delay worsening of prolapse and improve prolapse symptoms. PFME can help women delay or avert the need for surgery and pre- and postoperatively have been found to improve outcomes after surgery.

When surgery is being considered, the nature of the procedure and the likely outcome must be fully explained and discussed with the woman and her partner. Treatment options for POP include PFMEs, estrogen replacement therapy, dietary and lifestyle modifications, use of a pessary (a removable device placed into the vagina to support pelvic organs), and surgery (Evidence-Based Practice 7.1).

PELVIC FLOOR MUSCLE EXERCISES OR KEGEL EXERCISES

Pelvic floor muscle exercises strengthen the pelvic floor muscles to support the inner organs and prevent further prolapse. PFMEs are generally accepted as first-line

treatment for stress and urge UI and they are also widely used for anal incontinence. Over the past 30 years a wealth of research has proven the benefits of PFMEs in treating both UI and POP (McClurg, Gerrard, & Hove, 2015). The purpose of pelvic floor exercises is to increase the muscle volume, which will result in a stronger muscular contraction. PFMEs might limit the progression of mild prolapse and alleviate mild prolapse symptoms, including low back pain and pelvic pressure. They will not, however, help severe uterine prolapse.

EVIDENCE-BASED PRACTICE 7.1

PELVIC FLOOR MUSCLE TRAINING VERSES NO TREATMENT, OR INACTIVE CONTROL TREATMENTS, FOR URINARY INCONTINENCE IN WOMEN

STUDY

Involuntary leakage of urine (urinary incontinence) affects women of all ages, particularly older women who live in residential care such as nursing homes. Some women leak urine during exercise or when they cough or sneeze (stress urinary incontinence) and this may occur as a result of weakness of the pelvic floor muscles such as damage during childbirth. Other women leak urine before going to the toilet when there is a sudden and compelling need to pass urine (urgency urinary incontinence). This may be caused by involuntary contraction of the bladder muscle. Mixed urinary incontinence is the combination of both stress and urgency urinary incontinence. Pelvic floor muscle training is a supervised physical therapy treatment and it involves muscle-clenching exercises to strengthen the pelvic floor muscles. It is a common treatment used by women to stop urine leakage. Other treatments are also available which can either be used alone or in combination with pelvic floor muscle training (PFMT).

PFMT is a conservative treatment for urinary incontinence in women. This systematic review evaluated the effects of PFMT when compared to no treatment, placebo, or other inactive control treatments for urinary incontinence in women.

This study was done to compare the effects of PFMT to no treatment, placebo, or other inactive control treatments in the management of women with urinary incontinence.

Findings

Randomized or quasi-randomized trials were used. Twenty-one trials (1,281 women) met the eligibility criteria for inclusion, comprising women with stress urinary incontinence (SUI), urgency urinary incontinence (UUI), or mixed urinary incontinence (MUI), and they compared PFMT added to no treatment, placebo, or other inactive control treatments.

This systematic review found support for the widespread recommendation that PFMT be included in first-line conservative management programs for women with stress and any type of urinary incontinence. In women with stress incontinence, there was high-quality evidence that PFMT is associated with improvement or cure.

Nursing Implications

Overall, according to this study, there is sufficient evidence to support the widespread recommendation that PFMT should be included in a first-line conservative management program for women with stress, urge, or mixed urinary incontinence.

Previous studies have validated that pelvic floor exercises do help in bringing tone to the muscles that control micturition. Nurses can continue to instruct women with urinary incontinence to perform PFMT daily to improve their urinary control and their quality of life.

Adapted from Dumoulin, C., Hay-Smith, E. J., Mac Habee-Sequin, G. M., & Mercier, J. (2015). Pelvic floor muscle training verses no treatment, or inactive control treatments, for urinary incontinence in women. *Neurourology & Urodynamics, 34*(4), 300–308.

HORMONE REPLACEMENT THERAPY

Hormone replacement therapy, or HRT (orally, transdermally, low-dose vaginal ring or vaginal cream) may improve the tone, natural thickness, and vascularity of the supporting tissue in perimenopausal and menopausal women by increasing blood perfusion and the elasticity of the vaginal wall. HRT has many benefits, as well as risks. It is essential that the benefits are weighed out against the risks before this therapy is initiated.

Take Note!

Before hormone therapy is considered, a thorough medical history must be taken to assess a woman's risk for complications (e.g., endometrial cancer, myocardial infarction, stroke, breast cancer, pulmonary emboli, and deep vein thrombosis). Because of these risks, estrogens, with or without progestins, should be given at the lowest effective dose and for the shortest duration consistent with the treatment goals and risks for the individual woman (ACOG, 2015a).

DIETARY AND LIFESTYLE MODIFICATIONS

Dietary and lifestyle modifications may help prevent pelvic relaxation and chronic problems later in life. Specific lifestyle changes would include avoiding constipation, bladder irritants, heavy lifting, high impact exercise, weight loss, and smoking cessation. Dietary habits can exacerbate the prolapse by causing constipation and consequently chronic straining. The stools of a constipated woman are hard and dry, and typically she must strain while bearing down to defecate. This straining to pass a hard stool increases intra-abdominal pressure, which over time causes the pelvic organs to prolapse. Dietary modifications can help to establish regular bowel movements without discomfort and eliminate flatus and bloating. A weight loss regimen might also need to be instituted if the woman is overweight.

PESSARIES

Vaginal **pessaries** are synthetic devices inserted in the vagina to provide support to the bladder and other pelvic organs as a corrective measure for UI and/or POP (Fig. 7.2). Today almost all pessaries are made of medical-grade silicone, which provides many advantages. Silicone pessaries are pliable and have a long shelf life; lack odor and secretion absorption; are biologically inert, nonallergenic, and noncarcinogenic; and they can be boiled or autoclaved for sterilization. Because most pessaries are made of silicone, pessary style and size are the main considerations when selecting a pessary (Colyar, 2015). Although many types and shapes are available, the most commonly used pessary is a firm ring that presses against the wall of the vagina and urethra to help decrease leakage and support a prolapsed vagina or uterus. Pessaries are a low-risk treatment option with the advantage of being cost effective and minimally invasive, and provide immediate relief of symptoms.

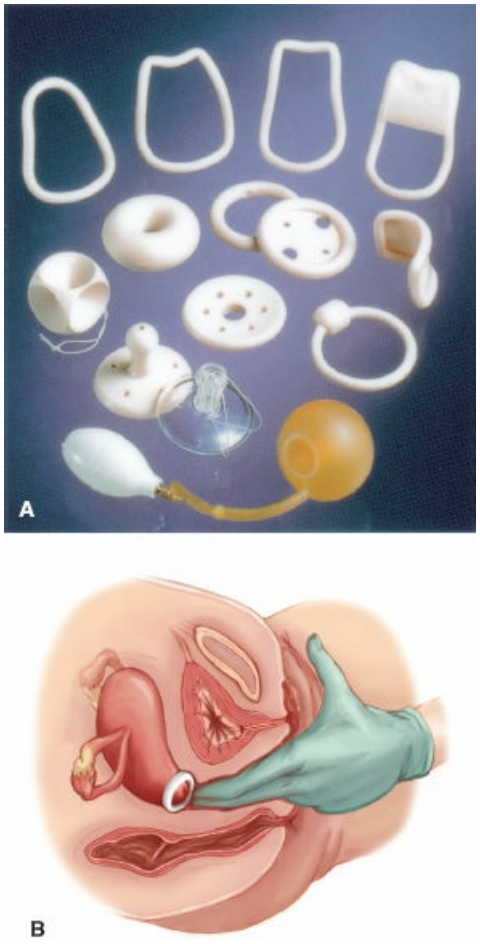

FIGURE 7.2 Examples of pessaries. A. Various shapes and sizes of pessaries available. B. Insertion of one type of pessary. A link to a web site for a picture of Colpexin Sphere is located on.

Indications for pessary use include uterine prolapse or cystocele, especially among elderly clients for whom surgery is contraindicated; younger women with prolapse who plan to have additional children; and women with marked prolapse who prefer to use a pessary rather than undergo surgery (Ralph & Tamussino, 2015). Many women use pessaries for only a short period of time and become free of symptoms. Long-term use can lead to pressure necrosis and the development of fistulas in some women; in this situation other methods of support should be explored. Pessaries are fitted by trial and error; the woman often needs to try several sizes or styles. The largest pessary that the woman can wear comfortably is generally the most effective. The woman should be instructed to report any discomfort or difficulty with urination or defecation while wearing the pessary and also to attend follow-up care appointments to check positioning.

Nurses need to be aware of the personal isolation and embarrassment and social and cultural implications that UI may cause as well as the subjective experiences of using a pessary. With appropriate support, vaginal pessaries can provide women with the freedom to lead active, engaged social lives.

SURGICAL INTERVENTIONS

Surgical interventions for pelvic or genital organ prolapse are designed to correct specific defects, with the goals being to restore normal anatomy and to preserve

function. Approximately 260,000 stress incontinence surgical procedures are performed annually in the United States (Kirby, Tan-Kim, & Nager, 2015). Surgery is not an option for all women. Women who are at high risk of suffering recurrent prolapse after a surgical repair or who have morbid obesity, chronic obstructive pulmonary disease, or medical conditions in which general anesthesia would be risky are not good candidates for surgical repair (Alexander et al., 2015), and noninvasive treatment strategies should be discussed with them.

Surgical interventions might include anterior or posterior colporrhaphy (to repair a cystocele or rectocele) and vaginal hysterectomy (for uterine prolapse). This can be done laparoscopically whereby the uterus is removed through the vagina. An anterior and posterior colporrhaphy may be effective for a first-degree prolapse. This surgical procedure tightens the anterior and posterior vaginal wall, thus repairing a cystocele or rectocele. The pubocervical fascia (supportive tissue between the vagina and bladder) is folded and sutured to bring the bladder and urethra in proper position (Nilsson, 2015).

A vaginal hysterectomy is the treatment of choice for uterine prolapse because it removes the prolapsed organ that is bringing down the bladder and rectum with it. It can be combined with an anterior and posterior repair if a cystocele or rectocele is present.

Nursing Assessment

Nursing assessment for women with POP includes a thorough health history, a physical examination, and several laboratory and diagnostic tests.

HEALTH HISTORY AND CLINICAL MANIFESTATIONS

A history and general assessment of the client is important to exclude pathology and evaluate various factors that may influence choice and success of management. Evaluation of systems such as bowel, urinary and sexual function, coexistent morbidities, medical and surgical history, any physical or mental impairment, and lifestyle are noticeably very important, particularly in older women. The client's social circumstances and support systems, desire for treatment, and expectations will have implications on the management options.

The cause of prolapse is multifactorial, with vaginal childbirth, advancing age, heavy work, poor nutrition, vaginal surgery, and increasing body mass index being the most consistent risk factors (Rodriguez-Mias et al., 2015). Assessment of risk factors (chronic straining, hysterectomy, normal aging, and abnormalities of connective tissue) in the woman's history will assist the health care provider in the diagnosis and treatment of POP. The history should include questions about:

- The woman's obstetrical history (number of pregnancies, weight of newborns, pregnancy spacing)
- Chronic respiratory condition (chronic coughing)
- Menopausal status
- Weight history (loss or gain)
- Constipation (frequency and chronicity)
- Age
- Work history (e.g., physical labor or light office work)
- Nutritional assessment
- Family history (family member with POP)

• UI
• Previous pelvic surgeries

Assess for clinical manifestations of POP. POP is often asymptomatic, but when symptoms do occur, they are often related to the site and type of prolapse. Symptoms common to all types of prolapses are a feeling of dragging, a lump in the vagina, or something "coming down." Women with POP can present either with one symptom, such as vaginal bulging or pelvic pressure, or with several complaints, including many bladder, bowel, and pelvic symptoms. Symptoms associated with POP are summarized in Box 7.1.

Women present with varying degrees of uterine descent. Uterine prolapse is the most troubling type of pelvic relaxation because it is often associated with concomitant defects of the vagina in the anterior, posterior, and lateral compartments (Lazarou & Grigorescu, 2015).

PHYSICAL EXAMINATION

The pelvic examination performed by the health care provider includes an external genital inspection to visualize any obvious protrusion of the uterus, bladder, urethra, or vaginal wall occurring at the vaginal opening. Usually the woman is asked to perform the Valsalva maneuver (bearing down) while the examiner notes which organ prolapses first and the degree to which it occurs. Any urine leakage during the examination is important to note. The woman is asked to contract the pubococcygeal muscles (PFME); the health care provider inserts two fingers into the vagina to assess the strength and symmetry of the contraction. Because pelvic or genital organ prolapse can cause urinary symptoms such as incontinence, bladder function should be assessed by determining postvoid residual with a catheter. If the woman has more than 100 mL of retained urine, she should be referred for further urodynamic evaluation and testing.

BOX 7.1

SYMPTOMS ASSOCIATED WITH PELVIC ORGAN PROLAPSE

- Urinary symptoms
  - Stress incontinence
  - Frequency (diurnal and nocturnal)
  - Urgency and urge incontinence
  - Hesitancy
  - Poor or prolonged stream
  - Feeling of incomplete emptying
- Bowel symptoms
  - Difficulty with defecation
  - Incontinence of flatus or liquid or solid stool
  - Urgency of defecation
  - Feeling of incomplete evacuation
  - Rectal protrusion or prolapse after defecation
- Sexual symptoms
  - Inability to have frequent intercourse

- Dyspareunia
  - Lack of satisfaction or orgasm
  - Incontinence during sexual activity
- Other local symptoms
  - Pressure or heaviness in the vagina
  - Pain in the vagina or perineum
  - Low back pain after long periods of standing
  - Palpable bulge in the vaginal vault
  - Difficulty walking due to a protrusion from the vagina
  - Difficulty inserting or keeping a tampon in place
  - Vaginal-cervical mucosa hypertrophy, excoriation, ulceration, and bleeding
  - Abdominal pressure or pain

Pelvic organ prolapse. *eMedicine.* Retrieved from http://emedicine.medscape.com/article/276259-overview

LABORATORY AND DIAGNOSTIC TESTS

Common laboratory tests that may be ordered to determine the cause of POP include a urinalysis to rule out a bacterial infection, urine culture to identify the specific organism if present, visualization of urine loss during the pelvic examination, and measurement of postvoid urine volume.

Nursing Management

Help the woman understand the nature of the condition, the treatment options, and the likely outcomes. Nursing considerations might include the following:

- Describe normal anatomy and causes of pelvic prolapse.
- Assess how this condition has affected the woman's life.
- Outline the options, with the advantages and disadvantages of each.
- Allow the client to make the decision that is right for her.
- Provide education.
- Schedule preoperative activities needed for surgery.
- Reassure the client that there is a solution for her symptoms.
- Provide community education about genital prolapse.

Nursing Care Plan 7.1 (at the end of the chapter)provides an overview of care for a woman with POP.

PROMOTE PREVENTION STRATEGIES

Limited data are available on ways to prevent POP, but a nurse needs first to understand its incidence, risk factors, prevalence, clinical implications, and treatment options to be an effective caretaker of the woman. The nurse's understanding will not only improve his or her ability to treat this growing client population, but will also help in developing preventive strategies to address a woman's suffering from this condition.

Approaches include lifestyle changes that reduce modifiable risk factors, such as losing weight, avoiding heavy lifting, and relieving constipation. Explore with the

woman what factors in her lifestyle might be modified to reduce her risk of developing POP (primary prevention) or to improve her quality of life after receiving treatment (secondary prevention).

ENCOURAGE PELVIC FLOOR MUSCLE TRAINING

Encourage the woman to perform PFMEs daily (Teaching Guidelines 7.1). Discuss current research findings and educate the woman about estrogen therapy, allowing the woman to make her own decision on whether to use hormones. Controversy still exists regarding the benefits versus the risks of taking hormones, so the woman must weigh this option carefully (ACOG, 2015a).

Teaching Guidelines 7.1
PERFORMING PELVIC FLOOR EXERCISES

- Squeeze the muscles in your rectum as if you are trying to prevent passing flatus.
- Stop and start urinary flow to help identify the pubococcygeus muscle.
- Tighten the pubococcygeus muscle for a count of three, and then relax it.
- Contract and relax the pubococcygeus muscle rapidly 10 times.
- Try to bring up the entire pelvic floor and bear down 10 times.
- Repeat pelvic floor muscle exercises at least five times daily.

ENCOURAGE DIETARY AND LIFESTYLE MODIFICATIONS

Instruct clients to increase dietary fiber and fluids to prevent constipation. A high-fiber diet with an increase in fluid intake alleviates constipation by increasing stool bulk and stimulating peristalsis. It is accomplished by replacing refined, low-fiber foods with high-fiber foods. The recommended daily intake of fiber for women is 25 g (Meyer, 2015). In addition to increasing the amount of fiber in her diet, also encourage the woman to drink eight 8-oz glasses of fluid daily and to engage in regular low-impact aerobic exercise, which promotes muscle tone and stimulates peristalsis.

Educate the client about other lifestyle changes that will assist with prolapse, such as:

- Achieve ideal weight to reduce intra-abdominal pressure and strain on pelvic organs, including pressure on the bladder.
- Wear a girdle or abdominal support to support the muscles surrounding the pelvic organs.
- Avoid lifting heavy objects to reduce the risk of increasing intra-abdominal pressure, which can push the pelvic organs downward.
- Avoid high-impact aerobics, jogging, or jumping repeatedly to minimize the risk of increasing intra-abdominal pressure, which places downward pressure on the organs.
- Give up smoking to minimize the risk for a chronic “smoker’s cough,” which increases intra-abdominal pressure and forces the pelvic organs downward.

PROVIDE TEACHING FOR PESSARY USE

Educate the woman about pessary use. Discuss complications as part of the

instruction. Although the pessary is a safe device, it is still a foreign body in the vagina. Because of this, the most common side effects of the pessary are increased vaginal discharge, urinary tract infections, vaginitis, and odor. Odors can be reduced by douching with dilute vinegar or hydrogen peroxide. Postmenopausal women with thin vaginal mucosa are susceptible to vaginal ulceration with the use of a pessary. Advise the woman to use estrogen cream to make the vaginal mucosa more resistant to erosion and to strengthen the vaginal walls.

The woman must be capable of managing use of the pessary, either alone or with the help of a caretaker. The most common recommendations for pessary care include removing the pessary twice weekly and cleaning it with soap and water; using a lubricant for insertion; and having regular follow-up examinations every 6 to 12 months after an initial period of adjustment.

Besides cleaning, clients must properly reinsert the device into their vaginal cavity, and the woman must also be willing to participate in all aspects of care of the pessary for this treatment option to be successful. All women choosing this option must be instructed in the care of her pessary so she feels comfortable with all aspects of it before leaving the health care facility. Health care visits should allow adequate time for women to share their concerns, anxieties, and fears surrounding the transition to life with a pessary.

PROVIDE PERIOPERATIVE CARE

Prepare the woman for surgery by reinforcing the risks and benefits of surgery and describing the postoperative course. Explain that a Foley catheter will be in place for up to 1 week, and that she might not be able to urinate due to the swelling after the catheter has been removed. Provide home care instructions for the Foley catheter. She should cleanse the perineal area daily with mild soap and water, especially around where the catheter enters the urinary meatus. If the woman is provided with a leg bag to be worn during waking hours, instruct her to empty it frequently and keep it below the level of the bladder to prevent backflow. The same principles are applied to the primary Foley bag when emptying it.

During the recovery period, instruct the client to avoid for several weeks activities that cause an increase in abdominal pressure, such as straining, sneezing, and coughing. In addition, advise her to avoid lifting anything heavy or straining to push anything. Explain to the woman that stool softeners and gentle laxatives might be prescribed to prevent constipation and straining with bowel movements. Avoiding vaginal intercourse will be recommended until the operative area is healed in 6 weeks.

Urinary Incontinence

Urinary incontinence (UI) is defined by the International Continence Society (2015) as the involuntary loss of urine that represents a hygienic or social problem to the individual. This disorder affects over 15 million women in the United States (Walters, 2015), but is underreported. It has been estimated that 50% of all women experience UT at some time in their life, varying in severity from mild to severe (Files, Mayer, & Chutka, 2015). The psychosocial costs and morbidities are even more difficult to quantify. Embarrassment and depression are common. The affected individual may experience a decrease in social interactions, excursions out of the

home, and sexual activity (Su, Sun, & Jiann, 2015). It is more common than diabetes and Alzheimer disease, both of which receive a great deal of press attention. Despite the considerable impact of incontinence on quality of life, many women are unlikely to bring up the subject of their lack of bladder control and very few women seek help or treatment for incontinence concerns. The following are several possible explanations for why clients do not talk about their bladder control issues. The client may:

- Feel that UI is inevitable and not amenable to treatment.
- Feel that UI is a "normal" part of aging.
- Believe that UI is part of being "female." Women tend to accept urinary symptoms such as UI more so than men.
- Feel embarrassment and try to deny that it is a real problem.
- Think that the only treatment option is surgical.
- The client may consider a UI a hygiene problem and not a medical condition.

Take Note!

Incontinence is preventable, treatable, and often curable. However, many women believe that loss of bladder function is a normal and expected part of aging.

Incontinence can have far-reaching effects. Some women experience anxiety, depression, social isolation, embarrassment, insomnia, fear, feelings of uncleanliness, worry, vulnerability, shame, limit her ability to travel far from home or have social engagements, and disruptions in their self-esteem and dignity. UI can cause the woman to stop working, traveling, socializing, and enjoying sexual relationships. In addition, incontinence can create a tremendous burden for caretakers and is a common reason for admission to a long-term care facility. Depression and high levels of stress are typical in these women (Kwak, Kwon, & Kim, 2015).

Women often try to cope with UI through lifestyle modifications such as wearing protective pads, avoiding certain activities, emptying the bladder frequently, and modifying diet/fluid intake. Women who experience UI are generally most distressed by the social implications and many go to great efforts to hide their symptoms. In some cultures, UI is abhorred to the point where women are shunned by their communities. A sense of control, normality, and self-esteem are central issues in living with UI. Generally with time and worsening of symptoms, women pursue medical evaluation and treatment (Waetjen et al., 2015).

The types of UI are defined based on their presenting symptoms and signs. The three most common types of incontinence are urgency UI (overactive bladder caused by detrusor muscle contractions), stress incontinence (inadequate urinary sphincter function), and mixed incontinence (involves both stress and urge incontinence) (King et al., 2015). Comparison Chart 7.1 details these types of UI.

Pathophysiology and Etiology

Urinary continence requires several factors, including effective functioning of the bladder, adequate pelvic floor muscles, neural control from the brain, and integrity of the neural connections that facilitate voluntary control. The bladder neck and proximal urethra function as a sphincter. During urination the sphincter relaxes and the bladder empties. The ability to control urination requires the integrated function

of numerous components of the lower urinary tract, which must be structurally sound and functioning normally.

Incontinence can develop if the bladder muscles become overactive due to weakened sphincter muscles, if the bladder muscles become too weak to contract properly, or if signals from the nervous system to the urinary structures are interrupted. A major factor in women that contributes to urinary continence is the estrogen level, because this hormone helps maintain bladder sphincter tone. In perimenopausal or menopausal women, incontinence can be a problem as estrogen levels begin to decline and genitourinary changes occur. In simple terms, the bladder is the reservoir, the urethra is the seal, and the levator ani muscle is the gate that holds pressure against the outflow of urine by supporting the urethra and bladder from below. When any of these three structures is not functioning normally, incontinence occurs.

Contributing factors in UI include:

- Fluid intake, especially alcohol, carbonated drinks, and caffeinated beverages
- Constipation: alters the position of the pelvic organs and puts pressure on the bladder
- Habitual "preventive" emptying: may result in training the bladder to hold only small amounts of urine
- Menopause and depletion of estrogen
- Chronic disease such as stroke, multiple sclerosis, or diabetes
- Smoking: nicotine increases detrusor muscle contractions
- Advancing age: age-related anatomic changes provide less pelvic support
- Pregnancy and childbirth: damage to pelvic structures during childbirth
- Obesity: increases abdominal pressure (Schuiling & Likis, 2016).

COMPARISON CHART 7.1

URGE INCONTINENCE VERSUS STRESS INCONTINENCE

	Urge Incontinence	Stress Incontinence
Description	Precipitous loss of urine, preceded by a strong urge to void, with increased bladder pressure and detrusor contraction	Accidental leakage of urine that occurs with increased pressure on the bladder from coughing, sneezing, laughing, or physical exertion
Etiology	Causes might be neurologic, idiopathic, or infectious	Develops commonly in women in their 40s and 50s, usually as the result of weakened muscles and ligaments in the pelvis following childbirth
Signs and Symptoms	Urgency, frequency, nocturia, and a large amount of urine loss	Involuntary loss of a small amount of urine in response to physical activity that raises intra-abdominal pressure

Therapeutic Management

Treatment options depend on the type of UI. In general, the least invasive procedure with the fewest risks is the first choice for treatment. Surgery is used only if other methods have failed. There is a widespread belief that UI is an inevitable problem of getting older and that little or nothing can be done to relieve symptoms or reverse it. Nothing is further from the truth, and attitudes must change so that women will

feel comfortable seeking help for this embarrassing condition.

For many women with urge incontinence, simple reassurance and lifestyle interventions might help. The promotion of a healthy weight can help to reduce incontinence related to obesity. However, if more than simple lifestyle measures are needed, effective treatments might include:

- Bladder training to establish normal voiding intervals (every 3 to 5 hours)
- Pelvic floor muscle exercises to strengthen the pelvic floor musculature
- Pessary ring to support pelvic structures that have weakened
- Pharmacotherapy to reduce the urge to void. Anticholinergic agents such as oxybutynin (Ditropan) or tolterodine (Detrol) or oxybutynin (Oxytrol) might be prescribed. The most common side effects of anticholinergic agents are dry mouth, blurred vision, constipation, nausea, dizziness, and headaches (King et al., 2015).

For women with stress incontinence, treatment is not always a cure, but it can minimize the impact of this condition on the woman's quality of life. Some treatment options for stress incontinence might include:

- Weight loss if needed
- Avoidance of constipation
- Smoking cessation
- PFMEs to strengthen the pelvic floor
- Pessaries
- Weighted vaginal cones to improve the tone of pelvic floor muscles
- Periurethral injection (injecting a bulking agent [collagen] to form a bulge that brings the urethral walls closer together to achieve a better closure)
- Medications such as duloxetine (Cymbalta, Yentreve) to increase urethral sphincter contractions during the storage phase of the urination cycle
- Estrogen replacement therapy to improve bladder sphincter tone
- Surgery to correct genital prolapse and improve urethral and bladder tone

Nursing Assessment

The assessment of the woman experiencing UI includes a history, physical examination, laboratory tests, and possibly urodynamic testing. The onset, frequency, severity, and pattern of incontinence should be determined, as well as any associated symptoms such as frequency, dysuria, urgency, and nocturia. Incontinence may be quantified by asking the woman if she wears a pad and how often the pad is changed. A review of the woman's current medications, including over-the-counter medications, should be included in the history.

A complete physical examination should be carried out by the health care provider; it should include a neurologic assessment and pelvic and rectal examinations. The presence of associated POP should be noted because it can contribute to the woman's voiding problems and may have an impact on diagnosis and treatment. A rectal examination is done to evaluate sphincter tone and perineal sensation. A "cough stress test" can be performed by asking the woman to cough with a full bladder and subsequently observing for leakage of urine from the urethra can also help in assessing the client's ability to control voiding.

Consider This

Life can be complicated and embarrassing at times when we least expect it. I met a man in church who seemed interested in me, and he asked me out for coffee after Sunday services. I have been alone for 10 years and this prospect seemed exciting to me. We talked for hours over coffee and seemed to have a great deal in common, especially since both of us had lost our spouses to cancer. He asked me to go square dancing with him, since that was an activity we both had enjoyed in the past with our spouses. I hadn't been out or physically active for ages and didn't realize how my body had changed with age.

It was during the first dance that I noticed a wet sensation between my legs, which I was unable to control. I managed to continue on and pretend that all was fine, but then realized what many of my friends were talking about —stress incontinence. Not being able to control one's urine is very embarrassing and it complicates your life, but I made up my mind that it wasn't going to control me!

Thoughts: Gravity and childbirth take a toll on women's reproductive organs by pushing them downward. This woman is not going to let stress incontinence curtail her outside activity, which demonstrates a good attitude. What can be done about her embarrassing accidents? Were there any preventive strategies she could have used at an earlier age?

A urinalysis is performed to look for hematuria, pyuria, glucosuria, or proteinuria. A urine culture is done if there is pyuria or bacteriuria. Postvoid residual should be measured either with pelvic ultrasound or directly with a catheter. If the residual exceeds the limit set, urodynamic testing is then used to diagnose the incontinence.

Nursing Management

Incontinence can be devastating and can cause psychosocial concerns and isolation. Nurses can encourage women with troublesome symptoms to seek help. Discuss the treatment options with the client, including benefits and potential outcomes, and encourage her to select the continence treatment best for her lifestyle. Provide education about good bladder habits and strategies to reduce the incidence or severity of incontinence (Teaching Guidelines 7.2). Provide support and encouragement to ensure adherence to the guidelines. Remember that aging can increase the risk of incontinence, but incontinence is not an inevitable part of aging. Review the anatomy and physiology of the urinary system and offer simple explanations to help the woman cope with urinary alterations. Therapeutic listening is important. Be aware of the courage it takes for a woman to disclose an embarrassing condition.

Teaching Guidelines 7.2
MANAGING URINARY INCONTINENCE

- Avoid drinking too much fluid (i.e., 1.5 L total daily limit), but do not decrease your intake of fluids.
- Reduce intake of fluids and foods that are bladder irritants and precipitate urgency, such as chocolate, caffeine, sodas, alcohol, artificial sweetener, hot spicy foods, orange juice, tomatoes, and watermelon.
- Increase fiber and fluids in your diet to reduce constipation.
- Control blood glucose levels to prevent polyuria.
- Treat chronic cough.

- Remove any barriers that delay you from reaching the toilet.
- Practice good perineal hygiene by using mild soap and water. Wipe from front to back to prevent urinary tract infections.
- Become aware of adverse drug effects.
- Take your medications as prescribed.
- Continue to do pelvic floor muscle exercises.

T. (2015). Reducing the incidence of incontinence. *British Journal of Midwifery*, *23*(1), 17–20; and Vasavada, S. P., Carmel, M. E., & Rackley, R. (2015).Urinary incontinence. eMedicine. Retrieved from http://emedicine.medscape.com/article/452289-overview

Take Note!

Simple diet and lifestyle alterations, combined with a proper pelvic floor muscle strengthening program, can often produce significant improvements for women of all ages.

BENIGN GROWTHS

The most common benign growths of the reproductive tract include cervical, endocervical, and endometrial polyps; uterine fibroids (leiomyomas); genital fistulas; Bartholin cysts; and ovarian cysts.

Polyps

Polyps are small, usually benign growths. The incidence of malignancy in cervical polyps is 1 in 1,000. Malignancy is more common in perimenopausal or postmenopausal women (Nelson, Papa, & Ritchie, 2015). The cause of polyp growth is not well understood, but they are frequently the result of infection. Polyps might be associated with chronic inflammation, an abnormal local response to increased levels of estrogen, or local congestion of the cervical vasculature (Stewart, 2016). Single or multiple polyps might occur. They are most common in multiparous women. Polyps can appear anywhere but are most common on the cervix and in the uterus (Fig. 7.3).

Cervical polyps often appear after menarche. They occur in 2% to 5% of women, and approximately 2% of these polyps have cancerous changes (Schuiling & Likis, 2016). Endocervical polyps are commonly found in multiparous women ages 40 to 60. Endocervical polyps are more common than cervical polyps, with a stalk of varied width and length. Endometrial polyps are benign tumors or localized overgrowths of the endometrium. Most endometrial polyps are solitary, and they rarely occur in women younger than 20 years of age. The incidence of these polyps rises steadily with increasing age, peaks in the fifth decade of life, and gradually declines after menopause. They are present in up to 25% of women being seen for abnormal bleeding (Lieng, 2015).

Therapeutic Management

Treatment of polyps usually consists of simple removal with small forceps done on an outpatient basis, removal during hysteroscopy, or dilation and curettage (D&C). The polyp base can be removed by laser vaporization. Because many polyps are

infected, an antibiotic may be ordered after removal as a preventive measure or to treat early signs of infection.

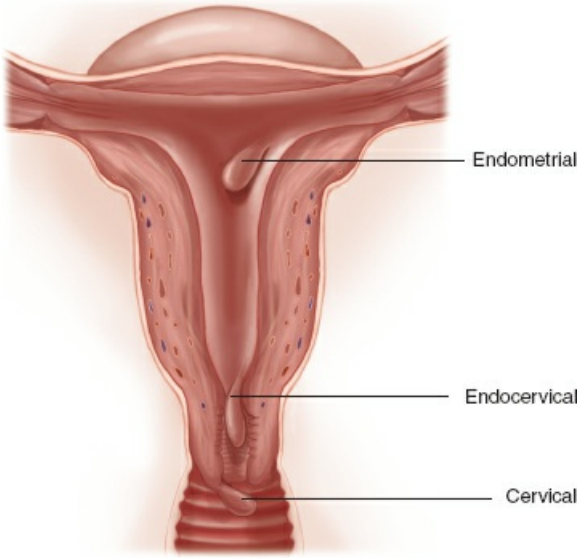

FIGURE 7.3 Cervical, endocervical, and endometrial polyps.

Although polyps are rarely cancerous, a specimen should be sent after surgery to a pathology laboratory to exclude malignancy. A cervical biopsy typically reveals mildly atypical cells and signs of infection. Polyps rarely return after they are removed. Regularly scheduled Pap smears are suggested for women with cervical polyps to detect any future abnormal growths that may be malignant.

Nursing Assessment

Nursing assessment for a woman with polyps includes assisting with the physical examination and preparing the collected specimen to be sent to the cytologist.

CLINICAL MANIFESTATIONS

Assess for clinical manifestations of polyps. Most endocervical polyps are cherry red, whereas most cervical polyps are grayish-white (Heller, 2015). Cervical and endocervical polyps are often asymptomatic, but they can produce mild symptoms such as abnormal vaginal bleeding (after intercourse or douching, between menses) or discharge. The most common clinical manifestation of endometrial polyps is metrorrhagia (irregular, acyclic uterine bleeding).

PHYSICAL EXAMINATION AND LABORATORY AND DIAGNOSTIC STUDIES

Typically, cervical polyps are diagnosed when the cervix is visualized through a speculum during the woman's annual gynecologic examination (Nelson et al., 2015). Endometrial polyps are not detected on physical examination, but rather with ultrasound or hysteroscopy (introduction of a small camera through the cervix to visualize the uterine cavity).

Nursing Management

Nursing management of polyps involves explaining the condition and the rationale

for removal and giving follow-up care instructions. The nurse also assists the health care provider with the removal procedure.

Uterine Fibroids

Uterine fibroids, also known as myomasor leiomyomas, are benign tumors composed of smooth muscle and fibrous connective tissue in the uterus. Unlike cancerous tumors, fibroids usually grow slower responding to present estrogen levels and their cells do not break away and invade other parts of the body. Fibroids are classified according to their position in the uterus and on the uterine layer most involved (Fig. 7.4):

- *Subserosol fibroids:* lie underneath the outermost peritoneal layer of the uterus and grow outside the uterus. They are attached to the uterus by a stalk or peduncle.
- *Intramural fibroids:* grow within the wall of the uterus and are the most common type.
- *Submucosal fibroids:* grow from immediately below the inner uterine surface (endometrium) into the uterine cavity (King et al., 2015).

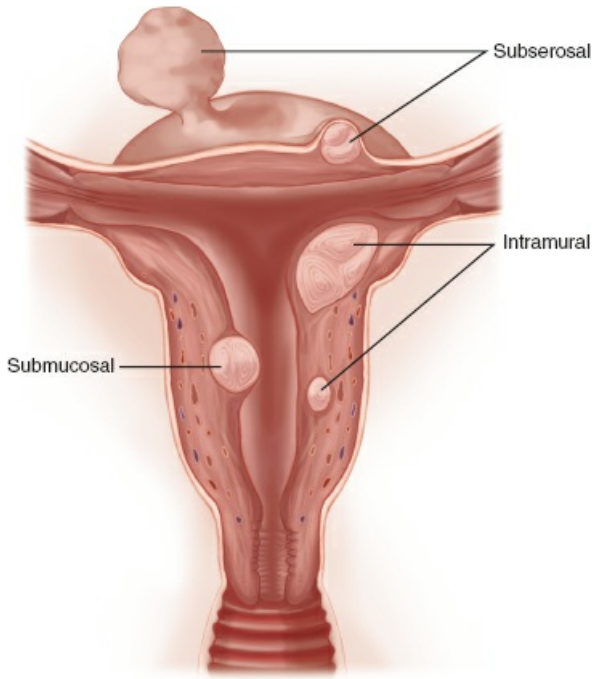

FIGURE 7.4 Submucosal, intramural, and subserosal fibroids.

Fibroids are estrogen-dependent and thus grow rapidly during the childbearing years, when estrogen is plentiful, but they shrink during menopause, when estrogen levels decline. It is believed that these benign tumors develop in up to 70% of all women over 30 years of age, but up to 50% are asymptomatic (Stewart, 2015). It is difficult to be precise because fibroids may cause no symptoms, and thus many women do not know they have them.

Fibroids are the most common indication for hysterectomy in the United States. The peak incidence occurs around age 45, and they are three times more prevalent in African American women than White women (Stewart, 2015).

Etiology

Although the cause of fibroids is unknown, several predisposing factors have been identified, including:
• Age (late reproductive years)
• Genetic predisposition
• African-American ethnicity
• Hypertension
• Nulliparity
• Obesity (Alexander et al., 2014).

Therapeutic Management

Treatment depends on the size of the fibroids and the woman's symptoms, which can include heavy or painful menses, feeling "full" in the lower pelvis, urinating frequently, pain during sexual relations, lower back pain, and infertility (NIH, 2015b). Several treatment options exist, ranging from watchful waiting to surgery.

MEDICAL MANAGEMENT

The goals of medical therapy are to reduce symptoms and/or to reduce the tumor size. This can be accomplished with pain medications to treat mild or occasional pain from fibroids; birth control pills to control heavy menses; or gonadotropin-releasing hormone (GnRH) agonists such as leuprolide (Lupron), nafarelin (Synarel), or goserelin (Zoladex), which stop ovulation and the production of estrogen, or low-dose mifepristone, a progestin antagonist. Both have produced regression and reduced the size of the tumors without surgery, but long-term therapy is expensive and not tolerated by most women. The side effects of GnRH medications include hot flashes, headaches, mood changes, vaginal dryness, musculoskeletal malaise, bone loss, and depression (King et al., 2015). Long-term mifepristone therapy can result in endometrial hyperplasia, which increases the risk of endometrial malignancy. Once either therapy is stopped, the fibroids typically recur.

Uterine artery embolization (UAE) is an option in which polyvinyl alcohol pellets are injected into selected blood vessels via a catheter to block circulation to the fibroid, causing it to shrink and producing symptom resolution. The procedure is carried out by an interventional radiologist who makes a tiny incision in the groin, introduces a fine catheter into the main artery leading to the uterus, and injects tiny particles of plastic or gelatin sponge into the artery that supplies blood to the fibroid. These particles stop the flow of blood, causing the fibroid to shrink or disappear completely over time. UAE has short-term advantages over surgery. Over the mid and long term, the benefits were similar, except for a higher reintervention rate after UAE (Hehenkamp, Huirne, & Brolmann, 2015). There remains a need for a treatment that is noninvasive and that preserves fertility.

SURGICAL MANAGEMENT

For women with large fibroids or severe menorrhagia, surgery is preferred over medical treatment. Surgical management might involve myomectomy, laser surgery, or hysterectomy.

Myomectomy. Myomectomy involves removing the fibroid alone. A myomectomy is performed via laparoscopy, through an abdominal incision or through a vaginal approach. The advantage is that only the fibroid is removed; fertility is not

jeopardized because this procedure leaves the uterine muscle walls intact. Myomectomy relieves symptoms but does not affect the underlying process; thus, fibroids grow back and further treatment will be needed in the future.

Laser Surgery. Laser surgery (or electrocauterization) involves destroying small fibroids with lasers. Laser therapy can be done using a vaginal approach or laparoscopically. The laser treatment preserves the uterus, but the process may cause scarring and adhesions, thus impairing fertility (Shigetomi et al., 2015). Fibroids can return after this procedure. Controversy remains as to whether laser treatment weakens the uterine wall and thus may contribute to uterine rupture in the future.

Hysterectomy. A hysterectomy is the surgical removal of the uterus. It is the most effective treatment for symptomatic fibroids with no recurrence. After cesarean section, it is the second most frequently performed surgical procedure for women in the United States. Approximately 600,000 hysterectomies are performed annually in the United States (Centers for Disease Control and Prevention [CDC], 2015). The top three conditions associated with hysterectomies are fibroids, endometriosis, and uterine prolapse (CDC, 2015). A hysterectomy to remove fibroids eliminates both the symptoms and the risk of recurrence, but it also terminates the woman's ability to bear children. Three types of hysterectomy surgeries are available: vaginal hysterectomy, laparoscopically assisted vaginal hysterectomy, and abdominal hysterectomy.

In a vaginal hysterectomy, the uterus is removed through an incision in the posterior vagina. Advantages include a shorter hospital stay and recovery time and no abdominal scars. Disadvantages include a limited operating space and poor visualization of other pelvic organs.

In a laparoscopically assisted vaginal hysterectomy, the uterus is removed through a laparoscope, through which structures within the abdomen and pelvis are visualized. Small incisions are made in the abdominal wall to permit the laparoscope to enter the surgical site. Advantages include a better surgical field, less pain, lower cost, and a shorter recovery time. Disadvantages include potential injury to the bladder and the inability to remove enlarged uteruses and scar tissue.

In an abdominal hysterectomy, the uterus and other pelvic organs are removed through an incision in the abdomen. This procedure allows the surgeon to visualize all pelvic organs and is typically used when a malignancy is suspected or a very large uterus is present. Disadvantages include the need for general anesthesia, a longer hospital stay and recovery period, more pain, higher cost, and a visible scar on the abdomen.

Complications of hysterectomy vary based on route of surgery and technique. The most common complications include infection, venous thromboembolic, genitourinary and gastrointestinal injuries, and hemorrhage (Goldman et al., 2015). With astute nursing observations and assessments, these complications can be reduced or minimized. A summary of treatment options for uterine fibroids is presented in Table 7.1.

TABLE 7.1 SUMMARY OF TREATMENT OPTIONS FOR UTERINE FIBROIDS

Method	Advantages	Disadvantages
Hormones	Noninvasive Reduces size of fibroids Symptom improvement	Serious side effects with long-term use Fibroids regrow when meds stopped
Uterine artery embolization	Minimally invasive Dramatic decrease in symptoms Future fertility possible	Procedure frequently painful Requires radiation and contrast dye Permanently implanted material Possible negative fertility impact
Myomectomy	Performed as minor surgery Uterus is preserved	Requires general anesthesia New growth of fibroids occurs
Hysterectomy	Complete removal of fibroids Immediate symptom relief	Requires general anesthesia Major surgery with associated risks Fertility not preserved
Laser surgery	Can be done as an outpatient procedure to destroy small fibroids	Vaporization process can cause scarring and adhesions, affecting future fertility

Nursing Assessment

Nursing assessment for the woman with uterine fibroids includes a thorough health history, physical examination, and laboratory and diagnostic studies.

HEALTH HISTORY AND CLINICAL MANIFESTATIONS

The history should include questions about the woman's menstrual cycle, including alterations in the menstrual pattern (e.g., pain or pressure, aggravating and alleviating factors), history of infertility, and any history of spontaneous abortion, which might indicate a space-occupying uterine lesion. Ask if any female relatives have had fibroids, because there is a familial predisposition. Assess for clinical manifestations of uterine fibroids. Symptoms of fibroids depend on their size and location and may include:

- Chronic pelvic pain
- Low back pain
- Iron-deficiency anemia secondary to bleeding
- Bloating
- Constipation
- Infertility (with large tumors)
- Dysmenorrhea
- Miscarriage
- Sciatica
- Dyspareunia
- Urinary frequency, urgency, incontinence
- Irregular vaginal bleeding (menorrhagia)
- Feeling of heaviness in the pelvic region

PHYSICAL EXAMINATION AND LABORATORY AND DIAGNOSTIC STUDIES

The bimanual examination performed by the health care provider typically shows an enlarged, irregular uterus. The uterus may be palpable abdominally if the fibroid is very large. Ultrasound may be used to confirm the diagnosis.

Nursing Management

The level of support that nurses can provide women with fibroids depends on the

type of treatment offered and her choice of them. Nurses should be able to explain any current treatment options and the implications of a diagnosis of fibroids. Many women have not heard of fibroids previously and need reassurance that they are both common and benign. If medication is prescribed, it is essential to explain the possible side effects and why medication can only be taken for a limited duration. If surgery is selected, verbal and written information about it and the aftercare should be addressed (Box 7.2).

A woman undergoing a hysterectomy for the treatment of fibroids often needs special care and can benefit from presurgical and postsurgical support provided by nurses. Personalized nursing, tailored to the individual woman's needs, enhances the client's coping strategies and alleviates different adverse psychological sequelae following gynecologic surgery. Women must cope with a variety of psychological adjustment difficulties, related to the changes in self-image, self-esteem, loss of femininity or identity, and sexual dysfunction. The incidence of postsurgical problems can be reduced greatly with proper client-centered perioperative nursing care.

Genital Fistulas

Genital fistulas are an underestimated problem worldwide and have devastating consequences for women. Genital fistulas are abnormal openings between a genital tract organ and another organ, such as the urinary tract or the gastrointestinal tract. A fistula can result from a congenital anomaly, surgical complications, Bartholin gland abscesses, radiation, or malignancy, but the majority of fistulas that occur worldwide are related to obstetric trauma and female genital cutting (Spurlock, 2015). During normal labor, the bladder is displaced upward into the abdomen, and the anterior vaginal wall, the base of the bladder, and the urethra are compressed between the fetal head and the posterior pubis. When labor is obstructed or prolonged, this unrelieved compression causes ischemia, which causes pressure necrosis and subsequent fistula formation.

Common types of fistulas include:

- *Vesicovaginal:* communication between the bladder and genital tract
- *Urethrovaginal:* communication between the urethra and the vagina
- *Rectovaginal:* communication between the rectum or sigmoid colon and the vagina

BOX 7.2

NURSING INTERVENTIONS FOR A WOMAN UNDERGOING A HYSTERECTOMY

Preoperative Care

- Instruct the client and her family about the procedure and aftercare.
- Provide interventions to reduce anxiety (due to perceived threats to the woman's self-concept and role functioning) and fear of alteration in body image, complications, and pain. Prepare the woman so she knows what to expect throughout her perioperative experience. Explain postoperative pain management procedures that will be used. Identify the high-risk woman early to reduce her stress.

- Teach turning, deep breathing, and coughing before surgery to prevent postoperative atelectasis and respiratory complications such as pneumonia.
- Encourage the woman to discuss her feelings. Some women equate their femaleness with their reproductive capability, and loss of the uterus could evoke grieving.
- Complete all preoperative orders in a timely manner to allow for rest.

Postoperative Care

- Provide comfort measures.
- Administer analgesics promptly or use a patient-controlled anesthesia (PCA) pump.
- Administer antiemetics to control nausea and vomiting per order.
- Change the client's linens and gown frequently to promote hygiene.
- Change the client's position frequently and use pillows for support to promote comfort and pain management.
- Assess the incision, the dressing, and vaginal bleeding and report if bleeding is excessive (soaking perineal pad within an hour).
- Monitor elimination and provide increased fluids and fiber to prevent constipation and straining.
- Encourage ambulation and active range-of-motion exercises when in bed to prevent thrombophlebitis and venous stasis.
- Monitor vital signs to detect early complications.
- Be comfortable discussing sexual concerns with the client.

Discharge Planning

- Advise the client to reduce her activity level to avoid fatigue, which might inhibit healing.
- Advise the client to rest when she is tired and to increase her activity level slowly.
- Educate the client on the need for pelvic rest (nothing in the vagina) for 6 weeks.
- Instruct the client to avoid heavy lifting or straining for about 6 weeks to prevent an increase in intra-abdominal pressure, which could weaken her sutures.
- Teach the client the signs and symptoms of infection.
- Advise the woman to take showers instead of tub baths to reduce the risk for infection.
- Encourage the client to eat a healthy diet with increased intake of fluids to prevent dehydration and fluid and electrolyte imbalance.
- Instruct the client to change her perineal pad frequently to prevent infection.
- Explain and schedule follow-up care appointments as needed.
- Provide information about community resources for support/help.

The direct consequences of this damage include UI and fecal incontinence if the rectum is involved. This tragic condition has plagued women since the beginning of history (Taylor & Rakinic, 2015). Another major cause of genital trauma leading to the development of genital fistulas is female genital cutting. This cultural practice, primarily carried out in Africa and Asia, is receiving worldwide attention as part of

the international public health agenda to move toward reducing its incidence. Reasons for continuing this practice include rite of passage, preserving chastity, ensuring marriageability, religion, hygiene, improving fertility, and enhancing sexual pleasure for men (Nour, 2015). Because of migration, health care providers are increasingly confronted with the range of negative urogynecologic effects that result from this practice. Nurses need to have a deeper understanding of the history, cultural beliefs, medical complications, and methods of surgical reconstruction to provide culturally competent care to this unique group of women. This cultural practice will be addressed in detail in Chapter 9.

Therapeutic Management

Many small fistulas will heal without treatment, but large fistulas often require surgical repair; surgery may be postponed until the edema or inflammation in the surrounding tissues has dissipated. Surgical repair of fistulas is associated with a high success rate if it is done in a timely manner, but larger fistulas and those of long duration have a poorer prognosis (Jellison & Raz, 2015).

Nursing Assessment

The history should include questions about any changes in the woman's urinary and bowel patterns. Assess for common signs and symptoms of fistulas, which are related to the type of fistula. If the opening involves the rectum, feces and flatus will leak through the vagina. If it involves the bladder, urine will leak from the vagina. Depending on the location and size of the fistula, the woman may or may not experience discomfort. The health care provider can detect these abnormal openings through inspection and palpation during the pelvic examination. Diagnostic or laboratory tests are generally not ordered once this condition is found.

Nursing Management

Provide guidance and support. Offer information to help the woman learn about her condition and, with appropriate intervention, to improve her quality of life. Begin by making sure the woman understands her anatomy and why she is having such symptoms. Provide a thorough explanation of the treatment options so that she can make an informed decision. Be sensitive to the woman's feeling of shame and fear about her incontinence; these feelings may be why she delayed seeking treatment. Address all of the woman's needs, both physical and emotional.

Bartholin Cysts

A Bartholin cyst is a swollen, fluid-filled, sac-like structure that results when one of the ducts of the Bartholin gland becomes blocked. The cyst may become infected and an abscess may develop in the gland. The Bartholin glands are two mucus-secreting glandular structures with duct openings bilaterally at the base of the labia minora near the opening of the vagina that provide lubrication during sexual arousal. Normally these glands cannot be felt or seen unless they are infected. Bartholin cysts are the most common cystic growths in the vulva, affecting approximately 2% of women at some time in their life (Reif et al., 2015).

Therapeutic Management

Treatment can be conservative or surgical depending on the symptoms, the size of the cyst, and whether it is infected or not. Small asymptomatic cysts do not require treatment. Sitz baths along with analgesics are used to reduce discomfort. Antibiotics are prescribed if the gland is infected. The aim of treatment for a cyst or abscess is to create a fistulous tract from the dilated duct to the outside vulva by incision and drainage. However, cysts or abscesses tend to return if this option is used.

Other treatment options beyond incision and drainage include placement of a Word catheter or a small loop of plastic tubing secured in place to prevent closure and to allow drainage. The use of a carbon dioxide laser to remove the cyst is also possible. After the Word catheter is inserted, the balloon tip is inflated and it is left in place for 4 to 6 weeks. The follow-up of the plastic tubing for removal is in approximately 3 weeks. Both procedures are safe and effective alternatives to surgery (Prabhu & Gardella, 2015). Treatment for a pregnant woman with a Bartholin cyst depends on the severity of the symptoms and whether an infection is present. Surgery may be delayed until after the woman gives birth if there are no symptoms.

Nursing Assessment

Nursing assessment for the woman with a Bartholin cyst includes a thorough health history, physical examination, and laboratory and diagnostic tests.

HEALTH HISTORY

The history should include questions about the woman's sexual practices and protective measures used. Assess for common signs and symptoms of Bartholin cysts. The woman may be asymptomatic if the cyst is small (less than 5 cm) and not infected. If infection is present, symptoms include varying degrees of pain, especially when walking or sitting; unilateral edema; redness around the gland; and dyspareunia. Extensive inflammation may cause systemic symptoms. Abscess formation occurs when the cystic fluid becomes infected. An abscess usually develops rapidly over a 2- to 3-day period and may spontaneously rupture. A history of sudden relief of pain following profuse discharge is highly suggestive of spontaneous rupture (Schuiling & Likis, 2016).

PHYSICAL EXAMINATION AND LABORATORY AND DIAGNOSTIC STUDIES

The diagnosis of Bartholin cysts or abscesses is primarily made during a physical examination when a protruding tender labial mass is located. In women over the age of 40, there is an increased risk of malignancy, typically sarcomas which account for 2% of all invasive vulvar malignancies. They are characterized by rapid growth, high metastatic potential, frequent recurrences, aggressive behavior, and high mortality rate (Chokoeva et al., 2015). Cultures of the purulent abscess fluid and of the cervix should be obtained for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* to rule out a sexually transmitted infection.

Nursing Management

Nurses must be aware of and knowledgeable about vulvar cysts and treatment options. The woman may be aware of a vulvar cyst secondary to the pain or may be

unaware of it if it is asymptomatic. A Bartholin cyst may be an incidental finding during a routine pelvic examination. Explain the cause of the cyst and assist with cultures if needed. Provide reassurance and support.

Ovarian Cysts

An **ovarian cyst** is a fluid-filled sac that forms on the ovary (Fig. 7.5). These very common growths are benign 90% of the time and are asymptomatic in many women. The cysts are discovered incidentally during an ultrasound or routine pelvic examination. Ovarian cysts occur in 30% of women with regular menses, 50% of women with irregular menses, and 7% of postmenopausal women (Templeman, 2015). When the cysts grow large and exert pressure on surrounding structures, women often seek medical help.

Types of Ovarian Cysts

The most common benign ovarian cysts are follicular cysts, corpus luteum (lutein) cysts, theca lutein cysts, and polycystic ovarian syndrome (PCOS).

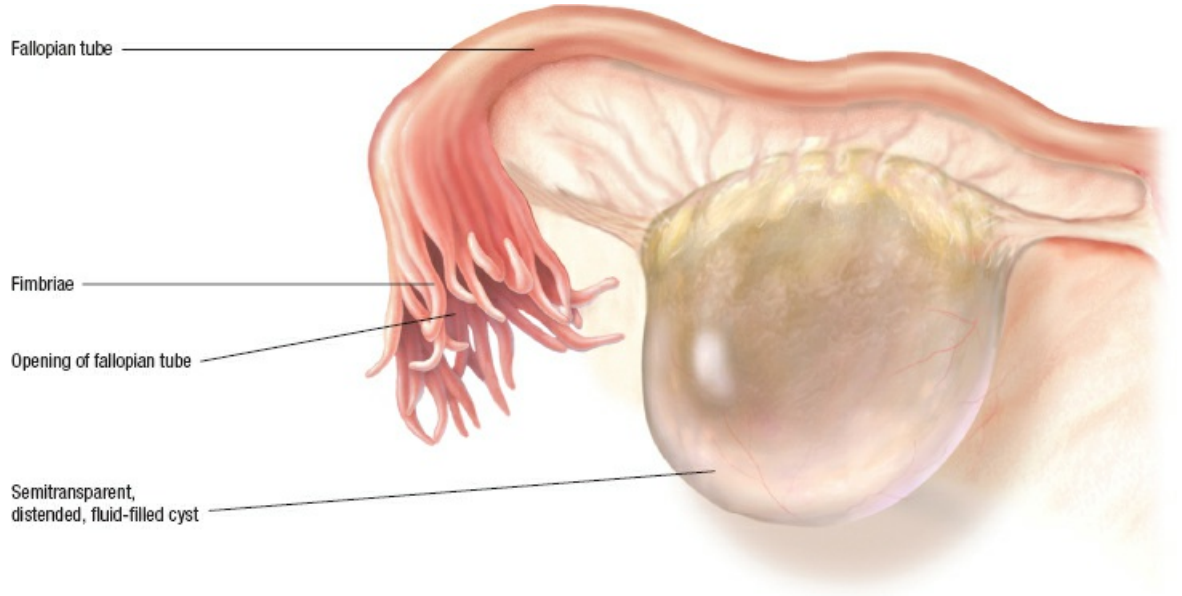

FIGURE 7.5 Ovarian cyst. (Asset provided by Anatomical Chart Co.)

FOLLICULAR CYSTS

Small follicular cysts are commonly found in the ovaries of prepubertal girls and women of reproductive age, and in most cases, they are of no clinical significance. They are usually self-limiting and resolve spontaneously. Follicular cysts are caused by the failure of the ovarian follicle to rupture at the time of ovulation. Follicular cysts seldom grow larger than 5 cm in diameter; most regress and require no treatment. They can occur at any age and are rare after menopause. They are detected by vaginal ultrasound.

CORPUS LUTEUM (LUTEIN) CYSTS

A corpus luteum cyst forms when the corpus luteum becomes cystic or hemorrhagic and fails to degenerate after 14 days. These cysts might cause pain and delay the next menstrual period. A pelvic ultrasound helps to make this diagnosis. Typically

these cysts appear after ovulation and resolve without intervention.

THECA LUTEIN CYSTS

Prolonged abnormally high levels of human chorionic gonadotropin (hCG) stimulate the development of theca lutein cysts. Although rare, these cysts are associated with hydatidiform mole, choriocarcinoma, polycystic ovary syndrome, and Clomid therapy.

POLYCYSTIC OVARY SYNDROME

Polycystic ovary syndrome (PCOS) is the most common endocrine condition in women of reproductive age. It is a heterogeneous condition that involves the presence of multiple inactive follicle cysts within the ovary that interfere with ovarian function. It is a multifaceted disorder, and central to its pathogenesis are hyperandrogenemia and hyperinsulinemia, which are targets for treatment (King et al., 2015). It is associated with obesity, hyperinsulinemia, elevated luteinizing hormone levels (linked to ovulation), elevated androgen levels (virilization), hirsutism (male-pattern hair growth), obstructive sleep apnea, follicular atresia (ovarian growth failure), ovarian growth and cyst formation, anovulation (failure to ovulate), infertility, type 2 diabetes, sleep apnea, amenorrhea (absence of menstruation or irregular periods), metabolic syndrome, which is characterized by abdominal obesity (waist circumference > 35 in), dyslipidemia (triglyceride level > 150 mg/dL, high-density lipoprotein cholesterol level < 50 mg/dL), elevated blood pressure, a proinflammatory state characterized by an elevated C-reactive protein level, and a prothrombotic state characterized by elevated PAI-1 and fibrinogen levels. Recent studies also indicate that PCOS is associated with an increase in the risk of uterine fibroids, depression, adverse pregnancy outcomes, and neonatal complications. A recent meta-analysis found that women with PCOS demonstrated a significantly higher risk of developing gestational diabetes, gestational hypertension, preeclampsia, preterm birth, and had a higher cesarean section rate when compared to controls (Kyrou, Weickert, & Randeva, 2015). With an estimated prevalence of 5% to 10% of all females, PCOS is the most common cause of medically treatable infertility and is responsible for 70% of cases of anovulatory subfertility and up to 20% of couples' infertility cases (NIH, 2015c).

Take Note!

Careful attention should be given to this condition because affected women are at increased risk for long-term health problems such as cardiovascular disease, hypertension, dyslipidemia, type 2 diabetes (half of all women), infertility, and cancer (endometrial, breast, and ovarian) (Moran, Norman, & Teede, 2015).

Initially PCOS was called Stein–Leventhal syndrome after its researchers, but it is now recognized to be an anabolic syndrome. Unfortunately, less than two thirds of women are aware of their diagnosis or the concomitant high risk for developing type 2 diabetes mellitus and cardiovascular disease related to metabolic syndrome. Its etiology is not clearly understood, but studies suggest a genetic (autosomal-dominant) component. Women with PCOS have abnormalities in the metabolism of androgens and estrogen and in the control of androgen production. In addition, they have peripheral insulin resistance and hyperinsulinemia and obesity (Trikudanathan, 2015). All of these clinical manifestations must be addressed

throughout the lifespan with an emphasis on prevention of cardiometabolic risks in the treatment plan.

Therapeutic Management

Treatment is centered on the clinical manifestations and should be initiated early to prevent/limit long-term complications such as metabolic syndrome, diabetes, endometrial carcinoma, and infertility (Ganie, Chakraborty, & Rehman, 2015). Oral contraceptives, antidiabetic agents, and statins are some of the common therapies used to address the symptoms of this complex hormonal condition. Weight loss and surgery may also be beneficial as nondrug options.

Treatment of ovarian cysts focuses on differentiating a benign cyst from a solid ovarian malignancy. Transvaginal ultrasound is useful in distinguishing fluid-filled cysts from solid masses. Laparoscopy may be needed to remove the cyst if it is large and pressing on surrounding structures. For smaller cysts, monitoring with repeat ultrasounds every 3 to 6 months might be in order (Lucidi, 2015). Oral contraceptives are often prescribed to suppress gonadotropin levels, which may help resolve the cysts. Pain medication is also prescribed if needed.

Medical management of PCOS is aimed at the treatment of metabolic derangements, anovulation, hirsutism, and menstrual irregularity. This includes both drug and nondrug therapy, along with lifestyle modifications. Goals of therapy focus on reducing the production and circulating levels of androgens, protecting the endometrium against the effects of unopposed estrogens, supporting lifestyle changes to achieve ideal body weight, lowering the risk of cardiovascular disease, avoiding the effects of hyperinsulinemia on the risk of cardiovascular disease and diabetes, and inducing ovulation to achieve pregnancy if desired (Evidence-Based Practice 7.2). Treatment modalities for PCOS are highlighted in Box 7.3.

Nursing Assessment

Nursing assessment for the woman with PCOS includes a thorough health history, physical examination, and laboratory and diagnostic tests.

BOX 7.3

TREATMENT MODALITIES FOR PCOS

- Oral contraceptives to treat menstrual irregularities and acne
- Mechanical hair removal (shaving, waxing, plucking, or electrolysis) to treat hirsutism
- Glucophage (metformin), which improves insulin uptake by fat and muscle cells, to treat hyperinsulinemia; thiazolidinediones (Actos, Avandia) to decrease insulin resistance
- Ovulation induction agents (Clomid) to treat infertility
- Lifestyle changes (e.g., weight loss, exercise, balanced low-fat diet)
- Referral to support groups to help improve emotional state and build self-esteem

and diabetes (pp. 99–113). London, England: Springer Publishers; and Lucidi, R.S. (2015). Polycystic ovarian syndrome. *EMedicine*. Available at: http://emedicine.medscape.com/article/256806-overview

EVIDENCE-BASED PRACTICE 7.2

IT'S NOT JUST PHYSICAL: THE ADVERSE PSYCHOSOCIAL EFFECTS OF POLYCYSTIC OVARY SYNDROME IN ADOLESCENTS

STUDY

The prevalence of depression and other psychological disorders in women with PCOS is high and varies in numerous studies. In particular, women with PCOS have been found to be at an increased risk of social phobia and suicide attempts. The reasons for a higher prevalence of psychological disorders in women with PCOS are likely to be complex. Some investigators suggest that physical symptoms experienced by women with PCOS are the likely cause of psychological distress. However, evidence is inconsistent. While acne, hirsutism, and obesity have been linked to increased psychological distress in some studies, no link is demonstrated in others. It is likely that multiple factors contribute to the high prevalence of psychosocial disorders in women with PCOS.

This study sheds light on the fact that this gynecologic disorder of endocrine origin can be associated with a great number of psychological symptoms (e.g., depression, anxiety, body image dissatisfaction, eating and sexual disorders, and poor quality of life). The goal of the study was to address the prevalence of psychological disorders and determinants of well-being.

Findings

An overwhelming majority of scientific literature on PCOS has focused on the medical approach to analyze the disorder and only a few studies have investigated its predisposing psychological factors. The literature review revealed several psychological disorders that accompany this syndrome with limited attention given to them to help women cope. The symptoms typically associated with PCOS, including amenorrhea, oligomenorrhea, hirsutism, obesity, infertility, anovulation, and acne, can lead to symptoms of depression, withdrawal from society, emotional distress, embarrassment, lower self-esteem, anxiety, body image disturbances, eating disorders, marital and social maladjustment, and impaired sexual functioning.

Nursing Implications

PCOS is closely associated with psychological disorders with important implications that necessitate identification and treatment of the disorders. The high prevalence rate of these psychological disorders in this population suggests that initial evaluation of all women with PCOS should also include an assessment of their mental health. Psychological support by nurses should take on an important role in the management of the affected women with PCOS. This should not suggest that medical treatment of PCOS is not required, but a thorough cooperation between medical treatment and psychological support would improve the situation of PCOS-affected women. The physical and psychosocial aspects of management of PCOS go hand in hand. Meeting physical management goals (e.g., weight loss, reduction in hyperandrogenism manifestations) can lessen some of the distressing psychosocial effects, and enhance

self-esteem.

Adapted from Lee, J. S. (2015). It's not just physical: The adverse psychosocial effects of polycystic ovary syndrome in adolescents. *Women's Healthcare*, *3*(1), 20–28.

HEALTH HISTORY

The history should include questions about the woman's symptoms, including onset, location, frequency, quality, intensity, and aggravating and alleviating factors of her discomfort. Note the last menstrual period and whether or not her cycles are regular. Ask about her overall general health and any changes recently noticed, such as a change in abdominal girth without a concomitant weight gain. Assess for common signs and symptoms of ovarian cysts. Findings might include:

- Hirsutism (face and chin, upper lip, areola, lower abdomen, and perineum)
- Alopecia (frontal region and crown of head)
- Virilization (clitoral hypertrophy, deepening of voice, increased muscle mass, breast atrophy, male-pattern baldness)
- Menstrual irregularity and infertility (menorrhagia, anovulation)
- Polycystic ovaries (12 or more follicles on ovaries)
- Obesity (occurs in more than 50% of women with PCOS; occurs in abdominal region, with an increase in the waist–hip ratio)
- Insulin resistance (chronic hyperinsulinemia leads to type 2 diabetes)
- Metabolic syndrome (elevated cholesterol, triglycerides, low-density lipoprotein; risk of cardiovascular disease)
- Increased risk for endometrial cancer, ovarian cancer, breast cancer
- Psychological impact (depression, frustration, anxiety, eating disorders)
- Acne (face and shoulders) (Lucidi, 2015)

PHYSICAL EXAMINATION AND LABORATORY AND DIAGNOSTIC STUDIES

The physical examination includes inspection, auscultation, and palpation of the abdomen because large ovarian masses may cause visible changes in the abdomen. A complete pelvic examination is performed to assess the location, size, shape, texture, mobility, and tenderness of any palpable mass.

Diagnostic tests include a pregnancy test to rule out ectopic pregnancy. Gonorrhea and chlamydia testing is warranted if an ovarian abscess is suspected. An ultrasound may be ordered to differentiate between functional or simple ovarian cysts and a solid tumor. Additional tests may be performed depending on the findings.

Remember Liz, the client with irregular menses, facial hair, and acne? Her glucose level is elevated, multiple cysts were felt on her ovaries during the pelvic examination, and laboratory tests found elevated lipid and lipoprotein levels. What education should the nurse provide Liz regarding her PCOS diagnosis? What medications might be prescribed to address her abnormal laboratory values?

Nursing Management

Nursing care should include education about the condition, treatment options,

diagnostic test arrangements, and referral for surgery if needed. Provide support and reassurance during the diagnostic period to allay anxiety in the client and her family. Reassure the woman that the majority of ovarian cysts are benign, but regardless stress the importance of follow-up care. Listen to the woman's concerns about her appearance, infertility, and facial hair growth. Offer suggestions to help the woman feel better about herself and her health.

Nurses can have a positive impact on women with PCOS through counseling and education. Provide support for women dealing with negative self-image secondary to the physical manifestations of PCOS. Through education, help the woman understand the syndrome and its associated risk factors to prevent long-term health problems. Encourage the woman to make positive lifestyle changes. Make community referrals to local support groups to help the woman build her coping skills.

***Liz* returns to the clinic a month later for reevaluation of her PCOS. She has been taking metformin to reduce her insulin resistance and has followed her exercise regimen and reduced her caloric intake to lose weight, but she still complains about her facial hair and acne. What interventions might be helpful to address this problem? What medication might also be prescribed to regularize her menses and relieve the hirsutism?**

NURSING CARE PLAN 7.1

Overview of a Woman with Pelvic Organ Prolapse

Katherine, a 62-year-old multiparous woman, came to her gynecologist with complaints of a chronic dragging or heavy painful feeling in her pelvis, lower backache, constipation, and urine leakage. Her symptoms increase when she stands for long periods. She has not had menstrual cycles for at least a decade. She tells you, "I'm not taking any of those menopausal hormones." She also states she is very self-conscious and embarrassed about her urine leakage and restricts her outside activities.

NURSING DIAGNOSIS: Body image changes related to relaxation of pelvic support and elimination difficulties

Outcome Identification and Evaluation

The client will report an improved body image after management of pelvic organ prolapse and improved urinary control.

Interventions: ***Providing Pain Management***

- Obtain a thorough history, including ongoing embarrassing experiences, methods of urine control used, what worked, what didn't, any changes in sexual practices related to this, and the effect of this condition on her activities of daily living *to provide a baseline and enable a systematic approach to address it.*
- Assess the frequency, severity, precipitating factors, and aggravating/alleviating factors *to identify characteristics of the client's abnormal urinary patterns to plan appropriate interventions.*
- Educate client about any medications prescribed (correct dosage, route, side effects, and precautions) *to increase the client's understanding of the therapy and promote compliance.*

- Assess problematic elimination patterns *to identify underlying factors from which to plan appropriate prevention strategies.*
- Encourage client to increase fluids and fiber in diet and increase physical activity daily *to promote peristalsis.*
- Assist client with establishing regular toileting patterns by setting aside time daily for bowel elimination *to promote regular bowel function and evacuation.*
- Urge client to avoid the routine use of laxatives *to reduce risk of compounding constipation.*

NURSING DIAGNOSIS: Deficient knowledge related to causes of structural disorders and treatment options

Outcome Identification and Evaluation

The client will demonstrate an understanding of current condition and treatments as evidenced by identifying treatment options, making health-promoting lifestyle choices, verbalizing appropriate health care practices, and adhering to treatment plan.

Interventions: *Providing Client Education*

- Assess client's understanding of pelvic organ prolapse and its treatment options *to provide a baseline for teaching.*
- Review information provided about surgical procedures and recommendations for healthy lifestyle, obtaining feedback frequently, *to validate client's understanding of instructions.*
- Discuss association between uterine, bladder, and rectal prolapse and symptoms *to help client understand the etiology of her symptoms and pain.*
- Have client verbalize and discuss information related to diagnosis, surgical procedure, preoperative routine, and postoperative regimen *to ensure adequate understanding and provide time for correcting or clarifying any misinformation or misconceptions.*
- Provide written material with pictures *to promote learning and help client visualize what has occurred to her body secondary to aging, weight gain, childbirth, and gravity.*
- Discuss pros and cons of hormone replacement therapy, osteoporosis prevention, and cardiovascular events common in postmenopausal women *to promote informed decision making by the client about available menopausal therapies.*
- Inform client about the availability of community resources and make appropriate referrals as needed *to provide additional education and support.*
- Document details of teaching and learning *to allow for continuity of care and further education, if needed.*

KEY CONCEPTS

- Pelvic floor disorders such as pelvic organ prolapse and urinary and fecal incontinence are prevalent conditions in aging women. They cause significant physical and psychological morbidity, with obvious detriment to women's social interactions, emotional well-being, and overall quality of life.
- The four most common types of genital prolapse are cystocele, rectocele, enterocele, and uterine prolapse.
- The purpose of pelvic floor muscle exercises is to increase the muscle volume, which will result in a stronger muscular contraction. These exercises might limit the progression of mild prolapse and alleviate mild prolapse symptoms,

including low back pain and pelvic pressure.

- UI is the involuntary loss of urine sufficient enough to be a social or hygiene problem. It affects approximately 15 million women in the United States.
- The three most common types of incontinence are urge incontinence (overactive bladder caused by detrusor muscle contractions), stress incontinence (inadequate urinary sphincter function), and mixed incontinence (involves both stress and urge incontinence).
- The most common benign growths of the reproductive tract include cervical, endocervical, and endometrial polyps; uterine fibroids (leiomyomas); genital fistulas; Bartholin cysts; and ovarian cysts.
- PCOS involves the presence of multiple inactive follicle cysts within the ovary that interfere with ovarian function. Hyperandrogenism, insulin resistance, and chronic anovulation characterize PCOS. Careful attention should be given to this condition because women with it are at increased risk for long-term health problems such as cardiovascular disease, hypertension, dyslipidemia, infertility, type 2 diabetes, and cancer (endometrial, breast, and ovarian).

CHAPTER WORKSHEET

MULTIPLE-CHOICE QUESTIONS

1. When you are interviewing a client with uterine fibroids, what subjective data would you expect to find in her history?
   a. Cyclic migraine headaches
   b. Urinary tract infections
   c. Chronic pelvic pain
   d. Chronic constipation
2. Conservative treatment options available for women with pelvic organ prolapse are:
   a. Pessaries and PFM exercises
   b. External pelvic fixation devices
   c. Weight gain and yoga
   d. Firm panty-and-girdle garments
3. Which of the following dietary and lifestyle modifications might the nurse recommend to help prevent pelvic relaxation as women age?
   a. Eat a high-fiber diet to avoid constipation and straining.
   b. Avoid sitting for long periods; get up and walk around frequently.
   c. Limit the amount of exercise to prevent overdeveloping muscles.
   d. Space children a year apart to reduce wear and tear on the uterus.
4. Women with polycystic ovarian syndrome (PCOS) are at increased risk for developing which of the following long-term health problems?
   a. Osteoporosis
   b. Lupus
   c. Type 2 diabetes
   d. Migraine headaches
5. Side effects experienced by women taking gonadotropin-releasing hormone (GnRH) agonists for the treatment of fibroids closely resemble those of:
   a. Anorexia nervosa
   b. Osteoarthritis
   c. Depression
   d. Menopause
6. In securing a health history of a 65-year-old woman, which clinical manifestation described by the client would the nurse suspect is related to pelvic organ prolapse?
   a. Chronic abdominal pain
   b. Heavy feeling or dragging in vagina
   c. Uterine cramping and backache
   d. Weight gain and edema of ankles

CRITICAL THINKING EXERCISE

1. Faith, a 42-year-old multiparous woman, presents to the women's health clinic complaining of pelvic pain, menorrhagia, and vaginal discharge. She says she has been having these problems for several months. On examination, her uterus is enlarged and irregular in shape. Her blood studies reveal anemia.
   a. What condition might Faith have, based on her symptoms?
   b. What treatment options are available to address this condition?
   c. What educational interventions should the nurse discuss with Faith?

STUDY ACTIVITIES

1. Prepare an educational session to teach women how to do pelvic floor muscle exercises to prevent stress incontinence and pelvic floor relaxation.
2. In a small group, discuss the personal, social, and sexual issues that might affect a woman with pelvic organ prolapse. How might these issues affect her socialization? How might a support group help?
3. List the symptoms that a woman with uterine fibroids might have. Discuss how these symptoms might mimic a more frightening condition and why the woman might delay seeking treatment.
4. A bladder that herniates into the vagina is a _____.
5. A rectum that herniates into the vagina is a _____.

BRINGING IT ALL TOGETHER: A CASE STUDY

Elizabeth, a 52-year-old woman presented to the gynecologic clinic to discuss a "horrible personal problem" that was ruining her life. She appeared very distressed and only wanted to talk to the nurse in private about it. A few months ago when she was out walking her dog, she experienced a sudden rectal urgency that she thought was gas, but she expelled feces instead. Over the past few months, her fecal incontinence has increased in severity and frequency causing her extreme stress. To avoid embarrassment, she has had to cover and excuse herself from work situations and turn down social invitations. She now has to wear a protective pad and disposable pants.

ASSESSMENT

Elizabeth is otherwise healthy and takes no prescription medications presently. She has had five vaginal births with three episiotomies. She has a body mass index of 27, mild stress urinary incontinence, and a low-grade rectocele with slightly decreased anal sphincter tone. Her pelvic examination demonstrated pelvic organ prolapse. The digital rectal examination ruled out fecal impaction and any rectal mass. A detailed history of her incontinence episodes was also taken.

1. What risk factors are associated with fecal incontinence? Which does Elizabeth have?
2. Is her condition common in women of her age? If so, why?
3. What treatment options might help Elizabeth with her condition?

Risk factors for fecal incontinence include increasing age, anorectal procedures, obesity, urinary incontinence, vaginal births, pelvic organ prolapse, and female gender. Fecal incontinence is not a disease state, but rather is a symptom of an

underlying pelvic disorder such as POP. It is a nonfatal condition, but can greatly reduce the individual's quality of life. Treatment options include nonoperative interventions such as bulking agents to improve stool consistency, pelvic floor muscle exercises, antidiarrheal agents, and surgery.

PLAN

1. What specific health promotion strategy can the nurse discuss to reduce her symptoms?
2. How can the nurse improve Elizabeth's coping strategies?
3. What dietary changes might be helpful for Elizabeth?
4. How can the nurse offer client-centered care to Elizabeth?

Since Elizabeth has a high BMI; a weight loss intervention would be helpful in reducing the intra-abdominal pressure on her pelvic organs. Obesity is a risk factor for this condition. The nurse can discuss ways to reduce her weight through diet and exercise. Coping strategies should include a discussion of continence products available, providing emotional and psychological support to her, the use of anal plugs, skin-care, odor control, bowel training, laundry advice and advice on preservation of dignity. Dietary changes might include starting a food and fluid diary to determine if there are food items increasing her stool frequency, advise her to modify one food at a time, and consuming foods that add bulk to her diet to increase formed stools. Management should be tailored to the needs of the individual. Information should be provided in a caring format in which Elizabeth can understand, so that she can participate in decisions about their treatment.

8

Cancers of the Female Reproductive Tract

WOW

Words of Wisdom

The word "cancer" can strike fear into anyone who hears it. But when it involves a reproductive organ, this fear is often magnified.

KEY TERMS

cervical cancer
cervical dysplasia
colposcopy
cone biopsy
cryotherapy
endometrial cancer
human papillomavirus
ovarian cancer
Papanicolaou (Pap) test
vaginal cancer
vulvar cancer

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Evaluate the major modifiable risk factors for reproductive tract cancers.
2. Analyze the screening methods and treatment modalities for cancers of the female reproductive tract.
3. Outline the nursing management needed for the most common malignant reproductive tract cancers in women.
4. Examine lifestyle changes and health screenings that can reduce the risk of or prevent reproductive tract cancers.
5. Assess at least three web site resources available for a woman diagnosed with cancer of the reproductive tract.
6. Appraise the psychological distress felt by women diagnosed with cancer, and outline information that can help them to cope.

***Carmella* is an obese, 55-year-old woman who presents to her woman's health care provider with vaginal bleeding. She has been through menopause and wonders why she is having a period again. Her history includes infertility and hypertension. Three years ago she had a mastectomy for breast cancer, and she has been taking tamoxifen (Nolvadex) to prevent recurrent breast cancer since her surgery. What risk factors in Carmella's history might predispose her to a reproductive tract cancer? What additional information is needed to make a diagnosis?**

INTRODUCTION

Cancer is the second leading cause of death for women in the United States, surpassed only by cardiovascular disease (Centers for Disease Control and Prevention [CDC], 2015a). Cardiovascular disease is, and should continue to be, a major focus of efforts in women's health. However, this should not overshadow the fact that many women between the ages of 35 and 74 are developing and dying of cancer (National Cancer Institute [NCI], 2015a). Women have a one-in-three lifetime risk of developing cancer, and one out of every four deaths is from cancer (Alexander et al., 2014). African-American women have the highest death rates from both heart disease and cancer (CDC, 2015a). The American Cancer Society (ACS) (2016) estimated that in 2016 there will be 1,685,210 new cancer cases diagnosed and 595,690 cancer deaths in the United States. Scientific evidence suggested that about one-third of these cancer deaths expected to occur in 2015 were related to obesity, physical inactivity, and poor nutrition and thus could have been prevented. Certain cancers are related to infectious agents, such as hepatitis B virus (HBV), **human papillomavirus** (HPV), human immunodeficiency virus (HIV), and *Helicobacter pylori,* and can be prevented through behavioral changes, vaccines, or antibiotics (Herrington, Coates, & Duprex, 2015). In addition, many of the more than 2 million skin cancers that are diagnosed annually could be prevented by protecting the skin from the sun's rays and avoiding indoor tanning. Sunburns, especially if they occur repetitively in childhood, may lead to melanoma. Most

melanomas are treated successfully if discovered early, but metastatic melanoma has no good treatment (Balk, 2015).

It has been estimated that in the United States half of all premature deaths, one-third of acute disabilities, and one-half of chronic disabilities are preventable, including some cancers (NCI, 2015b). Nurses need to focus their energies on screening, education, and early detection to reduce these numbers. Because cancer risk is strongly associated with lifestyle and behavior, screening programs are of particular importance for early detection. There is evidence that prevention and early detection have reduced cancer mortality rates and prevented reproductive cancers (CDC, 2015b).

This chapter begins with a nursing process overview of the care of women with reproductive cancer. It then describes selected cancers of the reproductive system: ovarian, endometrial, cervical, vaginal, and **vulvar cancer**. The chapter discusses the nurse's role through diagnosis, intervention, and follow-up care. Cancer management requires a multidisciplinary approach, including specialists in surgical, medical, and radiation oncology. The nurse can provide guidance and support to the client as she finds her way through the health care maze.

NURSING PROCESS OVERVIEW FOR THE WOMAN WITH CANCER OF THE REPRODUCTIVE TRACT

The word *cancer* is laden with fear and dread. These feelings may worsen when the cancer involves a woman's reproductive tract. The diagnosis of a reproductive tract cancer can have a profound impact on a woman's sexuality because it affects the very core of her identity as a female. The loss of the reproductive body part as well as the possible loss of childbearing ability can have a significant effect on women and their partners. Nurses need to remember this when counseling women and their partners about cancer treatment and side effects and changes in gender roles and sexuality.

When a woman is first diagnosed with a reproductive tract cancer, two primary needs arise: information and emotional support. When the diagnosis is made, the woman typically has many questions, such as "What is going to happen to me?" "How will this change my life?" and "Will I survive?" Nurses can play a major role in helping women find the answers to their questions and directing them to the resources they need. Two reliable sources of general cancer information are the NCI and the American Cancer Society. They can be reached via the Internet or by phone.

The nurse also plays a key role in offering emotional support, determining appropriate sources of support, and helping the woman use effective coping strategies. A recent research study found that social support from the woman's family, friends, and coworkers is one of the strongest predictors of how well she will cope (Garner et al., 2015). Implications for nurses working with women following a cancer diagnosis include assessing women's definitions and availability of support; respecting varied needs for informational support; providing a supportive clinical environment; educating clinicians, family, and friends regarding unsupportive responses within the cultural context; and validating

women's control and balancing of support needs. Nurses are well positioned to provide women with anticipatory guidance from diagnosis to the end of treatment (Shirvani & Alhani, 2015). Women without a social support network may need a social work referral or may need to be guided toward support groups to receive the emotional support they need.

In addition, cancer clients have a strong need for hope. Strategies for inspiring hope may include active listening, touch, presence, and helping clients overcome communication barriers. Often it is not what nurses say or do but just their presence that counts.

Assessment

Assessment of a woman with cancer of the reproductive tract involves a thorough history and physical examination. In addition, various laboratory and diagnostic tests may be done to evaluate for malignancy.

Health History and Physical Examination

Interview the woman carefully to determine any current or past factors that might increase her risk of cancer, such as early menarche, late menopause, sexually transmitted infections (STIs), use of hormonal agents, or infertility. Find out if the woman has a family history of cancer. Be thorough in obtaining the woman's past medical history, especially her reproductive, obstetric, and gynecologic history. Ask about her lifestyle and behaviors, including risky behaviors such as engaging in unprotected sexual intercourse or sexual intercourse with multiple partners. Find out if she has had routine or recommended screening procedures.

Ask if the woman has had any symptoms, such as abnormal vaginal bleeding or discharge or vaginal discomfort. Often the symptoms of cancer are vague and nonspecific and the woman may attribute them to another problem, such as aging, stress, or improper diet.

Perform a complete physical examination, including a review of body systems and a pelvic examination. Observe for lesions or masses in the perineal area. Note any masses when palpating the abdomen or when performing the pelvic examination.

Laboratory and Diagnostic Testing

Some of the laboratory and diagnostic tests used to help diagnose cancer of the reproductive tract are discussed in Common Laboratory and Diagnostic Tests 8.1.

COMMON LABORATORY AND DIAGNOSTIC TESTS 8.1

Test	Explanation	Indications	Nursing Implications
Clinical breast examination	Assessment of the breast for abnormal findings; client may discover lump herself; high-risk history for breast cancer	Identifies palpable mass, skin change, inverted nipple, or unresolved rash	• Educate client to perform breast self-examination and report any abnormalities if high risk • Reinforce need for frequent clinical breast examinations if risk factors are present
Mammography	Screening modality for breast cancer or any distortion in breast tissue architecture	Detects calcifications, densities, and nonpalpable cancer lesions	Stress importance of annual mammograms for all women after the age of 40 or 50, depending on their risk history
Pap smear	Cervical cytology screening to diagnose cervical cancers	Aids in detecting abnormal cells of the cervix (from squamocolumnar junction of the cervix; most cervical cancers arise here)	Encourage all sexually active women to receive a pelvic examination, including a Pap smear if they have a high-risk profile, to promote early detection of cervical cancer
Transvaginal ultrasound	Screening for pelvic pathology to assist in diagnosing endometrial cancers	Allows measurement of endometrial thickness to determine if endometrial biopsy is needed for postmenopausal bleeding	• Review the risk factors for the development of endometrial cancer and reason for this screening test • Assist in preparing the client for this examination
CA-125	Nonspecific blood test used as a tumor marker	Elevation of marker suggests malignancy but is not specific to ovarian cancer	• Review risk factors for ovarian cancer and explain that a series of diagnostic tests may be performed (transvaginal ultrasound, CT scan, CA-125) to assist in the diagnosis and treatment plan • Elevated marker levels are not specific to ovarian cancer; they can be elevated in other types of cancer

Nursing Diagnoses and Related Interventions

Upon completion of a thorough assessment, the nurse might identify several nursing diagnoses, including:

- Deficient knowledge
- Disturbed body image
- Anxiety
- Fear
- Pain

Nursing goals, interventions, and evaluation for the woman with reproductive cancer are based on the nursing diagnoses. Nursing Care Plan 8.1 (at the end of the chapter) may be used as a guide in planning nursing care for the woman with reproductive cancer. It should be individualized based on the woman's symptoms and needs.

Nurses have traditionally served as advocates in the health care arena and should continue to be on the forefront of health education and diagnosis, acting as leaders in the fight against cancer. Over half a million women in the United States will be diagnosed with cancer this year alone and more than half will die of it (Siegel, Miller, & Jemal, 2015). The public needs to know that not only are these deaths preventable, but many of the cancers themselves are preventable. Nurses need to work to improve the availability and quality of cancer-screening services,

making them accessible to underserved and socioeconomically disadvantaged clients. Through a unified effort by health care providers, health policy experts, government agencies, health insurance companies, the media, educational institutions, and women themselves, along with consistency and continuity, nurses can offer quality care to all women with cancer.

Educating to Prevent Cancer

Globally, there are nearly 13 million new cases of cancer and 8 million deaths from cancer each year. The most important cause of cancer is tobacco, which causes 30% of cancer deaths. Dietary factors, including obesity, are estimated to cause around 25% of cancer deaths, and alcohol about 6% of cancer deaths. All of these factors associated with cancer are preventable (Key, 2015). Nurses need to provide clients with information to help prevent disease and enhance quality of life. Educate women about the importance of consistent and timely screenings to identify cancer early. Emphasize the importance of having an annual pelvic examination. Also stress the need for follow-up screenings as recommended. Provide clients with information if further diagnostic testing is required. Nurses also play a key role in promoting cancer awareness, prevention, and control. Advocate improving the availability of cancer-screening services and work to provide public education about risk factors for cancer.

Nurses can be instrumental in helping women to identify and change behaviors that put them at risk for various reproductive tract cancers (Teaching Guidelines 8.1). Do not limit your interventions to providing preventive education only: inform women about the consequences of doing nothing about their conditions and what the long-range outcomes might be without treatment. For example, stress the importance of visiting a health care provider if certain signs and symptoms appear:

- Blood in a bowel movement is considered abnormal
- Unusual vaginal discharge or chronic vulvar itching
- Persistent abdominal bloating or constipation
- Irregular vaginal bleeding
- Persistent low backache not related to standing
- Elevated or discolored vulvar lesions
- Bleeding after menopause
- Pain or bleeding after sexual intercourse

Teaching Guidelines 8.1
REDUCING YOUR RISK FOR CANCER

- Do not smoke; smoking is linked to lung cancer development.
- Drink alcohol only in moderation (no more than one drink daily).
- Be physically active daily.
- Eat a healthy diet.
- Stay current with immunizations.
- Use a condom with every sexual encounter.
- Reach and maintain a healthy weight.

- Take preventive medicines if needed.
- Get recommended screening tests:
- Body mass index (BMI) to identify obesity
- Mammogram every 1 to 2 years starting at age 40
- Pap smear every 1 to 3 years if sexually active, between the ages of 21 and 65
- Cholesterol checked annually starting at age 45
- Blood pressure checked at least every 2 years
- Diabetes test if hypertensive or hypercholesterolemia
- Check for STIs if sexually active

Teaching the Client About Her Diagnosis

Provide information about tests that may be required to confirm or rule out the diagnosis. Review with the woman what she has been told about her diagnosis and her understanding of her condition. It is not unusual for the woman to hear the diagnosis and then become overwhelmed by the thought of cancer, blocking out whatever is said after that. Answer any questions she may have. Go slowly and repeat the information as necessary. Use written materials to explain and reinforce the teaching. Provide information about her condition and recommended therapies. For example, if a client is undergoing surgery, discuss postoperative issues such as incision care, pain, and activity level. Instruct the client on health maintenance activities after treatment, and inform her and her family about available support resources.

Providing Emotional Support

Once the diagnosis is made, provide the woman and her family with emotional support. Validate the client's feelings and provide realistic hope, using a nonjudgmental approach and therapeutic communication skills during all interactions. Nurses can be invaluable when assisting women who are coping with the uncertainty of their future by providing positive communication and support. Nurses need to focus on the physical, psychosocial, and economic concerns, from diagnosis through treatment and, if applicable, until the end of life, for all of the women for whom they care. Individualize the care based on the client's cultural traditions and beliefs, as explained in the following section.

ENSURING CULTURALLY COMPETENT CANCER CARE

Cultural diversity in America is increasing, and as diverse cultures interact, conflicts inevitably ensue. These conflicts can affect health care outcomes. Providing culturally competent cancer care can improve outcomes and decrease

disparities in care. If nurses are to meet the needs of ethnically diverse populations, they must be culturally sensitive, appreciative of differing health beliefs and practices, and very flexible in the way they approach health care. It is we who must adapt, expand, and learn.

Nurses have the opportunity to learn about diverse cultures, religions, and faith traditions that support clients and families during their cancer journey and while facing a serious life-limiting illness. Nurses' care practices embrace all clients with whom they come in contact and, by having a better understanding of diverse groups, nurses can build trust in clients seeking oncology care needs that range from detection to diagnosis and treatment possibly through palliative care and end of life.

Be aware of the client's cultural background, religion, migration history, degree of acculturation, living conditions, educational level, and legal status, because each of these factors can affect the client's understanding of her diagnosis and the eventual outcome. A woman's reaction to a cancer diagnosis and her decisions about treatment are influenced by an individual's cultural values and how the community views cancer. A diagnosis of cancer carries deep physical, psychosocial, and cultural implications. Sensitive cross-cultural communication and cultural competence are vital for all nurses to deliver equal care to all cancer clients. Nurses need to understand the disparities and the influence of those disparities on health outcomes. Women with cancer reflect the demographic changes occurring in the United States and represent increasing differences in culture, religion, socioeconomic status, race, and lifestyle. Through embracing and learning from these differences, nurses become stronger care providers (Surbone, 2015).

In some cultures, sharing news of a serious illness like cancer is considered disrespectful and impolite. For example, some Europeans view such sharing as inhumane; the Asian culture views a cancer diagnosis as unnecessarily cruel. The Chinese, out of respect for aging family members, withhold discussions of serious illness to avoid causing unnecessary anxieties (Lofters, 2015). Integrate this knowledge in your care to ensure a culturally competent approach.

Take Note!

When a diagnosis of cancer is made, assessing an individual's strengths and weaknesses from a cultural perspective will help the nurse to provide culturally competent care.

As life becomes increasingly multilingual, multicultural, and multireligious, learning about clients' values and cultural beliefs becomes challenging. Be willing to learn about client preferences; doing so promotes caring and nurturing.

SUPPORTING THE PREGNANT WOMAN WITH CANCER

Pregnancy complicated by cancer is relatively rare, occurring in 1 out of every 1,000 pregnancies (Cancer.Net, 2015a). The incidence is increasing because women in Western societies are tending to delay childbearing to the third and fourth decade of life; this phenomenon is going to be encountered more often in the future by nurses. The most frequent malignancies diagnosed during pregnancy are breast cancer, **cervical cancer**, hematologic malignancies (lymphomas and acute leukemia), and melanoma. Breast cancer is the most common cancer

diagnosed in pregnant women which affects approximately 1 in 3,000 pregnancies. Less common tumors during pregnancy include gastrointestinal, ovarian, urologic, and lung cancers (Amant et al., 2015).

Theoretically, changes in the mother's immune system during pregnancy can increase the risk of malignancy because cell-mediated immunity, which is suppressed in pregnant women, normally protects against cancerous tumors (Kim & Chu, 2015). Some research has hinted at an increased rate of progression and decreased survival times in women who develop breast and cervical cancer and then become pregnant, but this generally has not been validated by research studies. With the cooperation of multidisciplinary teams, treatment of cancer during pregnancy with normal fetal outcome is feasible (Andersson et al., 2015).

Ovarian cancer during pregnancy is rare because the disease typically occurs in older women. Because most pregnant women receive frequent medical care, including pelvic examinations, most ovarian cancers in pregnant women are found at early stages; this carries a good prognosis for both the mother and the newborn. The presence of ascites indicates advanced disease (de Haan, Verheecke, & Amant, 2015).

Endometrial cancer is the most common neoplasia of the female reproductive system, with the highest incidence among uterine malignancies. It is rarely associated with pregnancy. Adenocarcinoma associated with pregnancy is typically endometrioid, focal, well differentiated, and minimally invasive. Active treatment of endometrial cancer is incompatible with continuation of the pregnancy. Since routine screening for endometrial cancer is currently not recommended in the general population, few cases would be detected in the relatively young pregnant population (Cancer in Pregnancy, 2015a). Cervical cancer is more common in the pregnant population than other reproductive malignancies, and it can affect the woman's health status and the pregnancy. Approximately 30% of women diagnosed with cervical cancer are in their reproductive years, whereas 3% of cervical cancers are diagnosed during pregnancy (Cancer in Pregnancy, 2015b). Management of cervical cancer during pregnancy depends on the following factors:

- Stage of the disease (and the tumor size)
- Nodal status
- Histologic subtype of the tumor
- Term of the pregnancy
- Whether the client wishes to continue her pregnancy
- Woman's desire for future fertility

In women with early-stage disease and absence of nodal involvement who are diagnosed during the first two trimesters of pregnancy, there is an increasing tendency to preserve the pregnancy while awaiting fetal maturity. The birth (when the fetal maturity is attained) should be performed using a cesarean section (ACS, 2015c). Treatment decisions are influenced by the stage of the cancer, the histologic type, the stage of the pregnancy, and the client's wishes. Both maternal and fetal safety and well-being have to be taken into account. Termination of pregnancy is not indicated in all cases. Pregnancy preservation in tumors diagnosed during early gestation is feasible in carefully selected cases. Discussion with the client and her family is essential and treatment has to be individualized

(ACS, 2015c).

Nurses caring for young clients with cervical cancer must be aware of the surgical fertility preservation options, which clients are candidates for these surgeries, and the options for future assisted reproductive technology. Nurses need to be able to coordinate care for these clients with gynecologic oncologists and reproductive endocrinologists in order to facilitate optimal outcomes.

Women diagnosed with any malignancy during pregnancy must confront the reality of the disease and its impact on their future fertility and live with the risk of recurrence. The prognosis for a pregnant woman with cancer is often the same as other women of the same age with the same type of cancer (Cancer.Net, 2015a). The wishes of the pregnant woman and her family are of paramount importance when making decisions about continuing the pregnancy and undergoing cancer treatment. Some women will decide to terminate the pregnancy for the sake of their own health; others will undergo treatment during the pregnancy to preserve the life of the unborn child. Regardless of the woman's decision, provide support, hope, and education during treatment, birth, and beyond.

OVARIAN CANCER

Ovarian cancer is malignant neoplastic growth of the ovary (Fig. 8.1). It is the ninth most common cancer among women and the fifth most common cause of cancer deaths for women in the United States. It accounts for more deaths than any other cancer of the reproductive system (ACS, 2015d). A woman's risk of getting invasive ovarian cancer in her lifetime is about 1 in 75. Her lifetime chance of dying from invasive ovarian cancer is about 1 in 100 (ACS, 2015d). This cancer mainly develops in older women. About half of the women who are diagnosed with ovarian cancer are 63 years or older. It is more common in White women than African-American women (ACS, 2015d).

The most important variable influencing the prognosis is the extent of the disease. Survival depends on the stage of the tumor, grade of differentiation, gross findings at surgery, amount of residual tumor after surgery, and effectiveness of any adjunct treatment postoperatively. Many women with ovarian cancer will experience recurrence despite best efforts to eradicate the cancer through surgery, radiation, or chemotherapy to eliminate residual tumor cells. The likelihood of long-term survival in the event of recurrence is dismal (Matsumoto, Onada, & Yaegashi, 2015). The 5-year survival rates (the percentage of women who live at least 5 years after their diagnosis) are shown in Table 8.1 according to stage.

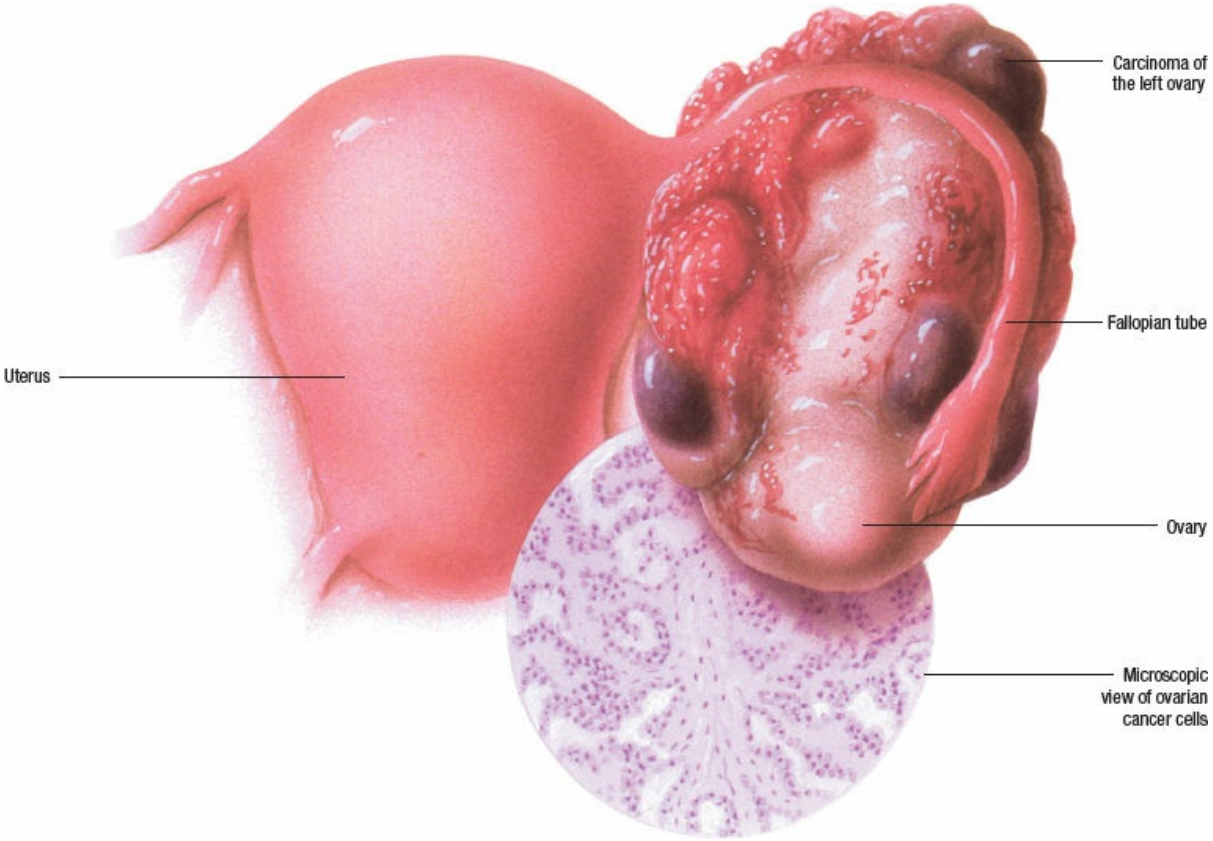

FIGURE 8.1 Ovarian cancer. (Asset provided by Anatomical Chart Co.)

Pathophysiology

Ovarian cancer, the cause of which is unknown, can originate from different cell types. Most ovarian cancers are thought to originate in the ovarian epithelium. New insights now propose a pivotal role for the fallopian tube during ovarian cancer pathogenesis. Increasing evidence suggests that serous ovarian cancer originates from the fimbriated distal end of the fallopian tube, whereas the ovary gets only involved at a later stage. These represent 50% to 60% of all epithelial ovarian cancers. Based on this finding, a post-reproductive salpingectomy deserves consideration as a prophylactic intervention that may confer protection against an often deadly disease (Poole et al., 2015).

Tumors usually present as solid masses that have spread beyond the ovary and seeded into the peritoneum prior to diagnosis. Thorough understanding of the true pathogenesis of this cancer's origin could lead to the development of new and more effective therapies as well as novel biomarkers in early detection.

TABLE 8.1 FIVE-YEAR SURVIVAL RATES FOR OVARIAN CANCER

Stage	Five-Year Relative Survival Rates
I	80–94%
II	57–76%
III	34–45%
IV	18%

Adapted from American Cancer Society [ACS]. (2015o). *Survival rates for ovarian cancer by stage*. Retrieved from http://www.cancer.org/cancer/ovariancancer/detailedguide/ovarian-cancer-survival-rates

Screening and Diagnosis

Women with ovarian cancer are typically diagnosed at a late stage, when the cancer has spread into the peritoneal cavity and complete surgical removal is challenging. Seventy-five percent of ovarian cancers are not diagnosed until the cancer has advanced to stage III or IV, primarily because there is still no adequate screening test. The 5-year survival time for women diagnosed at this stage is 30%, in contrast with a 5-year survival of 90% for women diagnosed at an early stage (Wright et al., 2015). The United States Preventive Services Task Force (USPSTF) (2015), along with the American College of Obstetricians and Gynecologists (ACOG), and the American Medical Association (AMA) recently reviewed the evidence for ovarian cancer screening and did not recommend screening for women at average risk. However, women with increased risk related to BRCA ½ mutations or a family history of ovarian cancer should be considered for genetic counseling to further evaluate their risk (Cliby et al., 2015).

Two genes, BRCA1 and BRCA2, are linked with hereditary breast and ovarian cancers. Blood tests can be performed to assess DNA in white blood cells to detect mutations in the BRCA genes. These genetic markers do not predict whether the person will develop cancer. Rather, they provide information regarding the risk of developing cancer: a woman who is BRCA positive may have up to an 80% chance of developing breast cancer and a 40% chance of developing ovarian cancer (Liede, Sun, & Narod, 2015).

To assist in screening, researchers have developed an ovarian cancer symptom index that includes pelvic and abdominal pain, urinary frequency and urgency, increased abdominal size (bloating), and difficulty eating (feeling full). But this symptom index is not much help in detecting the disease early, as these symptoms tend to go unrecognized, leading to delays in diagnosis. When the presentation of such symptoms triggers a medical evaluation for ovarian cancer, the disease is diagnosed in only 1 in 100 women. The NCI reports that the present symptom index has a "low positive predictive value," especially for early-stage disease discovery (NCI, 2015d).

Specific clinical guidelines for ovarian cancer screening have not been developed, so the disease is often not diagnosed until it has metastasized. The USPSTF recommends against routine screening for ovarian cancer with serum CA-125 or transvaginal ultrasound because earlier detection would have a small effect, at best, on mortality. CA-125 is a biologic tumor marker associated with ovarian cancer.

Although levels are elevated in many women with ovarian cancer, CA-125 is not specific for this cancer and levels may be elevated with other malignancies (pancreatic, liver, colon, breast, and lung cancers). Despite the discovery that CA-125 and other serum markers increase before the clinical onset of ovarian cancer, it has proven surprisingly difficult to devise a successful screening program for asymptomatic women with ovarian cancer. Currently, it is not sensitive enough to serve as a screening tool alone (Ebell et al., 2015). The USPSTF (2015) reports that there is no supporting evidence that any screening test, including a CA-125, ultrasound, or pelvic examination, reduces mortality from ovarian cancer. Thus they recommend against routine screening for ovarian cancer.

Therapeutic Management

Treatment options for ovarian cancer vary depending on the stage and severity of the disease. Usually a laparoscopy (abdominal exploration with an endoscope) is performed for diagnosis and staging, as well as evaluation for therapy. In stage I the cancer is limited to the ovaries. In stage II the growth involves one or both ovaries, with pelvic extension. Stage III cancer has spread to the lymph nodes and other organs or structures inside the abdominal cavity. In stage IV, the cancer has metastasized to distant sites (Alexander et al., 2014). Figure 8.2 shows the likely metastatic sites for ovarian cancer.

Surgical intervention remains the mainstay of management of ovarian cancer. Surgery generally includes a total abdominal hysterectomy, bilateral salpingo-oophorectomy, peritoneal biopsies, omentectomy (excision of all or part of the omentum, which is a sheet of fat covered by the peritoneum that protects the abdominal structures), and pelvic para-aortic lymph node sampling to evaluate cancer extension (Nick et al., 2015). Because most women are diagnosed with advanced-stage ovarian cancer, aggressive management involving debulking or cytoreductive surgery is commonly performed. This surgery involves resecting all visible tumors from the peritoneum, taking peritoneal biopsies, sampling lymph nodes, and removing all reproductive organs and the omentum. This aggressive surgery has been shown to improve long-term survival rates.

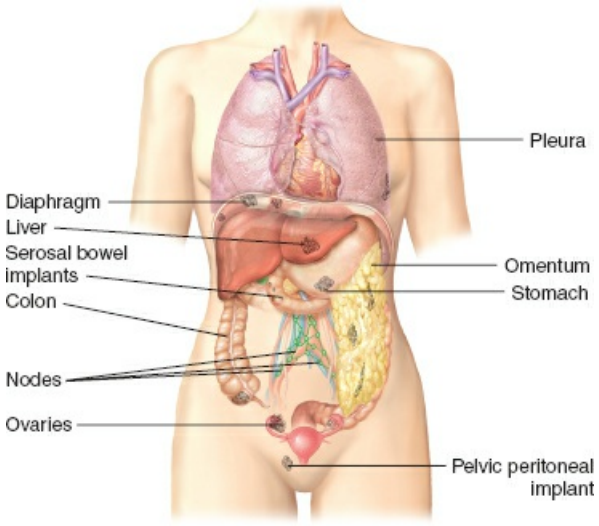

FIGURE 8.2 Common metastatic sites for ovarian cancer. (Asset provided by Anatomical Chart Co.)

Additional therapy with radiation may be warranted. Chemotherapy is recommended for all stages of ovarian cancer. Intraperitoneal chemotherapy, combined with surgery, has produced encouraging results for overall survivals at acceptable morbidity and mortality rates. Despite all of these therapies, virtually the only agreement about treatment for advanced disease is that surgery and chemotherapy play a role, and that current treatment is effective in far too many women (Helm, 2015a).

Nursing Assessment

Ovarian cancers are considered the worst of all the gynecologic malignancies, primarily because they develop slowly and remain silent without symptoms until the cancer is far advanced. It has been described as the "overlooked disease" or "silent killer" because women and health care providers often ignore or rationalize early symptoms. For example, women may attribute gastrointestinal problems to stress and midlife changes. However, these vague complaints may precede more obvious symptoms by months. The most common early symptoms include abdominal bloating, early satiety, fatigue, vague abdominal pain, urinary frequency, diarrhea or constipation, malaise, and unexplained weight loss or gain. The later symptoms include anorexia, dyspepsia, ascites, a palpable abdominal mass, pelvic pain, and back pain (Goldstein et al., 2015).

Obtain a thorough history of the woman's symptoms, including their onset, duration, and frequency. Review the woman's history for risk factors such as:

- Nulliparity
- Early menarche (before 12 years old)
- Late menopause (after 55 years old)
- Increasing age (after menopause)
- High-fat diet
- Obesity
- Persistent ovulation over time
- First-degree relative with ovarian cancer
- Genetics (women of Ashkenazi Jewish decent)
- Use of perineal talcum powder or hygiene sprays
- Older than 30 years at first pregnancy
- Positive BRCA1 and BRCA2 mutations
- Personal history of breast, bladder, or colon cancer
- Hormone replacement therapy (HRT) for more than 10 years
- Infertility (CDC, 2015c)

Perform a complete physical examination. Inspect the abdomen, noting any distention or bloating. Palpate the abdomen. Be alert for a mass or pain on palpation. Anticipate further testing to confirm the diagnosis.

Nursing Management

The complexities of ovarian cancer make a multidisciplinary approach necessary for optimal management. With the subtle nature and high risk of recurrence and mortality of this condition, most women find it an emotionally exhausting and devastating experience. The presence of hope is essential for women at the time of

the diagnosis; they want to believe in being cured and able to continue their life as usual with loved ones, friends, and relatives. Still, the newly received cancer diagnosis makes women oscillate between hope and hopelessness, between positive expectations of getting cured and frightening feelings of the disease taking command. Nurses are invaluable resources in inspiring clients to find hope in life when diagnosed with cancer. Nursing management needs to focus on measures to promote early detection, educate the woman about the disease and its treatments, and provide emotional support. Nurses should show a positive attitude that communicates understanding and reassurance.

Promoting Early Detection

Nurses need to ensure that women are aware of the risk factors for ovarian cancer. Urge women not to dismiss seemingly innocuous symptoms as "just a part of aging." Encourage women to describe such nonspecific complaints at health visits.

Assess the woman's family and personal history for risk factors and encourage genetic testing for women with affected family members. Outline screening guidelines for women with hereditary cancer syndrome and inform women at high risk about the appropriate screening strategies.

Urge women to have yearly bimanual pelvic examinations and a transvaginal ultrasound to allow identification of ovarian masses in their early stages. After menopause, a mass on an ovary is not a cyst: physiologic cysts can arise only from a follicle that has not ruptured or from the cystic degeneration of the corpus luteum. Ovarian cancer is not always silent, and may manifest with several vague gastrointestinal symptoms. Although screening the general population is not recommended, nurses need to know what factors place women at high risk and really listen to women's complaints to detect this type of cancer before it becomes advanced.

Take Note!

A small ovarian "cyst" found on ultrasound in an asymptomatic postmenopausal woman should arouse suspicion. Any mass or ovary palpated in a postmenopausal woman should be considered cancerous until proven otherwise (Helm, 2015b).

Educating the Client

Education is a major focus of nursing care. This teaching involves risk reduction and health promotion. Teach the woman about risk reduction strategies; for instance, pregnancy, use of oral contraceptives, and breast-feeding reduce the risk of ovarian cancer. Instruct women to avoid using talc and hygiene sprays on their genitals. Review the lifetime risks related to *BRCA1* and *BRCA2* genes and options available should the woman test positive for these genes. Help to promote community awareness of ovarian cancer by educating the public about risk-reducing behaviors. See research on reproductive cancer risk factor (Evidence-Based Practice 8.1).

Instruct the woman about the importance of healthy lifestyles. Stress the importance of maintaining a healthy weight to reduce risk. Encourage women to eat a low-fat diet. Factors associated with a reduced risk of ovarian cancer include the use of oral contraceptives for 3 years or longer, pregnancy and breast-feeding before the age of 30, bilateral tubal ligation, and removal of the ovaries (Memorial Sloan

Kettering Cancer Center, 2015).

For the woman who is diagnosed with ovarian cancer, describe in simple terms the tests, treatment modalities, and follow-up needed. For example, if the woman will be having surgery, provide thorough teaching about what to expect before, during, and after surgery. Outline treatment options and the implications of choices. Assist the woman and her family to decipher the myriad of information related to staging, tests, and treatments. Teach the woman about additional treatment measures, such as radiation therapy or chemotherapy, including how to handle the common adverse effects of treatment.

Supporting the Client and Family

The diagnosis of ovarian cancer, like any cancer, can be overwhelming. In addition, the treatments and their effects can be highly stressful, both physically and emotionally. Provide one-to-one support for women facing treatment for ovarian cancer. Ovarian cancer involves the reproductive system, which has a direct impact on the woman's view of herself. Encourage open discussion of sexuality and the impact of cancer. Listen and support the woman and her family as they try to cope with this disease. By being aware of women's individual needs and different coping strategies, nurses can improve support to women in this vulnerable situation. Encourage the use of appropriate coping strategies to allow for the best quality of life. Try to restore hope to women with ovarian cancer, and stress treatment compliance. Nurses should not forget about the family caregivers who need help with managing emotions about prognosis, balancing their own and the client's needs, work, and decision-making when there is uncertainty. If appropriate, encourage participation in clinical trials to offer hope for all women. Continue to offer support to the woman and her family members as they experience sadness and grief.

EVIDENCE-BASED PRACTICE 8.1

DOES OVARIAN STIMULATION FOR IVF INCREASE GYNECOLOGIC CANCER RISK? A SYSTEMATIC REVIEW AND META-ANALYSIS

STUDY

Drugs to stimulate ovulation have been widely used for various types of subfertility since the early 1960s, and their use has increased in recent years. The use of assisted reproductive techniques is increasing, but the possible link between fertility drugs and reproductive cancer remains controversial. Subfertile women are commonly exposed to these agents, which may be administered at high doses for long periods of time during treatment for subfertility. There is uncertainty about the safety of these drugs and the potential risk of causing cancers associated with their use. The objective of this study was to evaluate the risk of reproductive cancer in women previously treated with ovulation-stimulating drugs for infertility.

Findings

A systematic review and meta-analysis was conducted. Clinical trials that examined the association between ovarian stimulation for IVF and gynecologic cancers were included. Twelve cohort studies with 178,396 women exposed to IVF were included.

The meat-analysis found no significant association between ovarian stimulation for IVF and increased ovarian, endometrial, cervical, and breast cancer risk. Ovarian stimulation for IVF, therefore, does not increase the gynecologic risk, whether hormone-dependent endometrial and breast cancer risk or non–hormone-dependent ovarian and cervical cancer. This study found no convincing evidence of an increased risk of reproductive cancer with fertility drug treatment.

Nursing Implications

Nurses can use the information from this study to reassure women that having experienced infertility and undergone in vitro fertilization treatments in the past are not increasing their risk of having reproductive cancer later in life. When women are trying to decide to undergo fertility treatment using drug therapy, it can be very anxiety producing for them as well as their partners. Knowing that in vitro fertilization treatment will not increase their risk of reproductive cancer as they age based on earlier exposure to ovulation-stimulating drug therapy can reduce their anxiety regarding their decision.

Adapted from Li, Y., Zhao, J., Zhang, Q., & Wang, Y. (2015). Does ovarian stimulation for IVF increase gynecological cancer risk? A systematic review and meta-analysis. *Reproductive BioMedicine Online*, *31*(1), 20–29.

Consider This

I felt I was a lucky woman because I had been in remission from breast cancer for 12 years, and I had been given the gift of life to share with my beloved family. Recently I became ill with stomach problems: pain, indigestion, bloating, and nausea. My doctor treated me for gastric reflux disease, but the symptoms persisted. I then was referred to a gastroenterologist, a urologist, and then a gynecologist, who did an ultrasound, which was negative. I received reassurance from all three that there was nothing wrong with me. As time went by, I experienced more pain, more symptoms, and increased frustration. Six months after seeing all three specialists, a repeat ultrasound revealed I had ovarian cancer, and I needed surgery as soon as possible. I underwent a complete hysterectomy and my surgeon found I was in stage III. Since then, I have undergone chemotherapy and participated in a clinical cancer study that wasn't successful for me, and now I am facing the fact that I am going to die soon.

Thoughts: This woman has tried everything to save her life, but, alas, time has run out for her with advanced ovarian cancer. Women diagnosed with breast cancer are at a significant risk for developing ovarian cancer later in life. Of the string of doctors she saw, one has to ponder why none ordered more extensive testing, given her history of breast cancer. We are haunted with the question: If they had, would she be in stage III now? We will never know.

ENDOMETRIAL CANCER

Endometrial cancer (also known as uterine cancer) is malignant neoplastic growth of the uterine lining. It is the fourth most common gynecologic malignancy and accounts for 6% of all cancers in women in the United States or 1 in 37 women. The NCI (2015e) estimates that about 54,870 new cases will be diagnosed in women in 2015 and that approximately 10,170 of these women will die. Endometrial cancer is responsible for over 75,000 deaths annually among women worldwide (Siegel, Miller, & Jemal, 2015). It is uncommon before the age of 55, but as women age, their risk of endometrial cancer increases. Approximately 80% of these malignancies are carcinomas of the endometrium. Because endometrial cancer is usually

diagnosed in the early stages, it has a better prognosis than cervical or ovarian cancer (ACS, 2015e).

The increasing incidence and prevalence of endometrial cancer can be explained by the increase in life expectancy, increased caloric intake, increased obesity rates, infertility, null parity (never bearing children), older age of first pregnancy, and long-term use of unopposed estrogens for HRT. Protection against endometrial cancer includes increased parity, daily physical activity, use of combined oral contraceptives, and increased age of women at last childbirth (Schmid et al., 2015).

Pathophysiology

Two mechanisms are believed to be involved in the development of endometrial cancer. A history of exposure to unopposed estrogen is the cause in approximately 80% of women. Those that are spontaneous and are unrelated to estrogen or endometrial hyperplasia represent the other 20% of endometrial cancers. There has been an increase in incidence over the past several decades associated with and increased use of estrogen replacement therapy (without progestin) and obesity (adipose fat converts androstenedione to estrone, thereby increasing circulating estrogen levels) (Temple, 2015).

Endometrial cancer may originate in a polyp or in a diffuse multifocal pattern. The pattern of spread partially depends on the degree of cellular differentiation. Well-differentiated tumors tend to limit their spread to the surface of the endometrium. Metastatic spread occurs in a characteristic pattern and most commonly involves the lungs, inguinal and supraclavicular nodes, liver, bones, brain, and vagina (NCI, 2015f). Early tumor growth is characterized by friable and spontaneous bleeding. Later tumor growth is characterized by myometrial invasion and growth toward the cervix (Fig. 8.3).

Adenocarcinoma of the endometrium is typically preceded by hyperplasia. Carcinoma in situ is found only on the endometrial surface. Type I carcinomas, the most common, begin as endometrial hyperplasia and progress to carcinomas. Giving estrogen preparations without progestin for HRT leads to an increased risk for endometrial cancer. Type I is generally found at an earlier stage and treatment results are more favorable.

Unlike type I endometrial carcinoma, type II carcinomas appear spontaneously, are associated with a poorly differentiated cell type, and have a poor prognosis. They account for less than 10% of all endometrial cancers but contribute to the majority of all endometrial deaths. This type is unrelated to estrogen or endometrial hyperplasia (ACS, 2015f).

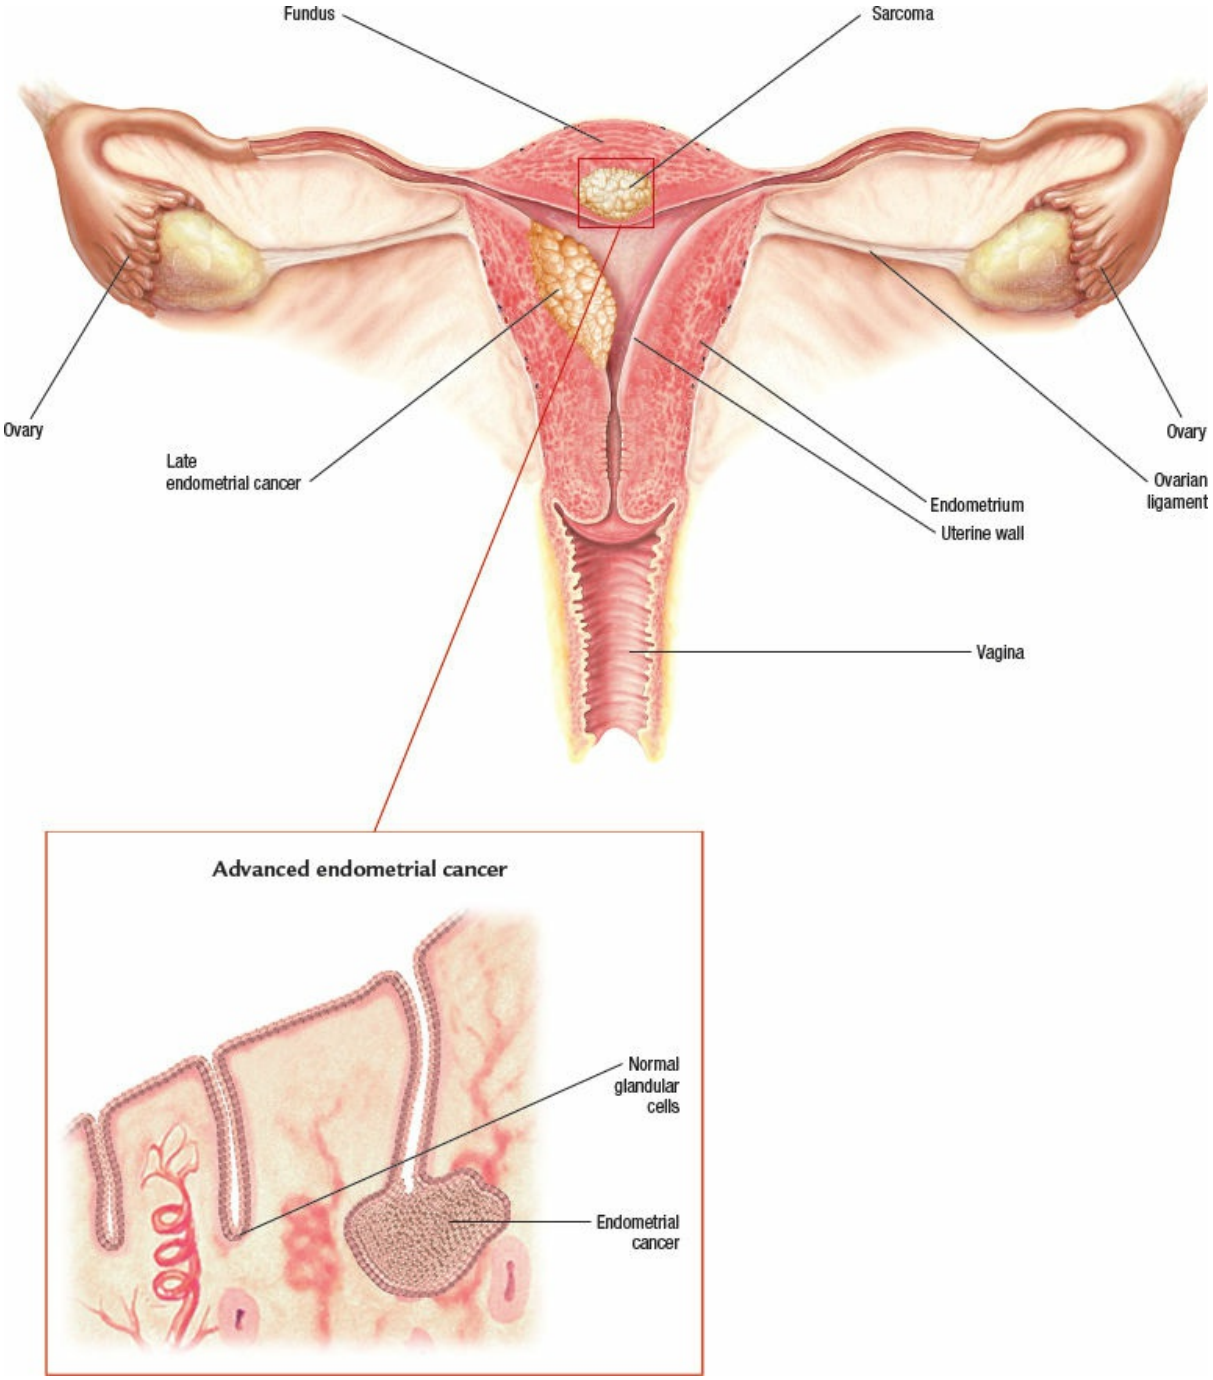

FIGURE 8.3 **Progression of endometrial cancer. (Image 1 provided by Anatomical Chart Co.)**

Remember Carmella, the woman with postmenopausal bleeding? In postmenopausal women, any bleeding is abnormal and warrants further assessment. What testing would the nurse anticipate as being ordered to confirm the diagnosis? What would be the nurse's role during this testing?

Screening and Diagnosis

There is no specific screening test currently available to detect endometrial cancer. Screening for endometrial cancer is not routinely done because it is not practical or

cost effective. The ACS (2015f) recommends that women be informed about the risks and symptoms of endometrial cancer at the onset of menopause and strongly encouraged to report any unexpected bleeding or spotting to their health care provider. A pelvic examination is frequently normal in the early stages of the disease. Changes in the size, shape, or consistency of the uterus or its surrounding support structures may exist when the disease is more advanced.

During the past two decades, the role of ultrasound in the evaluation of postmenopausal bleeding has changed markedly, from little or no role to a major role today. In the intervening years, numerous studies have shown that ultrasound is at least as sensitive as endometrial biopsy for endometrial cancer and that ultrasound can reliably exclude cancer without the need for biopsy in some women with postmenopausal bleeding. The depth of myometrium is an important diagnostic factor. In particular, numerous studies have shown that women with an endometrial thickness of 4 mm or less have an extremely low likelihood of endometrial cancer and thus do not need to undergo endometrial biopsy. Ultrasound can also help in the selection of an appropriate biopsy technique. In a woman with postmenopausal bleeding and a thick endometrium, a sonohysterogram can determine whether the endometrium is diffusely thick or has focal areas of thickening. With diffuse thickening, an endometrial biopsy is appropriate. When one or more focal areas of thickening are present, hysteroscopic biopsy is likely to be the better choice. Typically, the noninvasive ultrasound is done first before an invasive endometrial biopsy is attempted (Dueholm et al., 2015).

Transvaginal ultrasound can be used to evaluate the endometrial cavity and measure the thickness of the endometrial lining. It can be used to detect endometrial hyperplasia. If the endometrium measures less than 4 mm, then the client is at low risk for malignancy. Large prospective studies have shown that an endometrial thickness of ≤ 4 mm on transvaginal ultrasound in postmenopausal women with bleeding has a low risk of malignancy. Thus, in postmenopausal clients with bleeding, biopsy is not indicted when endometrial thickness is ≤ 4 mm, thereby avoiding invasive diagnostics (Wong et al., 2015).

Endometrial biopsy is an office procedure that is also one of the first steps in the diagnosis of endometrial cancer in a woman with postmenopausal bleeding. The biopsy is obtained through the use of an endometrial suction catheter that is inserted through the cervix into the uterine cavity and a tissue sample is taken. The sensitivity and specificity of the biopsy procedure tend to be in the range of 95% for detection of endometrial cancer or other pathologies (King et al., 2015).

As indicated earlier, staging is the process of looking at all of the information the doctors have learned about the tumor to determine how much the cancer may have spread. The stage of an endometrial cancer is the most important factor in choosing a treatment plan. It can spread *locally* to other parts of the uterus or *regionally* to nearby lymph nodes. The regional lymph nodes are found in the pelvis and farther away along the aorta. Finally, the cancer can spread (*metastasize*) to distant lymph nodes or organs such as lung, liver, bone, brain, and others.

In stage I, the tumor is confined to the corpus uteri. In stage II, it has spread to the cervix, but not outside the uterus. In stage III, it has spread locally and regionally. In stage IV, it has invaded the bladder mucosa, bowel with distant metastases to the lungs, liver, and bone (International Federation of Gynecology & Obstetrics, 2015).

Therapeutic Management

Typically, the stage of the disease directs treatment. It usually involves surgery with adjunct therapy based on pathologic findings. Surgery most often involves removal of the uterus (hysterectomy) and the fallopian tubes and ovaries (salpingo-oophorectomy). Removal of the fallopian tubes and ovaries is recommended because tumor cells spread early to the ovaries, and any dormant cancer cells could be stimulated to grow by ovarian estrogen. In more advanced cancers, radiation and chemotherapy are used as adjuncts to surgery. Routine surveillance intervals for follow-up care are typically every 3 to 4 months for the first 2 years, since 85% of recurrences occur in the first 3 years after diagnosis (Brennan et al., 2015).

Nursing Assessment

Obtain a thorough history from the woman, ascertaining her primary complaint. Most commonly, the major initial symptom of endometrial cancer is abnormal and painless vaginal bleeding. Obtain a menstrual history and inquire if the woman is taking any hormones. Also ascertain if she has a personal or family history of breast, ovarian, or colon cancer. These key pieces of information will assist in identifying the woman at high risk for endometrial cancer.

Take Note!

Any episode of bright-red bleeding that occurs after menopause should be investigated. Abnormal uterine bleeding is rarely the result of uterine malignancy in a young woman, but in the postmenopausal woman it should be regarded with suspicion.

Also review the woman's history for any risk factors, including:

- Nulliparity
- Obesity (more than 50 lb overweight)
- Liver disease
- Infertility
- Diabetes mellitus
- Hypertension
- History of pelvic radiation
- Polycystic ovary syndrome
- Early menarche (before 12 years old)
- High-fat diet
- Use of prolonged exogenous unopposed estrogen with an intact uterus
- Endometrial hyperplasia
- Family history of endometrial cancer
- Personal history of hereditary nonpolyposis colon cancer
- Personal history of breast, colon, or ovarian cancer
- History of uterine fibroids
- Late onset of menopause (after age 52 years)
- Tamoxifen use
- Chronic anovulation (Moses, 2015)

Assess the woman for additional manifestations, such as dyspareunia, low back pain, purulent genital discharge, dysuria, pelvic pain, weight loss, and a change in

bladder and bowel habits. These may suggest advanced disease.

Perform a physical examination or assist with, as appropriate, a pelvic examination. Observe for vaginal discharge. Note any changes in the size, shape, or consistency of the uterus or surrounding structures or client reports of pain during examination. Anticipate the need for transvaginal ultrasound to identify endometrial hyperplasia (usually greater than 4 mm) and endometrial biopsy to identify malignant cells.

Nursing Management

Ensure that the woman understands all of the treatment options. Address any concerns the woman expresses, including questions about sexuality. Ensure that follow-up appointments are scheduled appropriately. Refer the client to a support group. Offer the woman and family explanations and emotional support throughout.

Educate the client about preventive measures or follow-up care if she has been treated for cancer. Education may be the most important tool currently available for the early detection of endometrial cancer. Many risk factors for endometrial cancer are modifiable or treatable, including obesity, hypertension, and diabetes. Educating women about risk factors and ways to decrease the risks is essential so that women can learn about their own risk and can become partners in the fight against the number-one gynecologic cancer (Teaching Guidelines 8.2).

Teaching Guidelines 8.2
PREVENTIVE AND FOLLOW-UP MEASURES FOR ENDOMETRIAL CANCER

- Schedule regular pelvic examinations after the age of 21.
- Visit health care practitioner for early evaluation of any abnormal bleeding after menopause.
- Maintain a low-fat diet throughout life.
- Exercise daily.
- Manage weight to discourage hyperestrogenic states, which predispose to endometrial hyperplasia.
- Pregnancy serves as a protective factor by reducing estrogen.
- Ask your doctor about the use of combination estrogen and progestin pills.
- When combination oral contraceptives are taken to facilitate the regular shedding of the uterine lining, take risk reduction measures.
- Be aware of risk factors for endometrial cancer and make modifications as needed.
- Report any of the following symptoms immediately:
  - Bleeding or spotting after sexual intercourse
  - Bleeding that lasts longer than a week
  - Reappearance of bleeding after 6 months or more of no menses
- After cancer therapy, schedule follow-up appointments for the next few years.
- After cancer therapy, frequently communicate with your health care provider concerning your status.

• After surgery, maintain a healthy weight.

***Carmella's* endometrial biopsy indicates endometrial adenocarcinoma. Her health care provider recommends surgery and adjuvant radiation therapy. How long will Carmella need to follow up after surgery? What lifestyle changes will the nurse need to stress with Carmella?**

CERVICAL CANCER

Cervical cancer is cancer of the uterine cervix. It is the third most common genital malignancy in women in the United States, after cancers of the endometrium and the ovary. The ACS (2015g) estimates that over 13,000 cases of invasive cervical cancer will be diagnosed in the United States in women in 2015 and that approximately 4,100 of these women will die. Some researchers estimate that noninvasive cervical cancer (carcinoma in situ) is about four times more common than invasive cervical cancer. The 5-year survival rate for all stages of cervical cancer is 72% (ACS, 2015g). Cervical cancer is five to eight times more common in women affected with HIV or AIDS than those who do not have this virus.

Hispanic women are most likely to get cervical cancer, followed by African Americans, Asians and Pacific Islanders, and Whites. Cervical cancer remains a disease of socioeconomic disparity. The high mortality rates of minorities are indicative of barriers to health care among those living in poverty. Hispanic women also have the highest rates of poverty, poor access to health care, and language and cultural barriers. Barriers to screening and prevention of cervical cancer include procrastination, fear of finding out that they have cancer, and embarrassment about having a **Papanicolaou (Pap) test**. In addition, most have little to no knowledge about HPV and its link with cancer (Strohl et al., 2015).

The incidence and mortality rates of cervical cancer have decreased noticeably in the past several decades, with most of the reduction attributed to the Pap test, which detects cervical cancer and some precancerous lesions. The Pap test (also known as a Pap smear) is a procedure used to obtain cells from the cervix for cytology screening. Cervical cancer is one of the most treatable cancers when detected at an early stage (ACS, 2015g). *Healthy People 2020* identifies several goals that address cervical cancer (Healthy People 2020 8.1; U.S. Department of Health & Human Services, 2015). Cervical cancer tends to occur in midlife. Most cases are found in women younger than age 50. It rarely develops in women younger than age 20. Many older women do not realize that the risk of developing cervical cancer is still present as they age. The probability of a woman in the United States developing cervical cancer is approximately 1 in 120, but this statistic is age dependent; the highest incidence is in women 40 to 49 years of age (Sawaya et al., 2015).

Pathophysiology

Cervical cancer starts with abnormal changes in the cellular lining or surface of the cervix. Typically, these changes occur in the squamous–columnar junction of the cervix. Here, cylindrical secretory epithelial cells (columnar) meet the protective flat

epithelial cells (squamous) from the outer cervix and vagina in what is termed the transformation zone. The continuous replacement of columnar epithelial cells by squamous epithelial cells in this area makes these cells vulnerable to taking up foreign or abnormal genetic material (ACS, 2015h). Figure 8.4 shows the pathophysiology of cervical cancer.

HPV infection must be present for cervical cancer to occur. HPV infections occur in a high percentage of sexually active women, but a successful immune response results in viral control or clearance of HPV. Most people who have HPV are asymptomatic and, therefore, do not realize they have the virus. More than 90% of squamous cervical cancers contain HPV DNA, and the virus is now accepted as a major causative factor in the development of cervical cancer and its precursor, **cervical dysplasia** (disordered growth of abnormal cells). Since only a small proportion of HPV infections progress to cancer, other factors must be involved in the process of carcinogenesis.

HEALTHY PEOPLE 2020

Objectives	Nursing Significance
C-3 Reduce the female breast cancer death rate **C-4** Reduce the death rate from cancer of the uterine cervix **C-10** Reduce invasive uterine cervical cancer **C-11** Reduce late-stage female breast cancer **C-15** Increase the proportion of women who receive a cervical cancer screening based on the most recent guidelines **C-17** Increase the proportion of women who receive a breast cancer screening based on the most recent guidelines **C-18** Increase the proportion of women who were counseled about mammograms and Pap smear cancer screening consistent with current guidelines **C-20** Increase the proportion of persons who participate in behaviors that reduce their exposure to harmful ultraviolet (UV) irradiation and avoid sunburn	• Will help improve mortality rates and quality of life for women, and reduce health care costs related to treatment of malignancies. • Will help to promote screening and early detection. The National Institutes of Health (2015) reported that half of the women diagnosed with invasive cervical cancer have never had a Pap smear and 10% have not had Pap smears during the past 5 years • Will raise awareness of cancer screening and prevention on a local and national level to improve and promote the health of all women. • Will reduce the number of new cancer cases, as well as the illness, disability, and death caused by cancer. • Will reflect the importance of promoting evidence-based screening for cervical and breast cancer by lower mortality rates.

Note: *All cancer objectives project a 10% improvement from the baseline by 2020.*
Healthy People objectives based on data from http://www.healthypeople.gov

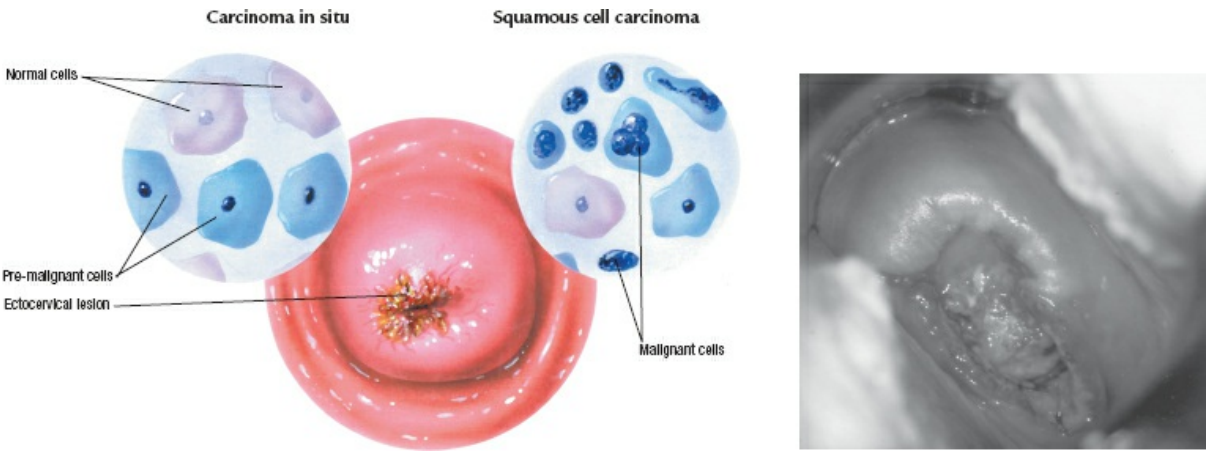

FIGURE 8.4 Cervical cancer. (Illustration is from The Anatomical Chart Company. [2009]. ***Atlas of pathophysiology*** **[3rd**

ed.]. Philadelphia, PA: Lippincott Williams & Wilkins.)

Screening and Diagnosis

Screening for cervical cancer is very effective because the presence of a precursor lesion, cervical intraepithelial neoplasia, helps determine whether further tests are needed. Lesions start as *dysplasia* and progress in a predictable fashion over a long period, allowing ample opportunity for intervention at a precancerous stage. Progression from low-grade to high-grade dysplasia takes an average of 9 years, and progression from high-grade dysplasia to invasive cancer takes up to 2 years. Three main factors have been postulated to influence the progression of low-grade dysplasia to high grade. These include the type and duration of viral infection, with high-risk HPV type and persistent infection predicting a higher risk for progression; host conditions that compromise immunity, such as multiparity or poor nutritional status; and environmental factors such as smoking, oral contraceptive use, or vitamin deficiencies. In addition, various gynecologic factors, including age of menarche, age of first intercourse, and number of sexual partners, significantly increase the risk for cervical cancer (Broadman & Matthews, 2015).

Widespread use of the Pap test is credited with saving tens of thousands of women's lives and decreasing deaths from cervical cancer. Routine Pap smear testing for all sexually active women has been one of the primary screening methods for early detection of cervical irregularities related to HPV and is crucial for the prevention of cervical cancer.

Despite its outstanding record of success as a screening tool for cervical cancer (it detects approximately 90% of early cancer changes), the conventional Pap smear has a 20% false-negative rate. High-grade abnormalities missed by human screening are frequently detected by computerized instruments (NCI, 2015g). Thus, many technologies have been developed to improve the sensitivity and specificity of Pap testing, including:

- *Thin-Prep:* In this liquid-based technique, the cervical specimen is placed into a vial of preservative solution rather than on a glass slide.
- *Computer-assisted automated Pap test rescreening (Autopap):* An algorithm-based decision-making technology identifies slides that should be rescreened by cytopathologists by selecting samples that exceed a certain threshold for the likelihood of abnormal cells.
- *HPV-DNA typing (Hybrid Capture):* This system uses the association between certain types of HPV (16, 18, 31, 33, 35, 45, 51, 52, and 56) and the development of cervical cancer. This system can identify high-risk HPV types and improves detection and management.
- *Computer-assisted technology (Cytyc CDS-1000, AutoCyte, AcCell):* These computerized instruments can detect abnormal cells that are sometimes missed by technologists (CDC, 2015d).

The high rate of false-negative results may also be due to other factors, including errors in sampling the cervix, in preparing the slide, and in client preparation. Although cytology-based nationwide cervical screening has been helpful in identifying abnormal cervical cells, the sensitivity of cytology for the detection of high-grade precursor lesions is limited. Additionally, adenocarcinoma and its precursors are often missed by cytology. The current insight that infection with HPV

is the causative agent of cervical cancer and its precursors has led to the development of molecular tests for the detection of HPV. Strong evidence now supports the use of HPV testing in the prevention of cervical cancer. It is evident that HPV can be detected in urine-based testing which might eventually become a helpful tool in cervical cancer screening and HPV surveillance efforts. Nurses need to keep up to date on the latest research developments as well as the strengths and weaknesses of various screening methods (Fontenot, 2015).

Although professional medical organizations disagree as to the recommended frequency of screening for cervical cancer, ACOG (2015) recommends that cervical cancer screening should begin at age 21 years (regardless of sexual history), since women younger than age 21 are at very low risk of cancer. In addition, ACOG advises Pap smears every 3 years for women between the ages of 21 and 29 years and every 3 years for women between ages 30 and 65 years old. An HPV co-test should be done every 5 years for this older age group. Cervical cancer screening can be stopped >65 years old with an adequate screening history. Women who have had a hysterectomy should stop screening. Women who have received the HPV vaccine should be screened according to the same guidelines as women who have not been vaccinated. In addition, women must have a clear understanding of the results of Pap smear testing and follow-up guidelines. High-risk women should continue to have annual Pap smears throughout their life (Table 8.2).

TABLE 8.2 PAP SMEAR GUIDELINES

First Pap	Cervical cancer screening should begin at age 21. Women under age 21 should not be tested.
Ages 21–30	Should have a Pap smear every 3 years. HPV testing should not be used in this age group unless it is needed after an abnormal Pap test result.
Ages 30–65	Should have a Pap smear plus an HPV test every 5 years. This is the preferred approach, but having a Pap smear alone every 3 years is also okay.
Age >65 years	Women who have had regular cervical testing with normal results should not be tested for cervical cancer. Women with a history of serious cervical precancer lesions should continue testing for at least 20 years after that diagnosis, even if it continues after age 65.
HPV vaccination	Women who have received the HPV vaccine should follow the screening recommendations for her age group.

Adapted from American Cancer Society [ACS]. (2015b). *American Cancer Society guidelines for the early detection of cancer.* Retrieved from http://www.cancer.org/healthy/findcancerearly/cancerscreeningguidelines/american-cancer-society-guidelines-for-the-early-detection-of-cancer

BOX 8.1

THE BETHESDA SYSTEM FOR CLASSIFYING PAP SMEARS

Specimen Type: Conventional Pap smear vs. liquid-based
Specimen Adequacy: Satisfactory or unsatisfactory for evaluation
General Categorization: (optional)
• Negative for intraepithelial lesion or malignancy
• Epithelial cell abnormality; see interpretation/result
Automated Review: If case was examined by automated device or not
Ancillary Testing: Provides a brief description of the test methods and report results so health care provider understands
Interpretation/Result:
• Negative for intraepithelial lesion or malignancy
• Organisms: *Trichomonas vaginalis;* fungus; bacterial vaginosis; herpes simplex
• Other non-neoplastic findings: Reactive cellular changes associated with inflammation, radiation, intrauterine devices, atrophy
• Other: Endometrial cells in a woman >40 years of age
• Epithelial cell abnormalities:
• *Squamous cell*

- Atypical squamous cells
  - Of undetermined significance (ASC-US)
  - Cannot exclude HSIL (ASC-H)
- Low-grade squamous intraepithelial lesion (LSIL)
  - Encompassing HPV/mild dysplasia/CIN-1
- High-grade squamous intraepithelial lesion (HSIL)
- Encompassing moderate and severe dysplasia CIS/CIN-2 and CIN-3
- With features suspicious for invasion
- Squamous cell carcinoma
- Glandular Cell: Atypical
  - Endocervical, endometrial, or glandular cells
    - Endocervical cells—favor neoplastic
    - Glandular cells—favor neoplastic
    - Endocervical adenocarcinoma in situ
  - Adenocarcinoma
    - Endocervical, endometrial, extrauterine
- Other malignant neoplasms (specify)

Educational Notes and Suggestions: (optional)

Adapted from American Society of Cytopathology (2015). *The Bethesda System for reporting cervical cytology: Definitions, criteria and explanatory notes.* Retrieved from http://www.cytopathology.org/the-bethesda-system-for-reporting-cervical-cytology-definitions-criteria-and-explanatory-notes-3rd-edition/; National Cancer Institute [NCI] (2015k). *Cervical cancer prevention.* Retrieved from http://www.cancer.gov/cancertopics/pdq/prevention/cervical/Patient/page3; Schuiling, K. D., & Likis, F. E. (2016). *Women's gynecologic health* (3rd ed.). Sudbury, MA: Jones & Bartlett.

Pap smear results are classified using the Bethesda System (Box 8.1), which provides a uniform diagnostic terminology that allows clear communication between the laboratory and the health care provider. The information provided by the laboratory is divided into three categories: specimen adequacy, general categorization of cytologic findings, and interpretation/result (ACS, 2015h).

Therapeutic Management

Treatment for abnormal Pap smears depends on the severity of the results and the health history of the woman. Therapeutic choices all involve destroying as many affected cells as possible. With the introduction of multimodality therapy for cervical cancer, many women will be long-term survivors in need of comprehensive surveillance care. Obesity and smoking are significant comorbidities that may complicate care in cervical cancer survivors. Nurses can focus their interventions at modifying these risk factors to increase the quality of life for cervical cancer survivors. Box 8.2 describes treatment options.

BOX 8.2

TREATMENT OPTIONS FOR CERVICAL CANCER

- **Cryotherapy**—destroys abnormal cervical tissue by freezing with liquid nitrogen, Freon, or nitrous oxide. Studies show a 90% cure rate (NCI, 2015g).

Healing takes up to 6 weeks, and the client may experience a profuse, watery vaginal discharge for 3 to 4 weeks.

- **Cone biopsy or conization**—removes a cone-shaped section of cervical tissue. The base of the cone is formed by the ectocervix (outer part of the cervix) and the point or apex of the cone is from the endocervical canal. The transformation zone is contained within the cone sample. The cone biopsy is also a treatment and can be used to completely remove any precancers and very early cancers. Two methods are commonly used for cone biopsies:
- **LEEP (loop electrosurgical excision procedure) or LLETZ (large loop excision of the transformation zone)**—the abnormal cervical tissue is removed with a wire that is heated by an electrical current. For this procedure, a local anesthetic is used. It is performed in the health care provider's office in approximately 10 minutes. Mild cramping and bleeding may persist for several weeks after the procedure.
- **Cold knife cone biopsy**—a surgical scalpel or a laser is used instead of a heated wire to remove tissue. This procedure requires general anesthesia and is done in a hospital setting. After the procedure, cramping and bleeding may persist for a few weeks.
- **Laser therapy**—destroys diseased cervical tissue by using a focused beam of high-energy light to vaporize it (burn it off). After the procedure, the woman may experience a watery brown discharge for a few weeks. Very effective in destroying precancers and preventing them from developing into cancers.
- **Hysterectomy**—removes the uterus and cervix surgically.
- **Radiation therapy**—delivered by internal radium applications to the cervix or external radiation therapy that includes lymphatics of the pelvis.
- **Chemoradiation**—weekly cisplatin therapy concurrent with radiation. Investigation of this therapy is ongoing (ACS, 2015h).

Using the Bethesda System, the following management guidelines for abnormal Pap results were developed by the NCI to provide direction to health care providers and clients:

- *ASC-US:* Repeat the Pap smear in 4 to 6 months or refer for **colposcopy**.
- *ASC-H:* Refer for colposcopy with HPV testing.
- *Atypical glandular cells (AGC) and adenocarcinoma in situ (AIS):* Immediate colposcopy; follow-up is based on the findings.

Colposcopy is a microscopic examination of the lower genital tract using a magnifying instrument called a colposcope. Specific patterns of cells that correlate well with certain histologic findings can be visualized.

Nursing Assessment

Obtain a thorough history and physical examination of the woman. Investigate her history for risk factors such as:

- Early age at first intercourse (within 1 year of menarche)
- Lower socioeconomic status
- Promiscuous male partners
- Unprotected sexual intercourse

• Family history of cervical cancer (mother or sisters)
• Sexual intercourse with uncircumcised men
• Female offspring of mothers who took diethylstilbestrol (DES)
• Infections with genital herpes or chronic chlamydia
• Multiple sex partners
• Cigarette smoking
• Immunocompromised state
• HIV infection
• Oral contraceptive use
• Moderate dysplasia on Pap smear within past 5 years
• HPV infection (CDC, 2015e)

Question the woman about any signs and symptoms. Clinically, the first sign is abnormal vaginal bleeding, usually after sexual intercourse. Also be alert for reports of vaginal discomfort, malodorous discharge, and dysuria. In some cases the woman is asymptomatic, with detection occurring at an annual gynecologic examination and Pap test.

Perform a physical examination. Inspect the perineal area for vaginal discharge or genital warts. Perform or assist with a pelvic examination, including the collection of a Pap smear as indicated (Nursing Procedure 8.1).

Take Note!

Suspect advanced cervical cancer in women with pelvic, back, or leg pain, weight loss, anorexia, weakness and fatigue, and fractures.

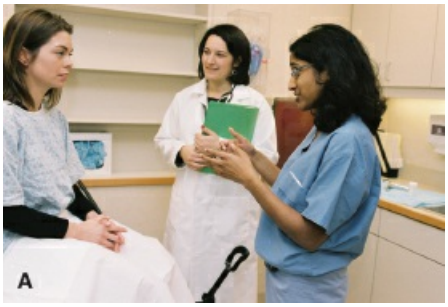
Prepare the woman for further diagnostic testing if indicated, such as a colposcopy. In a colposcopy, the woman is placed in the lithotomy position and her cervix is cleansed with acetic acid solution. Acetic acid makes abnormal cells appear white, which is referred to as *acetowhite*. These white areas are then biopsied and sent to the pathologist for assessment. Although this test is not painful, has minor side effects (minor bleeding, cramping, and a risk of an infection developing after the biopsy), and can be performed safely in the clinic or office setting, women may be apprehensive or anxious about it because it is done to identify and confirm potential abnormal cell growth. Some health care providers request that the woman premedicate with a mild analgesic such as ibuprofen prior to undergoing the procedure.

NURSING PROCEDURE 8.1

Assisting with Collection of a Pap Smear

Purpose: To Obtain Cells from the Cervix for Cervical Cytology Screening

1. Explain procedure to the client (Fig. A).
2. Instruct client to empty her bladder.

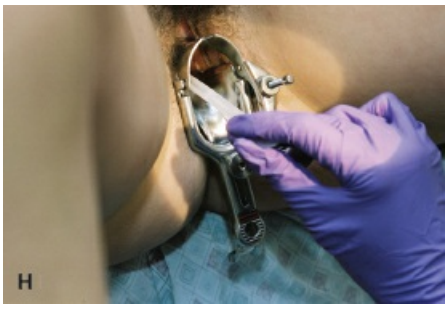


3. Wash hands thoroughly.
4. Assemble equipment, maintaining sterility of equipment (Fig. B).

1. Position client on stirrups or foot pedals so that her knees fall outward.
2. Drape client with a sheet for privacy, covering the abdomen but leaving the perineal area exposed.
3. Open packages as needed.
4. Encourage client to relax.

5. Provide support to client as the practitioner obtains a sample by spreading the labia; inserting the speculum; inserting the cytobrush and swabbing the endocervix; and inserting the plastic spatula and swabbing the cervix (Figs. C–H).

1. Transfer specimen to container (Fig. I) or slide. If a slide is used, spray the fixative on the slide holding the spray container about 12 in away from the slide.
2. Place sterile lubricant on the practitioner's fingertip when indicated for the bimanual examination.
3. Wash hands thoroughly.



4. Label specimen according to facility policy.
5. Rinse reusable instruments and dispose of waste appropriately (Fig. J).
6. Wash hands thoroughly.
7. Assist the client up after the examination is completed.

D., & Likis, F. E. (2016). *Women's gynecologic health* (3rd ed.). Burlington, MA: Jones & Bartlett Learning.

Nursing Management

The nurse's role involves primary prevention by educating women about risk factors and ways to prevent cervical dysplasia. Cervical cancer rates have decreased in the United States because of the widespread use of Pap testing, which can detect precancerous lesions of the cervix before they develop into cancer.

Concept Mastery Alert

Cervical Cancer Prevention

The key points to remember in cervical cancer prevention are smoking cessation, limiting alcohol consumption, and encouraging teens to refrain from early sexual activity.

Gardasil and Cervarix are vaccines approved by the United States Food and Drug Administration to protect girls and women from HPV and thus prevent cervical cancer. The vaccines prevent infection from four HPV types: HPV 6, 11, 16, and 18. These types are responsible for 70% of cervical cancers and 90% of genital warts (NCI, 2015h). Clinical trials indicate that the vaccine has high efficacy in preventing persistent HPV infection, cervical cancer precursor lesions, vaginal and vulvar

cancer precursor lesions, and genital warts (NCI, 2015h). The vaccine is administered by intramuscular injection, and the recommended schedule is a three-dose series with the second and third doses administered 2 and 6 months after the first dose. The recommended age for vaccination of females is 9 to 26 years old (Castle & Schmeler, 2015). The vaccines protect against infection with these types of HPV for 6 to 8 years. It is not known if the protection lasts longer. The vaccines do not protect women who are already infected with HPV (NCI, 2015h). However, the vaccine is not a substitute for routine cervical cancer screening, and vaccinated women should have Pap smears as recommended.

Focus primary prevention education on the following:

- Identify high-risk behaviors in clients and teach them how to reduce such behaviors:
  - Take steps to prevent STIs.
  - Avoid early sexual activity.
  - Faithfully use barrier methods of contraception.
  - Avoid smoking and drinking.
  - Receive the HPV vaccine.
  - Instruct women on the importance of screening for cervical cancer by having annual Pap smears. Outline the proper preparation before having a Pap smear (Teaching Guidelines 8.3). Reinforce specific guidelines for screening.

Teaching Guidelines 8.3

STRATEGIES TO OPTIMIZE PAP SMEAR RESULTS

- Schedule your Pap smear appointment about 2 weeks (10 to 18 days) after the first day of your last menses to increase the chance of getting the best sample of cervical cells without menses.
- Refrain from intercourse for 48 hours before the test because additional matter such as sperm can obscure the specimen.
- Do not douche within 48 hours before the test to prevent washing away cervical cells that might be abnormal.
- Do not use tampons, birth control foams, jellies, vaginal creams, or vaginal medications for 72 hours before the test, because they could cover up or obscure the cervical cell sample.
- Cancel your Pap appointment if vaginal bleeding occurs, because the presence of blood cells interferes with visual evaluation of the sample (Schuiling & Likis, 2016).

Nurses also can advocate for clients by making sure that the Pap smear is sent to an accredited laboratory for interpretation. Doing so reduces the risk of false-negative results. The identification and treatment of early precancerous lesions is critical to prevention of cervical cancer. Prevention measures should include educating women that the risk of infection can be reduced by delaying the onset of sexual activity, decreasing the number of sexual partners, using condoms consistently, and never start smoking.

Secondary prevention focuses on reducing or limiting the area of cervical dysplasia. Tertiary prevention focuses on minimizing disability or the spread of cervical cancer. Explain in detail all procedures that might be needed. Encourage the client who has undergone any cervical treatment to allow the pelvic area to rest for approximately 1 month. Discuss this rest period with the client and her partner to gain his cooperation. Outline alternatives to vaginal intercourse, such as cuddling, holding hands, and kissing. Remind the woman about any follow-up procedures that are needed and assist her with scheduling if necessary.

Tertiary prevention of cervical cancer involves the diagnosis and treatment of confirmed cases of cancer. Treatment is typically through surgery, radiotherapy, and frequently chemotherapy. Palliative care is provided to women when the disease has already reached an incurable stage. Knowing that the woman and her family have been told about her prognosis, the nurse is in a position to support them when the impact of the diagnosis is realized.

Throughout the process, provide emotional support to the woman and her family. During the decision-making process, the woman may be overwhelmed by the diagnosis and all the information being presented. Refer the woman and her family to appropriate community resources and support groups as indicated. It is crucial for all women to be given correct information regarding safe sexual practices, informed about the preventive role of the HPV vaccination, and become educated about the role of the Pap test as a secondary screening measure for cervical cancer. The emotional needs of the woman diagnosed with cancer can best be met by a warm, friendly personality, an attitude of empathy rather than sympathy, and skilled communication. Nurses across all settings are in a powerful position to be advocates for safe health care practices of women through education at personal, community, and national levels.

VAGINAL CANCER

Vaginal cancer is a rare malignant tissue growth arising in the vagina. Only about 1 of every 1,100 women will develop vaginal cancer in her lifetime. In 2015, the ACS (2015i) estimate that more than 4,000 new cases will be diagnosed in women and that over 900 of those women will die from this cancer. The peak incidence of vaginal cancer occurs at 60 to 65 years of age. The prognosis of vaginal cancer depends largely on the stage of disease and the type of tumor. The overall 5-year survival rate for squamous cell carcinoma is about 42%; that for adenocarcinoma is about 78% (NCI, 2015i). Vaginal cancer can be effectively treated, and when found early it is often curable.

Pathophysiology

The etiology of vaginal cancer has not been identified. Malignant diseases of the vagina are either primary vaginal cancers or metastatic forms from adjacent or distant organs. About 80% of vaginal cancers are metastatic, primarily from the cervix and endometrium. These cancers invade the vagina directly. Cancers from distant sites that metastasize to the vagina through the blood or lymphatic system are typically from the colon, kidneys, skin (melanoma), or breast. Tumors in the vagina commonly occur on the posterior wall and spread to the cervix or vulva (NCI, 2015i).

Squamous cell carcinomas that begin in the epithelial lining of the vagina account for about 85% of vaginal cancers. This type of cancer usually occurs in women over the age of 50. The SCCs develop slowly over a period of years, commonly in the upper third of the vagina. They tend to spread early by directly invading the bladder and rectal walls. They also metastasize through blood and lymphatics. The remaining 15% are adenocarcinomas, which differ from SCC by an increase in pulmonary metastases and supraclavicular and pelvic node involvement (ACS, 2015j).

Therapeutic Management

Treatment of vaginal cancer depends on the type of cells involved and the stage of the disease. If the cancer is localized, radiation, laser surgery, or both may be used. If the cancer has spread, radical surgery might be needed, such as a hysterectomy, or removal of the upper vagina with dissection of the pelvic nodes in addition to radiation therapy.

Nursing Assessment

Begin the history and physical examination by reviewing for risk factors. Although direct risk factors for the initial development of vaginal cancer have not been identified, associated risk factors include advancing age (over 60 years old), previous pelvic radiation, exposure to DES in utero, vaginal trauma, history of genital warts (HPV infection), HIV infection, cervical cancer, chronic vaginal discharge, smoking, and low socioeconomic level (ACS, 2015k).

Question the woman about any symptoms. Most women with vaginal cancer are asymptomatic. Those with symptoms have painless vaginal bleeding (often after sexual intercourse), abnormal vaginal discharge, dyspareunia, dysuria, constipation, and pelvic pain (NCI, 2015i). During the physical examination, observe for any obvious vaginal discharge or genital warts or changes in the appearance of the vaginal mucosa. Anticipate colposcopy with biopsy of suspicious lesions to confirm the diagnosis.

Nursing Management

Nursing management for this cancer is similar to that for other reproductive cancers, with emphasis on sexuality counseling and referral to local support groups. Women undergoing radical surgery need intensive counseling about the nature of the surgery, risks, potential complications, changes in physical appearance and physiologic function, and sexuality alterations. Nurses should focus their care on client education, client pain and symptom management, communication with the woman and her family, and coordination of care across of all settings.

VULVAR CANCER

Vulvar cancer is an abnormal neoplastic growth on the external female genitalia including the clitoris, vaginal lips, and opening to the vagina (Fig. 8.5). Vulvar cancer accounts for approximately 5% of all female genital malignancies. In the United States, women have a 1 in 333 chance of developing vulvar cancer at some point in their lifetime. It is the fourth most common gynecologic cancer, after

endometrial, ovarian, and cervical cancers (NCI, 2015j). The ACS (2015h) estimates that in 2015, over 5,000 cancers of the vulva will be diagnosed in the United States and over 1,000 women will die of this cancer. When detected early, it is highly curable. Typically, it can be advanced at diagnosis, though it is a visible cancer. Awareness is essential for early detection of this rare cancer.

Vulvar cancer is found most commonly in older women in their mid-60s to mid-70s, but the incidence in women younger than 35 years old has increased during the past few decades. The overall 5-year survival rate when lymph nodes are not involved is 90%, but it drops to 50% to 70% when the lymph nodes have been invaded (ACS, 2015m).

Pathophysiology

Vulvar cancer can be classified into two groups according to predisposing factors: the first type correlates with a HPV infection and occurs mostly in younger women. The second group is not HPV associated and occurs in elderly women without cancerous disorders. Approximately 80% of vulvar tumors are squamous cell carcinomas. This type of cancer forms slowly over several years and is usually preceded by precancerous changes. These precancerous changes are termed vulvar intraepithelial neoplasia (VIN). The two major types of VIN are classic (undifferentiated) and simplex (differentiated). Classic VIN, the more common one, is associated with HPV infection (genital warts due to types 16, 18, 31, 33, 35, 45, and 54) and smoking (Alkatout et al., 2015). It typically occurs in women between 30 and 40 years. In contrast to classic VIN, simplex VIN usually occurs in postmenopausal women and is not associated with HPV but chronic irritation over time (Cancer.Net, 2015b).

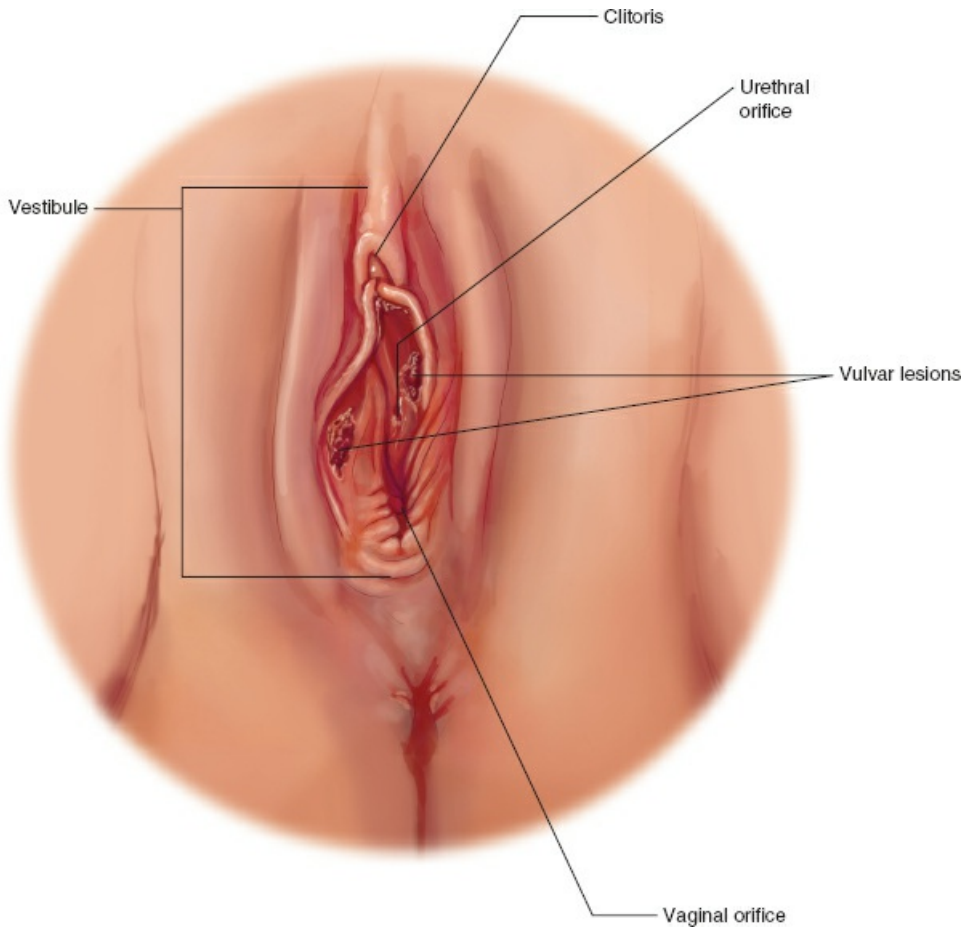


FIGURE 8.5 Vulvar cancer. (The Anatomical Chart Company. [2009]. *Atlas of pathophysiology* [3rd ed.]. Philadelphia, PA: Lippincott Williams & Wilkins.)

Screening and Diagnosis

Annual vulvar examination is the most effective way to prevent vulvar cancer. Careful inspection of the vulva during routine annual gynecologic examinations remains the most productive diagnostic technique. Liberal use of biopsies of any suspicious vulvar lesion is usually necessary to make the diagnosis and to guide treatment. However, many women do not seek health care evaluation for months or years after noticing an abnormal lump or lesion. Leading presenting complaints of women with vulvar cancer include dyspareunia, long history of pruritus, ulcers on the "outside" genitalia, vulvar swelling, vulvar bleeding, and urinary problems (Alkatout et al., 2015). The diagnosis of vulvar cancer is made by a biopsy of the suspicious lesion, which is usually found on the labia majora.

Take Note!

Vulvar pruritus or a lump is present in the majority of women with vulvar cancer. Lumps should be biopsied even if the woman is asymptomatic.

Therapeutic Management

Treatment varies depending on the extent of the disease. Laser surgery, cryosurgery, or electrosurgical incision may be used. Larger lesions may need more extensive surgery and skin grafting. The traditional treatment for vulvar cancer has been

radical vulvectomy, but more conservative techniques are being used to improve psychosexual outcomes and less morbidity, without compromising survival (Forner, Dakhil, & Lampe, 2015).

Nursing Assessment

Typically, no single specific clinical symptom heralds this disease, so diagnosis is often delayed significantly. Therefore, it is important to review the woman's history for risk factors such as:

- Exposure to HPV type 16
- Age over 50 years
- HIV infection
- VIN
- Lichen sclerosus (a patchy skin disorder)
- Melanoma or atypical moles
- Exposure to HSV type 2
- Multiple sex partners
- Smoking
- Herpes simplex
- History of breast cancer
- Immune suppression
- Hypertension
- Diabetes mellitus
- Obesity (ACS, 2015n)

In most cases, the woman reports persistent vulvar itching, burning, and edema that do not improve with the use of creams or ointments. A history of condyloma, gonorrhea, and herpes simplex are some of the factors for greater risk for VIN. Diagnosis of vulvar carcinoma is often delayed. Women neglect to seek treatment for an average of 6 months from the onset of symptoms. In addition, a delay in diagnosis often occurs after the client presents to her physician or nurse practitioner. In many cases, a biopsy of the lesion is not performed until the problem fails to respond to numerous topical therapies. During the physical examination, observe for any masses or thickening of the vulvar area. A vulvar lump or mass most often is noted. The vulvar lesion is usually raised and may be fleshy, ulcerated, leukoplakic (looking like white patches), or warty. The cancer can appear anywhere on the vulva, although about three-fourths arise primarily on the labia (Vargo & Beriwal, 2015). Less commonly, the woman may present with vulvar bleeding, discharge, dysuria, and pain.

Nursing Management

Women with vulvar cancer must clearly understand their disease, treatment options, and prognosis. To accomplish this, provide information and establish effective communication with the client and her family. Act as an educator and advocate.

Teach the woman about healthy lifestyle behaviors, such as smoking cessation and measures to reduce risk factors. For example, instruct the woman how to examine her genital area, urging her to do so monthly between menstrual periods. Tell her to look for any changes in appearance (e.g., whitened or reddened patches

of skin); changes in feel (e.g., areas of the vulva becoming itchy or painful); or the development of lumps, moles (e.g., changes in size, shape, or color), freckles, cuts, or sores on the vulva. Urge the woman to report these changes to the health care provider (ACS, 2015m).

Teach the woman about preventive measures such as not wearing tight undergarments and not using perfumes and dyes in the vulvar region. Also educate her about the use of barrier methods of birth control (e.g., condoms) to reduce the risk of contracting HIV, HSV, and HPV. Other prevention measures include delaying first sexual intercourse, avoiding sexual intercourse with multiple partners, not starting smoking or quitting if a smoker already, and getting the HPV vaccine available for all boys and girls and women between 9 and 26 years.

For the woman diagnosed with vulvar cancer, provide information and support. Discuss potential changes in sexuality if radical surgery is performed. Encourage her to communicate openly with her partner. Refer her to appropriate community resources and support groups. All nurses come in contact with women in their clinical practices who have the potential to become cancer clients, already have suspicious signs or symptoms of cancer, are already undergoing cancer treatment, or are terminal cancer clients. The nurse will be involved with all aspects of cancer, from diagnosis through palliative care. Each nurse has an obligation to keep informed of current developments in the cancer field to function effectively and be able to educate the woman and her family.

NURSING CARE PLAN 8.1

Overview of a Woman with a Reproductive Tract Cancer

Molly, a thin 28-year-old woman, comes to the free health clinic complaining of a thin, watery vaginal discharge and spotting after sex. Molly says she has had multiple sex partners since the age of 15 years. She had an abnormal Pap smear "a while back" but did not return to the clinic for follow-up. Cervical cancer is suspected.

NURSING DIAGNOSIS: Anxiety related to uncertainty of diagnosis, possible diagnosis of cancer, and eventual outcome as evidenced by client's report of signs and symptoms and statements of being worried and not knowing what she would do

Outcome Identification and Evaluation

The client will demonstrate measures to cope with anxiety *as evidenced by statements acknowledging anxiety, use of positive coping strategies, and verbalization that anxiety has decreased.*

Interventions: *Reducing Anxiety*

- Encourage client to express her feelings and concerns *to reduce her anxiety and to determine appropriate interventions.*
- Assess the meaning of the diagnosis to the client, clarify misconceptions, and provide reliable, realistic information *to enhance her understanding of her condition, subsequently reducing her anxiety.*
- Assess client's psychological status *to determine degree of emotional distress related to diagnosis and treatment options.*
- Identify and address verbalized concerns, providing information about what to expect *to decrease uncertainty about the unknown.*

- Assess the client's use of coping mechanisms in the past and their effectiveness *to foster use of positive strategies.*
- Teach client about early signs of anxiety and help her recognize them (e.g., fast heartbeat, sweating, or feeling flushed) *to minimize escalation of anxiety.*
- Provide positive reinforcement that the client's condition can be managed *to relieve her anxiety.*

NURSING DIAGNOSIS: Deficient knowledge related to diagnosis, prevention strategies, disease course, and treatment as evidenced by client's statements about hoping nothing bad is wrong, lack of follow-up for previous abnormal Pap test, and high-risk behaviors

Outcome Identification and Evaluation

The client will demonstrate an understanding of diagnosis, *as evidenced by making health-promoting lifestyle choices, verbalizing appropriate health care practices, describing condition once diagnosed, and adhering to measures to comply with therapy.*

Interventions: ***Providing Client Teaching***

- Assess client's current knowledge about her diagnosis and proposed therapeutic regimen *to establish a baseline from which to develop a teaching plan.*
- Review contributing factors associated with development of reproductive tract cancer, including lifestyle behaviors, *to foster an understanding of the etiology of cervical cancer.*
- Review information about treatments and procedures and recommendations for healthy lifestyle, obtaining feedback frequently *to validate adequate understanding of instructions.*
- Discuss strategies, including using condoms and limiting the number of sexual partners, *to reduce the risk of transmission of STIs,* including HPV, which is associated with cervical cancer.
- Encourage client to obtain prompt treatment of any vaginal or cervical infections *to minimize the risk for cervical cancer.*
- Urge the client to have an annual Pap smear and/or HPV test *to allow screening and early detection.*
- Describe the treatment measures used *to provide client with knowledge of what may be necessary.*
- Provide written material with pictures *to allow for client review and to help her visualize what is occurring in her body.*
- Inform client about available community resources and make appropriate referrals as needed *to provide additional education and support.*
- Document details of teaching and learning *to allow for continuity of care and further education, if needed.*

NURSING DIAGNOSIS: Disturbed body image related to suspected reproductive tract cancer and impact on client's sexuality and sense of self as evidenced by statement of being worried about not being the same

Outcome Identification and Evaluation

The client will verbalize or demonstrate a positive self-esteem in relation to body image as evidenced by positive statements about self, sexuality, and participation in activities with others.

Interventions: ***Promoting Healthy Body Image***

- Assess client's use of self-criticism *to determine client's current state of coping and adjustment.*
- Determine if the client's change in body image has contributed to social isolation *to provide a direction for care.*
- Provide opportunities for client to explore her feelings related to issues of sexuality, including past behaviors that may have placed her at risk, *to minimize feelings of guilt about her condition.*
- Acknowledge the client's feelings about possible changes in her body and sexuality and her illness *to foster trust and allow client to ventilate feelings and concerns.*
- Facilitate contact with other clients with the same type of cancer *to promote sharing of feelings and decrease feelings of isolation.*

• Initiate referrals for counseling and community support groups as necessary *to assist client in gaining a positive image of herself.*

KEY CONCEPTS

- Women have a one-in-three lifetime risk of developing cancer, and one out of every four deaths is from cancer; thus, nurses must focus on screening and educating all women regardless of risk factors.
- The nurse plays a key role in offering emotional support, determining appropriate sources of support, and helping the woman use effective coping strategies when facing a diagnosis of cancer of the reproductive tract. Although reproductive tract cancer is rare during pregnancy, the woman's vigilance and routine screenings should continue throughout.
- A woman's sexuality and culture are inextricably interwoven, and it is essential that nurses working with women of various cultures recognize this and remain sensitive to the vast changes that will take place when the diagnosis of cancer is made.
- Ovarian cancer is the eighth most common cancer among women and the fourth most common cause of cancer deaths for women in the United States, accounting for more deaths than any other cancer of the reproductive system.
- Ovarian cancer has been described as the "overlooked disease" or "silent killer" because women and health care practitioners often ignore or rationalize early symptoms. It is typically diagnosed in advanced stages.
- Unopposed endogenous and exogenous estrogens, obesity, nulliparity, menopause after the age of 52 years, and diabetes are the major etiologic risk factors associated with the development of endometrial cancer.
- The American Cancer Society recommends that women should be informed about risks and symptoms of endometrial cancer at the onset of menopause and strongly encouraged to report any unexpected bleeding or spotting to their health care providers.
- Malignant diseases of the vagina are either primary vaginal cancers or metastatic forms from adjacent or distant organs. Vaginal cancer tumors can be effectively treated and, when found early, are often curable.
- Cervical cancer incidence and mortality rates have decreased noticeably in the past several decades, with most of the reduction attributed to the Pap test, which detects cervical cancer and precancerous lesions.
- The nurse's role involves primary prevention of cervical cancer through education of women regarding risk factors and preventive vaccines to avoid cervical dysplasia.
- Diagnosis of about 80% of vaginal cancers is metastatic, primarily from the cervix and endometrium. These cancers invade the vagina directly. Vulvar cancer is often delayed significantly because there is no single specific clinical

symptom that heralds it. The most common presentation is persistent vulvar itching that does not improve with the application of creams or ointments.

CHAPTER WORKSHEET

MULTIPLE-CHOICE QUESTIONS

1. When describing ovarian cancer to a local women's group, the nurse states that ovarian cancer often is not diagnosed early because:
   a. The disease progresses very slowly.
   b. The early stages produce very vague symptoms.
   c. The disease usually is diagnosed only at autopsy.
   d. Clients do not follow up on acute pelvic pain.
2. A postmenopausal woman reports that she has started spotting again. Which of the following would the nurse do?
   a. Instruct the client to keep a menstrual diary for the next few months.
   b. Tell her not to worry, since this a common but not serious event.
   c. Have her start warm-water douches to promote healing.
   d. Anticipate that the doctor will assess her endometrium thickness.
3. Which of the following would the nurse identify as the priority psychosocial need for a women diagnosed with reproductive cancer?
   a. Research findings
   b. Hand-holding
   c. Cheerfulness
   d. Offering of hope
4. When teaching a group of women about screening and early detection of cervical cancer, the nurse would include which of the following as most effective?
   a. Fecal occult blood test
   b. CA-125 blood test
   c. Pap smear and HPV test
   d. Sigmoidoscopy
5. After teaching a group of students about reproductive tract cancers, the nursing instructor determines that the teaching was successful when the students identify which of the following as the deadliest type of female reproductive cancer?
   a. Vulvar
   b. Ovarian
   c. Endometrial
   d. Cervical
6. The nurse is attempting to reassure her obese female client about the discovery of an ovarian cyst after her pelvic examination. Which of the following statements is true concerning ovarian cysts? They are:
   a. Frequently seen in polycystic kidney disease
   b. Always painful and need to be removed surgically
   c. A precursor to ovarian carcinoma

d. Part of a syndrome that includes hypertension and diabetes

7. Which of the following is considered a risk factor for vulvar cancer?
   a. Vitamin B_{12} deficiency
   b. Epstein–Barr virus
   c. Human papillomavirus
   d. Adenovirus

CRITICAL THINKING EXERCISES

1. A 27-year-old sexually active White woman visits the Health Department family planning clinic and requests information about the various available methods of contraception. In taking her history, the nurse learns that she started having sex at age 15 and has had multiple sex partners since then. She smokes two packs of cigarettes daily. Because she has been unemployed for a few months, her health insurance policy has lapsed. She has never previously obtained any gynecologic care.
   a. Based on her history, which risk factors for cervical cancer are present?
   b. What recommendations would you make for her and why?
   c. What are this client's educational needs concerning health maintenance?

2. A 60-year-old nulliparous woman presents to the gynecologic oncology clinic after her health care provider palpated an adnexal mass on her right ovary. In taking her history, the nurse learns that she has experienced mild abdominal bloating and weight loss for the past several months but felt fine otherwise. She was diagnosed with breast cancer 15 years ago and was treated with a lumpectomy and radiation. She has occasionally used talcum powder in her perineal area over the past 20 years.

   A transvaginal ultrasound reveals a complex mass in the right adnexa. She undergoes a total abdominal hysterectomy and bilateral salpingo-oophorectomy and lymph node biopsy. Pathology confirms a diagnosis of stage III ovarian cancer with abdominal metastasis and positive lymph nodes.
   a. Is this client's profile typical for a woman with this diagnosis?
   b. What in her history might have increased her risk for ovarian cancer?
   c. What can the nurse do to increase awareness of this cancer for all women?

STUDY ACTIVITIES

1. During your surgical clinical rotation, interview a female client undergoing surgery for cancer of her reproductive organs. Ask her to recall the symptoms that brought her to the health care provider. Ask her what thoughts, feelings, and emotions went through her mind before and after her diagnosis. Finally, ask her how this experience will change her life in future.

2. Visit an oncology and radiology treatment center to find out about the various treatment modalities available for reproductive cancers. Contrast the various treatment methods and report your findings to your class.

3. Visit one of the web sites listed in the extensive list of web sites provided to explore a topic of interest concerning reproductive cancers. How correct and current is the content? What is its level? Share your assessment with your

classmates.

4. Taking oral contraceptives provides protection against _____ cancer.
5. Two genes, *BRCA1* and *BRCA2,* are linked with hereditary _____ and _____ cancers.

BRINGING IT ALL TOGETHER: A CASE STUDY

Jill, a 38-year-old obese female with a history of infertility and irregular bleeding, returned to her OB/GYN doctor for a follow-up appointment. She had a D&C the week before to stop a profuse bleeding episode. She is informed by the doctor that her pathology report came back from the D&C showing endometrial adenocarcinoma. She is in shock over the diagnosis at her young age.

ASSESSMENT

The nurse took Jill's history, which included irregular menstrual cycles since her menarche. She has a BMI of 32. She takes medication to manage her diabetes and hypertension. She had been previously diagnosed with PCOS when she was a teenager. Her pelvic examination demonstrated an enlarged uterus. She had been to see her doctor several times because of her irregular bleeding, but she had been treated with medications until a D&C was done after months of unsuccessful drug therapy.

1. What risk factors for endometrial cancer does Jill have?
2. Is it unusual for a woman of Jill's age to have this diagnosis? Why or why not?
3. What treatment options might Jill need to consider after her diagnosis?

PLAN

Jill's histopathology at the time of surgery was reported as grade III adenocarcinoma with pelvic lymph node involvement. Jill underwent a total hysterectomy with bilateral salpingo-oophorectomy and went through three courses of chemotherapy also.

1. What health promotion instructions can the nurse impart to Jill when she returns for her postoperative office visit?
2. In what ways can the nurse assist Jill during this challenging time?
3. What is the "take-home" message learned from this case study?

9

Violence and Abuse

WOW

Words of Wisdom

After being traumatized, women can decide to stay in the shallow end of the pool or they can find support and swim in the ocean.

KEY TERMS

acquaintance rape
battered women syndrome
cycle of violence
date rape
female genital cutting (FGC)
human trafficking
incest
intimate partner violence (IPV)
posttraumatic stress disorder (PTSD)
rape
sexual abuse
statutory rape

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Examine the incidence of violence in women.
2. Characterize the cycle of violence and appropriate interventions.
3. Evaluate the various myths and facts about violence.
4. Analyze the dynamics of rape and sexual abuse.
5. Select the resources available to women experiencing abuse.
6. Outline the role of the nurse who cares for abused women.

***Dorothy* came to the prenatal clinic with a complaint of recurring headaches. She had been in twice this week already, but insisted she be seen today and started to cry. When the nurse called her into the examination room, Dorothy's cell phone rang. She hurried to answer it and told the person on the other end that she was at the store. When the nurse asked if she was afraid at home, Dorothy answered "at times." What cues did the nurse pick up on to ask that question? How frequent is this problem in women?**

INTRODUCTION

Imagine if you were subjected to assault, **rape**, sexual slavery, torture, verbal abuse, mutilation, even murder—all because of your gender. It is rarely acknowledged that violence against women and girls exists on the scale it does. Many of these females are brutalized from cradle to grave simply because of their gender. This abuse is the most pervasive human rights violation in the world today, and yet remains silent to many ears around the globe.

Gender-based violence is a major global public health and human rights problem and one that often goes unrecognized and unreported. It is a common source of physical, psychological, and emotional morbidity. It occurs in all countries, irrespective of social, economic, religious, or cultural group. It affects women across race, ethnicity, age, socioeconomic status, religion, sexual orientation, and geographic boundaries. No segments of society are immune from the vestiges of this problem. Due to the unequal power relations between men and women, women are violated either in the family, in the community, or in the country in which they live. The causes are multidimensional and are social, economic, cultural, political, and religious. Pregnancy is a time of unique vulnerability to **intimate partner violence (IPV)** victimization because of changes in women's physical, social, emotional, and economic needs during pregnancy. Although the true prevalence of violence during pregnancy is unclear, research suggests it is substantial and often continues into the postpartum period. Gender-based violence is one of the most rigorous challenges of women's health and well-being; it is a harrowing worldwide public health concern with serious consequences for individuals, families, and societies (Berthold, 2015).

Female-perpetrated violence against male partners receives little attention. Although women are victims of violence more frequently than men, the prevalence of violence among men nonetheless represents a significant public health concern.

One out of every four men has experienced rape, physical violence, and/or stalking by an intimate partner in their lifetime. (National Coalition Against Domestic Violence, 2015).

Although women can be violent in relationships with men, and also in same-sex partnerships, the overwhelming burden of partner violence is borne by women at the hands of men. Nearly 4 in 10 women and 1 in 10 men in the United States have experienced rape, physical violence, and/or stalking by a partner with IPV-related impact (World Health Organization [WHO], 2015a).

Of all the strides American women have made in the past 100 years, obliterating violence against themselves is not one of them. Violence against women is a growing problem and in many countries is still accepted as part of normal behavior. According to the Federal Bureau of Investigation (FBI, 2015), up to half of all women in the United States will experience some form of physical violence during their lifetime. In North America 40% to 60% of murders of women are committed by intimate partners (FBI, 2015). Recently, the FBI has broadened its definition of rape. The new definition, as it appears on the FBI web site, is "Penetration, no matter how slight, of the vagina or anus with any body part or object, or oral penetration by a sex organ of another person, without the consent of the victim." This broader definition will have a dramatic impact on the way rape is tracked and reported nationwide (FBI 2015).

Federal funding for the problem is trickling down to local programs, but it is not reaching victims fast enough. For example, the United States has three times more shelters for animals than for battered women (Bouchet & Braswell, 2015). In many cases, a victim escapes her abuser only to be turned away from a local shelter because it is full. The number of abused women is staggering: one woman is being battered every 12 seconds in the United States (Centers for Disease Control & Prevention [CDC], 2015a).

Nurses play a major role in assessing women who have suffered some type of violence. Nurses have a central ethic of caring and an agenda of early intervention and health promotion for their clients to improve their health status and well-being. Often, after a woman is victimized, she will complain about physical ailments that will give her the opportunity to visit a health care setting. A visit to a health care agency is an ideal time for women to be assessed for violence. Because nurses are viewed as trustworthy and sensitive about very personal subjects, women often feel comfortable confiding in them and discussing these issues with them. As a professional nurse, the act of screening women seen in every health care setting is often the first step for a victim to start thinking about a better future. Remember, your words carry weight with your client who looks to you for help, support, and encouragement.

Take Note!

Nurses will come in contact with violence and sexual abuse no matter what health care setting they work in. Nurses must be ready to ask the right questions and to act on the answers, because such action could be lifesaving.

This chapter addresses several types of gender-based violence: IPV, **female genital cutting (FGC)**, **human trafficking**, and **sexual abuse**. All of these types of violence against women have devastating and costly consequences for all of society.

INTIMATE PARTNER VIOLENCE

IPV is actual or threatened physical or sexual violence or psychological/emotional abuse. Research suggests that physical violence in intimate relationships is often accompanied by psychological abuse and in one-third to over one-half of cases by sexual abuse (CDC, 2015b). Intimate partners include individuals who are currently in dating, cohabitating, or marital relationships, or those who have been in such relationships in the past. Some of the common terms used to describe IPV are domestic abuse, spouse abuse, domestic violence, gender-based violence, battering, and rape. IPV affects a distressingly high percentage of the population and has physical, psychological, social, and economic consequences (Fig. 9.1).

Because a nurse may be the first health care provider to assess and identify the signs of IPV, a nurse can have a profound impact on a woman's decision to seek help. Thus, it is important for nurses to be able to identify abuse and aid the victim. IPV can leave significant psychological scars, and a well-trained nurse can have a positive impact on the victim's mental and emotional health.

FIGURE 9.1 Intimate partner violence has significant physical, psychological, social, and economic consequences. An important role of the health care provider is to identify abusive or potentially abusive situations as soon as possible and provide support for the victim.

Incidence

Overall, lifetime, and 1-year estimates for sexual violence, stalking, and IPV are alarmingly high for adult Americans, with IPV alone affecting more than 12 million people each year. On average, 20 persons per minute are victims of rape, physical violence, or stalking by an intimate partner in the United States. Women are disproportionately affected. The estimated cost of violence in the United States exceeds $70 billion each year. Each year, IPV results in an estimated 2500 deaths and 3 million injuries among women (CDC, 2015c).

Women are at risk for violence at nearly every stage of their lives. Old, young, beautiful, unattractive, married, single—no woman is completely safe from the risk of IPV. Current or former husbands or lovers kill over half of the murdered women in the United States. IPV against women causes more serious injuries and deaths than automobile accidents, rapes, and muggings combined. IPV is expensive. The medical cost of IPV approaches $4.4 trillion each year globally to pay for medical and surgical care, counseling, child care, burden on the justice system, incarceration, attorney fees, and loss of work productivity (Lomborg, 2015).

IPV is pervasive and crosses all boundaries of sexual orientation, race, and class. The intimidation of another person through abusive acts and words is not a gender issue. Violence within these relationships may go unreported for fear of harassment

or ridicule. The medical community's efforts to address IPV have often neglected members of the lesbian, gay, bisexual, and transgender (LGBT) population. Heterosexual women are primarily targeted for IPV screening and intervention despite the similar prevalence of IPV in LGBT individuals and its detrimental health effects (Cannon & Buttell, 2015). Perhaps because of the multiple barriers that confront LGBT abuse victims and the invisibility of the problem in the context of IPV services, the role of the nurse as their advocate is all the more critical.

Little is known about the national prevalence of IPV, sexual violence, and stalking among the LGBT community in the United States. Research documents that rates of IPV among LGBT individuals are equal to or greater than rates observed among heterosexual individuals. Risk factors are also similar to those documented among heterosexual individuals, in addition to help-seeking leaving, and recovery process (Edwards, Sylaska, & Neal, 2015). Current findings seem to also indicate some disparities in perceptions of what constitutes abuse among same and opposite sex couples (Russell & Chapleau, 2015). The *Violence against Women Act* has recently been renewed. It now includes coverage of same-sex partners—a big sign that attitudes are changing and improving for gays seeking shelters and help. As individuals and society come to realize same-sex partner violence as an existing problem, there is hope.

Background

Until the mid-1970 s, our society tended to legitimize a man's power and control over a woman. The United States legal and judicial systems considered intervention into family disputes wrong and a violation of the family's right to privacy. IPV was often tolerated and even socially acceptable. Fortunately, attitudes and laws have changed to protect women and punish abusers. There are 13 measurable violence prevention objectives displayed in the Healthy People 2020 table that follows. In addition to the 13 objectives listed, there are 7 developmental objectives that focus on preventing sexual violence across the lifespan and preventing the different forms of partner violence including physical and sexual violence, emotional abuse, and stalking by a current or former partner.

HEALTHY PEOPLE 2020

Violence Prevention Objectives	Baseline (Year)	Target (2020)
IVP-29 Reduce homicides per 100,000 population	6.1 (2007)	5.5
IVP-30 Reduce firearm-related deaths per 100,000 population	10.3 (2007)	9.3
IVP-31 Reduce nonfatal firearm-related injuries per 100,000 population	20.7 (2007)	18.6
IVP-32 Reduce nonfatal physical assault injuries per 100,000 population	512.5 (2008)	461.2
IVP-33 Reduce physical assaults per 1,000 population (12+ years)	21.2 (2008)	19.2
IVP-34 Reduce physical fighting among adolescents in grades 9–12	31.5 (2009)	28.4
IVP-35 Reduce bullying among adolescents in grades 9–12	19.9 (2009)	17.9
IVP-36 Reduce weapon carrying by adolescents on school property	5.6 (2009)	4.6
IVP-37Reduce child maltreatment deaths per 100,000 population	2.3 (2008)	2.1
IVP-38 Reduce nonfatal child maltreatment per 100,000 population	9.4 (2008)	8.5
IVP-41 Reduce nonfatal intentional self-harm injuries per 100,000 population	124.9 (2008)	112.4
IVP-42 Reduce children's exposure to violence <18 years old	58.8 (2008)	52.9
IVP-43 Increase the number of States that link data on violent deaths	16 states	50 states

Nursing Significance

- Will increase men and women's quality and years of healthy life
- Eliminate health disparities for survivors of violence
- Goal is to have improved adherence to screening for IPV by health care providers.
- Meeting these objectives will reflect the importance of early detection, intervention, and evaluation
- Eliminating LGBT health disparities and enhancing efforts to improve LGBT health are necessary to ensure that LGBT individuals can lead long, healthy lives

Healthy People objectives based on data from http://www.healthypeople.gov

Characteristics of Intimate Partner Violence

Although more research is needed in this area, studies have found certain risk factors for IPV in men. These risk factors can be divided into four different categories: individual factors, relationship factors, community factors, and societal factors. Specific risk factors within each category are listed in Table 9.1.

Generation-to-Generation Continuum of Violence

Violence is a learned behavior that, without intervention, is self-perpetuating. It is a cyclical health problem. The long-term effects of violence on victims and children can be profound. Children who witness one parent abuse another are more likely to become delinquents or batterers themselves because they see abuse as an integral part of a close relationship. Thus, an abusive relationship between father and mother can perpetuate future abusive relationships. Violence in childhood and adolescence is linked to the child's perception of the family as a hostile environment and of violence against women as a corrective measure, and insults, swearing, and humiliation by their partner as acceptable (Song et al., 2015). If one considers violence against children and spouses, the psychological consequences are huge, stemming from the paradox of the victim being abused by a member of the family with whom he or she expects to have a supportive, loving, and respectful relationship. Research has found that children who witness IPV are at risk for developing psychiatric disorders, **posttraumatic stress disorder (PTSD)**,

developmental problems, school failure, violence against others, and low self-esteem (Cater et al., 2015).

TABLE 9.1 COMMON MYTHS AND FACTS ABOUT VIOLENCE

Myths	Facts
Battering of women occurs only in lower socioeconomic classes.	Violence occurs in all socioeconomic classes.
Substance abuse causes the violence.	Violence is a learned behavior and can be changed. The presence of drugs and alcohol can make a bad problem worse.
Men have the right to discipline their partners. Battering is not a crime	In the past, our patriarchal legal system afforded men the right to physically chastise their wives and children; we no longer live under that system. Women and children are no longer considered the property of men, and violence against them is a crime in every state.
Violence occurs to only a small percentage of women.	One in four women will be victims of violence.
Intimate partner violence (IPV) is typically a one time, isolated occurrence.	Battering is a pattern of coercion and control that one person exerts over another. It is repeated using a number of tactics, including intimidation, threats, physical injury, economic deprivation, isolation, and sexual abuse. The various forms of abuse utilized by batterers help to maintain power and control over their victims.
Women can easily choose to leave an abusive relationship.	Women stay in the abusive relationship because they feel they have no options.
Only men with mental health problems commit violence against women.	Abusers often seem normal and do not appear to suffer from personality disorders or other forms of mental illness.
Pregnant women are protected from abuse by their partners.	One in five women is physically abused during pregnancy. The effects of violence on infant outcomes can include preterm delivery, fetal distress, low birth weight, and child abuse.
Women provoke their partners to abuse them.	Women may be willing to blame themselves for someone else's bad behavior, but nobody deserves to be beaten.
Violent tendencies have gone on for generations and are accepted.	The police, justice system, and society are beginning to make IPV socially unacceptable.
IPV is only a heterosexual issue.	There is as much IPV in the lesbian/gay/bisexual/transgender (LGBT) population as in heterosexual relationships with the added psychological abuse of "outing" (when one partner threatens to disclose the others sexual preference in an effort to maintain power and control).

(2015). *Myths about intimate partner violence in the LGBTQUA community.* Retrieved from http://tahoesafealliance.org/for-lgbqtia/lgbtqiamyths/; Medicine Net. (2015b). *Domestic violence.* Retrieved from http://www.medicinenet.com/domestic_violence/page4.htm#what_are_the_causes_or_risk_factors_for_intimate_partner_violence

Childhood maltreatment is a major health problem that is associated with a wide range of physical conditions and leads to high rates of psychiatric morbidity and social problems in adulthood. Consequences of violence extend far beyond the physical and mental suffering of victims and their families and have an impact on schools, neighborhoods, businesses, and the legal and health care systems. Women who were physically or sexually abused as children have an increased risk of victimization and fear of crime, poor general health, and in addition experience adverse mental health conditions such as depression, anxiety, and low self-esteem as adults (Barrios et al., 2015).

In many cases when a parent is abused, the children are abused as well. Approximately 1 in 8 children are abused annually in the United States. The lifetime economic cost to society due to childhood maltreatment is estimated to be $124

billion dollars (Jackson & Deye, 2015). Young children who live with family violence represent a disempowered group. Developmentally, young children have relatively limited verbal skills and emotional literacy. In addition, the environment becomes one of secrecy and intimidation, as well as reduced emotional availability from the child's main caretaker. Taken together, these factors severely restrict these young children's capacity and opportunity to make their voices and needs heard (Jackson & Deye, 2015). Exposure to violence has a negative impact on children's physical, emotional, and cognitive well-being. The cycle continues into another generation through learned responses and violent acting out. Although there are always exceptions, most children deprived of their basic physical, psychological, and spiritual needs do not develop healthy personalities. They grow up with feelings of fear, behavioral problems, substance abuse, relationship difficulties, inadequacy, anxiety, anger, hostility, guilt, and rage. They often lack coping skills, blame others, demonstrate poor impulse control, have early delinquent behavior, and generally struggle with authority (Huang et al., 2015). Unless this cycle is broken, more than half become abusers themselves (CDC, 2015e).

The Cycle of Violence

In an abusive relationship, the **cycle of violence** comprises three distinct phases: the tension-building phase, the acute battering phase, and the honeymoon phase (Lawrence, 2015). The cyclical behavior begins with a time of tension-building arguments, progresses to violence, and settles into a making-up or calm period. This cycle of violence increases in frequency and severity as it is repeated over and over again. The cycle can cover a long or short period of time. The honeymoon phase gradually shortens and eventually disappears altogether. Abuse in relationships typically becomes accelerated and thus more dangerous over time. The abuser no longer feels the need to apologize and indulge in a honeymoon phase as the woman becomes increasingly disempowered in the relationship.

PHASE 1: TENSION BUILDING

During the first—and usually the longest—phase of the cycle, tension escalates between the couple. Excessive drinking, jealousy, or other factors might lead to name-calling, hostility, and friction. The woman might sense that her partner is reacting to her more negatively, that he is on edge and reacts heatedly to any trivial frustration. A woman often will accept her partner's building anger as legitimately directed toward her. She internalizes what she perceives as her responsibility to keep the situation from exploding. In her mind, if she does her job well, he remains calm. But if she fails, the resulting violence is her fault.

PHASE 2: ACUTE BATTERING

The second phase of the cycle is the explosion of violence. The batterer loses control both physically and emotionally. This is when the victim may be assaulted or murdered. After a battering episode, most victims consider themselves lucky that the abuse was not worse, no matter how severe their injuries. They often deny the seriousness of their injuries and refuse to seek medical treatment.

PHASE 3: HONEYMOON

The third phase of the cycle is a period of calm, loving, contrite behavior on the part

of the batterer. He may be genuinely sorry for the pain he caused his partner. He attempts to make up for his brutal behavior and believes he can control himself and never hurt the woman he loves. The victim wants to believe that her partner really can change. She feels responsible, at least in part, for causing the incident, and she feels responsible for her partner's well-being (Box 9.1).

Types of Abuse

Abusers may use whatever it takes to control a situation—from emotional abuse and humiliation to physical assault. Victims often tolerate emotional, physical, financial, and sexual abuse. Many remain in abusive relationships because they believe they deserve the abuse.

BOX 9.1

CYCLE OF VIOLENCE (FEMALE VICTIM AND MALE ABUSER)

- *Phase 1—Tension building:* Verbal or minor battery occurs. Almost any subject, such as housekeeping or money, may trigger the buildup of tension. There is a breakdown of communication. The victim attempts to calm the abuser. Victim feels like "walking on egg shells" around the abuser.
- *Phase 2—Acute battering:* Characterized by uncontrollable discharge of tension. Violence is rarely triggered by the victim's behavior: she is battered no matter what her response. The start of the battering episode is unpredictable and beyond the victim's control.
- *Phase 3—Reconciliation (honeymoon)/calm phase:* First, the abuser is ashamed of his behavior. The batterer tries to minimize the abuse and blame it on the partner. The batterer becomes loving, kind, and apologetic and expresses guilt. Then the abuser works on making the victim feel responsible. This loving behavior strengthens the bond between partners and will probably convince the victim, once again, that leaving the relationship is not necessary.

(2015). *The cycle of domestic violence.* Retrieved from http://www.domesticviolenceroundtable.org/domestic-violence-cycle.html; National Stress Clinic. (2015). *Domestic abuse: Understanding and breaking the cycle of violence.* Retrieved from http://www.nationalstressclinic.com/domestic-abuse-understanding-and-breaking-the-cycle-of-violence/

Emotional Abuse

Emotional abuse includes:
- Promising, swearing, or threatening to hit the victim
- Forcing the victim to perform degrading or humiliating acts
- Threatening to harm children, pets, or close friends
- Humiliating the woman by name-calling and insults
- Threatening to leave her and the children
- Isolation from family and friends
- Destroying valued possessions
- Controlling the victim's every move

Physical Abuse

Physical abuse includes:
• Hitting or grabbing the victim so hard that it leaves marks
• Throwing things at the victim
• Slapping, spitting at, biting, burning, pushing, choking, or shoving the victim
• Kicking or punching the victim, or slamming her against things
• Attacking the victim with a knife, gun, rope, or electrical cord
• Controlling access to health care for injury

Financial Abuse

Financial abuse includes:
• Preventing the woman from getting a job
• Sabotaging a current job
• Controlling how all money is spent
• Failing to contribute financially

Sexual Abuse

Sexual abuse includes:
• Forcing the woman to have vaginal, oral, or anal intercourse against her will
• Biting the victim's breasts or genitals
• Shoving objects into the victim's vagina or anus
• Forcing the woman to do something sexual that she finds degrading or humiliating
• Forcing the victim to perform sexual acts on other people or animals

Myths and Facts About Intimate Partner Violence

Table 9.2 lists many of the myths about IPV. Health care providers should take steps to dispel these myths.

Abuse Profiles

Victims

Ironically, victims rarely describe themselves as abused. In **battered woman syndrome**, the woman has experienced deliberate and repeated physical or sexual assault by an intimate partner. She is terrified and feels trapped, helpless, and alone. She reacts to any expression of anger or threat by avoidance and withdrawal behavior. Some women believe that the abuse is caused by a personality flaw or inadequacy in themselves (e.g., inability to keep the man happy). These feelings of failure are reinforced and exploited by their partners. After being told repeatedly that they are "bad," some women begin to believe it. Many victims were abused as children and may have poor self-esteem, poor health, PTSD, depression, insomnia, low education achievement, or a history of suicide attempts, injury, or drug and alcohol abuse (Barrios et. al., 2015).

Abusers

Abusers come from all walks of life and often feel insecure, powerless, and helpless, feelings that are not in line with the macho image they would like to project. The abuser expresses his feelings of inadequacy through violence or aggression toward

others (Lawson, 2015).

Violence typically occurs at home and is usually directed toward the man's intimate partner or the children who live there. Abusers refuse to share power and choose violence to control their victims. They often exhibit childlike aggression or antisocial behaviors. They may fail to accept responsibility or blame others for their own problems. They might also have a history of substance abuse problems, trouble with the justice system, few close relationships, being sensitive to criticism, having a tendency to hold grudges, involved in power struggles, emotionally disregulated, lacking in insight, prone to feeling misunderstood, mistreated, or victimized, mental illness, arrests, troubled relationships, obsessive jealousy, controlling behaviors, generally violent behavior, erratic employment history, and financial problems (Lawson, 2015).

Violence Against Pregnant Women

Many think of pregnancy as a time of celebration and planning for the unborn child's future, but in a troubled relationship it can be a time of escalating violence. The strongest predictor of abuse during pregnancy is prior abuse. Violence against pregnant women seems to be more prevalent than diseases routinely investigated during prenatal care, such as preeclampsia and diabetes (Lévesque & Chamberland, 2015). For women who have been abused before, beatings and violence during pregnancy are "business as usual" for them.

Women are at a higher risk for violence during pregnancy. Recent research findings indicate that having children does not protect women from IPV. On the contrary, the IPV appears to last longer if women have children, and this also seems to be the case even after the partnership has come to an end (Mauri et al., 2015). Pregnant women are vulnerable during this time, and abusers can take advantage of it. An estimated 325,000 pregnant women are abused by their partners each year (CDC, 2015a). Abuse during pregnancy poses special risks and dynamics. Various factors may lead to battering during pregnancy, including:

- Inability of the couple to cope with the stressors of pregnancy
- Young age at time of pregnancy
- Having less than a high school education for both partners
- Unemployment for either or both in partnership
- Violence in the family of origin
- Cohabitation and single marital status
- Sexual proprietariness on the part of the male partner
- Heavy drinking by partner
- Resentment toward the interference of the growing fetus and change in the woman's shape
- Doubts about paternity or the expectant mother's fidelity during pregnancy
- Perception that the baby will be a competitor
- Outside attention the pregnancy brings to the woman
- Unwanted pregnancy
- The woman's new interest in herself and her unborn baby
- Insecurity and jealousy about the pregnancy and the responsibilities it brings
- Financial burden related to expense of pregnancy and loss of income
- Stress of role transition from adult man to becoming the father of a child

• Physical and emotional changes of pregnancy that make the woman vulnerable
• Previous isolation from family and friends that limit the couple's support system

TABLE 9.2 COMMON MYTHS AND FACTS ABOUT RAPE

Myths	Facts
Women who are raped get over it quickly.	It can take several years to recover emotionally and physically from rape.
Most rape victims tell someone about it.	The majority of women never tell anyone about it. In fact, almost two-thirds of victims never report it to the police.
Once the rape is over, a survivor can again feel safe in her life.	The victim feels vulnerable, betrayed, and insecure afterward.
If a woman does not want to be raped, it cannot happen.	A woman can be forced and overpowered by most men.
Women who feel guilty after having sex then say they were raped.	Few women falsely cry "rape." It is very traumatizing to be a victim.
Victims should report the violence to the police and judicial system.	Only 1% of rapists are arrested and convicted. Factoring unreported rapes together with the odds of being arrested and getting a felony conviction, only 6% of rapists will ever spend a day in jail. In other words: 15 of 16 rapists walk free.
Women blame themselves for the rape, believing they did something to provoke the rape.	Women should never blame themselves for being the victim of someone else's violence.
When it comes to sex, men can be provoked to "a point of no return."	Men are physically able to stop at any point during sexual activity. Rape is not an act of impulsive, uncontrolled passion; it is a premeditated act of violence.
Women who wear tight, short clothes are "asking for it."	No victim invites sexual assault, and what she wears is irrelevant.
Women have rape fantasies and want to be raped.	Reality and fantasy are different. Dreams have nothing to do with the brutal violation of rape.
Only attractive women are raped.	Anyone can be raped. Children, the elderly, and people with physical and mental disabilities are easy targets of rape because of their vulnerability.
Medication can help women forget about the rape.	Initially medication can help, but counseling is needed.

(2015). *Common myths about rape*. Retrieved from http://www.rapecrisis.org.uk/commonmyths2.php; Women Against Violence Against Women [WAVAW]. (2015). *Rape myths*. Retrieved from http://www.wavaw.ca/mythbusting/rape-myths/; WELLWVU The Student's Center of Health. (2015). *Rape myths and facts*. Retrieved from https://well.wvu.edu/articles/rape_myths_and_facts

Abuse during pregnancy threatens the well-being of the mother and fetus. Physical violence may involve injuries to the head, face, neck, thorax, breasts, and abdomen. The mental health consequences are also significant. Several studies have confirmed the relationship between abuse and poor mental health, especially depression and PTSD; poor quality of life; increased distress, fearfulness, anxiousness, and stressfulness; and increased use of tobacco, alcohol, and/or illicit drugs (Lawson, 2015). For the pregnant woman, many of these conditions most often manifest during the postpartum period.

Take Note!

Frequently the fear of harm to her unborn child will motivate a woman to escape an abusive relationship.

Women assaulted during pregnancy are at risk for:

- Injuries to themselves and the fetus
- Depression
- Panic disorder
- Fetal and maternal deaths
- Chronic anxiety
- Miscarriage
- Stillbirth
- Poor nutrition
- Insomnia
- Placental abruption
- Uterine rupture
- Excessive weight gain or loss
- Smoking and substance abuse
- Delayed or no prenatal care
- Preterm labor
- Higher rate of surgical births
- Chorioamnionitis
- Vaginitis
- Sexually transmitted infections (STIs)
- Urinary tract infections
- Premature and low–birth-weight infants (Association of Women's Health, Obstetric and Neonatal Nurses [AWHONN], 2015).

Signs of abuse can emerge during pregnancy and may include poor attendance at prenatal visits, unrealistic fears, weight fluctuations, difficulty with pelvic examinations, and nonadherence to treatment. See Evidence-Based Practice 9.1 for an intervention utilized for pregnant women experiencing IPV.

Uncovering abuse in pregnant women requires a consistent and direct approach to every client by the nurse. Multiple assessments may enhance reporting by enabling the nurse to establish trust and rapport with the woman and identify changes in her behavior. Once abuse is discovered in a pregnant woman, interventions should include safety assessment, emotional support, counseling, referral to community services, and ongoing prenatal care to avoid adverse health outcomes (Hewitt, 2015).

EVIDENCE-BASED PRACTICE 9.1

EFFECTIVENESS OF HOME VISITING IN REDUCING PARTNER VIOLENCE FOR FAMILIES EXPERIENCING ABUSE: A SYSTEMATIC REVIEW

STUDY

Intimate partner violence against women is a major, global societal problem with tremendous health consequences both for mother and child. Home-visiting interventions by nurses for families at risk of abuse seem promising in decreasing IVP. In this systematic review the effectiveness of home visiting was assessed as an intervention to reduce IPV experienced by mothers.

Findings

A systematic review was conducted of 1258 articles; 19 of them met the inclusion criteria and were examined in detail. Sixteen reported lower rates of physical assault with home visits by nurses and three studies showed no significant reduction of IPV. This systematic review found that home-visiting interventions that support abused women during their pregnancy and beyond to stop IPV seem to be effective in reducing the incidence of IPV. However, it is not known whether these results are effective long term.

Nursing Implications

By nurses making home visits, a trusting relationship can be established between the client and nurse. By addressing factors that may increase the risk of IPV in general, such as stress as well as other contributing factors, IPV can be reduced and the cycle of violence can be broken. A major benefit of home-visiting interventions is that they succeed in reaching high-risk young pregnant women, who are notoriously hard to reach for regular prenatal services during a vulnerable stage in their lives. Nurses can see the home environment and can detect risk factors and plan interventions to address them.

Adapted from Prosman, G. J., Wong, S. H. L. F., van der Wouden, J. C., & Lagro-Janssen, A. L. (2015). Effectiveness of home visiting in reducing partner violence for families experiencing abuse: A systematic review. *Family Practice*, (Online: 5/6/15) doi: 10.1093/fampra/cmu091

Violence Against Older Women

IPV affects women of all ages, but often the literature focuses on women in the childbearing years, ignoring the problems of aging women who experience abuse. Elder mistreatment (i.e., abuse and neglect) is defined as intentional actions that cause harm or create a serious risk of harm to a vulnerable elder by a caregiver or other person who stands in a trust relationship to the elder. All 50 states have laws requiring health care providers to report elder or vulnerable person abuse. Estimates suggest that 500,000 to 2 million cases of elder abuse and neglect occur annually in the United States. It is estimated that 1 in 10 older adults experience abuse, but only 1 in 5 to as little as 1 in 24 are reported. Research suggests that female elders are abused at a higher rate than males and that the older one is, the more likely one is to be abused. Elder abuse is expected to increase as the population ages (Wang et al., 2015). Types of abuse experienced by the older woman may include physical abuse, neglect, emotional abuse, sexual abuse, and financial/exploitation abuse (National Center on Elder Abuse, 2015).

Although an injury may bring the older woman into the health care system, the physical and emotional sequelae of IPV may be more subtle and may include depression, insomnia, chronic pain, difficulty trusting others, low self-esteem, thoughts of suicide, substance abuse, anger issues, atypical chest pain, or other kinds of somatic symptoms. Research suggests that older women usually have endured long-term abuse, have developed unhealthy strategies to cope (substance abuse, keeping the family together at all cost, and physical/mental health consequences), and shoulder blame from their adult children, yet have developed empowerment from within to be able to cope with the abuse (Policastro & Finn, 2015).

Accurate detection and assessment of abuse in older women are essential duties of

all nurses. Nurses have frequent contact with older victims of abuse, providing them the opportunity to play a significant role in detecting, reporting, and intervening in such cases. As part of a thorough screening, nurses should determine what the client has done to attempt to resolve the abuse and the effectiveness of those strategies. Actions taken by the client, prior to revealing her abuse issue to the nurse, might have included passive acceptance, calling law enforcement, counseling, or other measures. In addition, taking time to establish rapport with older women builds a sense of trust, safety, and openness. Nurses must listen carefully and nonjudgmentally. Judging or criticizing the victim for her decisions might lead to the impression that she deserves the abuse or that she is to blame. Finally, nurses should attempt to stay current in their knowledge of referral resources to assist the older woman experiencing abuse. Some of these resources may be housing, transportation, medical services, employment, social services, and local support groups. A coordinated and comprehensive response to IPV is essential to reduce its sequelae.

Nursing Management of Intimate Partner Violence Victims

Nurses encounter thousands of abuse victims each year in their practice settings, but many victims slip through the cracks. As universal violence assessment has increased in recent years, nurses need to be aware of not only how to screen for violence, but how to respond in a way that is helpful, sincere, nonjudgmental, and legally adequate. This will require nurses to move beyond a description of violence toward a response that is action-oriented and evidence based, which includes safety planning and referrals. There are many things that nurses can do to help victims. Early recognition and intervention can significantly reduce the morbidity and mortality associated with IPV. To stop the cycle of violence, nurses need to know how to assess for and identify IPV and implement appropriate actions.

Assessment

Routine screening for IPV is the first way to detect abuse. The nurse should build rapport by listening, showing an interest in the concerns of the woman, and creating an atmosphere of openness. Communicating support through a nonjudgmental attitude and telling the woman that no one deserves to be abused are first steps toward establishing trust and rapport. Rather than overlooking abused women as "chronic complainers," astute nurses need to be vigilant for subtle clues of abuse. Learning how to assess for abuse is critical. Some basic assessment guidelines follow.

SCREEN FOR ABUSE DURING EVERY HEALTH CARE VISIT

Screening for violence takes only a few minutes and can have an enormously positive effect on the outcome for the abused woman. Any woman could be a victim; no single sign marks a woman as an abuse victim, but the following clues may be helpful:

- Injuries: bruises on their chest and abdomen, scars from blunt trauma, minor lacerations or weapon wounds on the face, head, and neck
- Injury sequelae: headaches, hearing loss from ruptured ear drums, joint pain, sinus infections, teeth marks, clumps of hair missing, dental trauma, pelvic pain, breast

or genital injuries
- Reported history of injury that is not consistent with the actual presenting problem
- Mental health problems: depression, anxiety, substance abuse, eating disorders, suicidal ideation or suicide attempts, anger toward health care provider, PTSD
- Frequent tranquilizer or sedative use
- Delay in seeking medical attention and patterns of repeated injury
- Bruises to the upper arm, neck and face, abdomen, or breasts
- Comments about emotional or physical abuse of "a friend"
- STIs or pelvic inflammatory disease
- Appears nervous, ashamed, or evasive when asked questions
- Frequent health care visits for chronic, stress-related disorders such as chest pain, headaches, back or pelvic pain, insomnia, injuries, anxiety, and gastrointestinal disturbances
- Partner's behavior at the health care visit: appears overly solicitous or overprotective, is unwilling to leave her alone with the health care provider, answers questions for her, and attempts to control the situation (Ghandour, Campbell, & Lloyd, 2015).

***Dorothy*, who you met at the beginning of the chapter, has been frequenting the clinic with vague somatic complaints in recent weeks and admits she is sometimes afraid at home. She tells the nurse her partner doesn't want her to work, although he is only sporadically employed at low-paying jobs. What cues in her assessment might indicate abuse? What physical signs might the nurse observe?**

ISOLATE CLIENT IMMEDIATELY FROM FAMILY

If abuse is detected, immediately isolate the woman to provide privacy and to prevent potential retaliation from the abuser. Asking about abuse in front of the perpetrator may trigger an abusive episode during the interview or at home. Ways to ensure the woman's safety would be to take the victim to an area away from the abuser to ask questions. The assessment can take place anywhere that is private and away from the abuser, for example, x-ray area, ultrasound room, elevator, ladies' room, or laboratory.

If abuse is detected, the nurse can do the following to enhance the nurse–client relationship:
- Educate the woman about the connection between the violence and her symptoms.
- Help the woman acknowledge what has happened to her and begin to deal with the situation.
- Offer her referrals so she can get the help that will allow her to begin to heal.

***Dorothy* returns to the prenatal clinic a month later with anemia, inadequate weight gain, bruises on her face and neck, and second-trimester bleeding. This time she is accompanied by her partner, who stays close to Dorothy. What questions should the nurse ask to assess the situation? Where is the appropriate location to ask these questions? What legal**

responsibilities does the nurse have concerning her observations?

ASK DIRECT OR INDIRECT QUESTIONS ABOUT ABUSE

Violence against women is often unseen, unknown, and hidden in families. Questions to screen for abuse should be routine and handled just like any other question. Many nurses feel uncomfortable asking questions of this nature, but broaching the subject is important even if the answer comes later. Opening up the possibility for women to express themselves about their experience of abuse to a nurse sends out a clear message that violence should never be tolerated and not kept hidden; it also conveys the message that nurses care about women's experiences and want to offer a best practice initial response. Just knowing that someone else knows about the abuse offers a victim some relief and may help her disclose it.

Ask difficult questions in an empathetic and nonthreatening manner and remain nonjudgmental in all responses and interactions. Choose the type of question that makes you most comfortable. Direct and indirect questions produce the same results. "Does your partner hit you?" or "Have you ever been or are you now in an abusive relationship?" are direct questions. If that approach feels uncomfortable, try indirect questions: "We see many women with injuries or complaints like yours and often they are being abused. Is that what is happening to you?" or "Many women in our community experience abuse from their partners. Is anything like that happening in your life?" With either approach, nurses need to maintain a nonjudgmental acceptance of whatever answers the woman offers. The SAVE Model is a screening protocol that nurses can use when assessing women for violence (Box 9.2).

ASSESS IMMEDIATE SAFETY

It is essential to assist the woman by assessing her safety and the safety of her children. To do this, speak to the woman alone and ask her:

- Does she feel safe going home after her meeting with you?
- Does she need an immediate place of safety for herself or her children?
- Does she have a plan of escape if she becomes at risk for her safety?
- Does she need to consider an alternative exit from this building?
- Who are the people she could contact for help or support?

BOX 9.2

SAVE MODEL

SCREEN all of your clients for violence by asking:

- Within the last year, have you been physically hurt by someone?
- Do you feel you are in control of your life?
- Within the last year, has anyone forced you to engage in sexual activities?
- Can you talk about your abuse with me now?
- In general, how would you describe your present relationship?

ASK direct questions in a nonjudgmental way:

- Begin by normalizing the topic to the woman.

• Make continuous eye contact with the woman.
• Stay calm; avoid emotional reactions to what she tells you.
• Never blame the woman, even if she blames herself.
• Do not dismiss or minimize what she tells you, even if she does.
• Wait for each answer patiently. Do not rush to the next question.
• Do not use formal, technical, or medical language.
• Avoid using leading questions; be direct and to the point.
• Use a nonthreatening, accepting approach.

VALIDATE the client by telling her:

• You believe her story.
• You do not blame her for what happened.
• It is brave of her to tell you this.
• Help is available for her.
• Talking with you is a hopeful sign and a first big step.

EVALUATE, educate, and refer this client by asking her:

• What type of violence was it?
• Is she now in any danger?
• How is she feeling now?
• Does she know that there are consequences to violence?
• Is she aware of community resources available to help her?

Screening for domestic violence in health care settings. *Office of the Assistant Secretary for Planning and Evaluation.* Retrieved from http://aspe.hhs.gov/hsp/13/dv/pb_screeningdomestic.cfm; Association of Women's Health, Obstetric and Neonatal Nurses [AWHONN]. (2015). Intimate partner violence. *Journal of Obstetric, Gynecologic, and Neonatal Nursing*, *44*(3), 405–408.; Canadian Domestic Homicide Prevention Initiative. (2015). *Risk assessment, risk management and safety planning.* Retrieved from http://www.learningtoendabuse.ca/cdhpi/risk-assessment-risk-management-and-safety-planning

The Danger Assessment Tool (Box 9.3) helps women and health care providers assess the potential for homicidal behavior in an ongoing abusive relationship. It is based on research that showed several risk factors for abuse-related murders:
• Increased frequency or severity of abuse
• Presence of firearms
• Sexual abuse
• Substance abuse
• Precipitated by arguments and conflicts
• Generally violent behavior outside of the home
• Control issues (e.g., daily chores, friends, job, money)
• Physical abuse during pregnancy
• Suicide threats or attempts (victim or abuser)
• Child abuse (Sugg, 2015).

DOCUMENT AND REPORT YOUR FINDINGS

If the interview reveals a history of abuse, accurate documentation is critical because this evidence may support the woman's case in court. Documentation must include details about the frequency and severity of abuse; the location, extent, and outcome of injuries; and any treatments or interventions. When documenting, use

direct quotes and be very specific: “He choked me.” Describe any visible injuries, and use a body map (outline of a woman’s body) to show where the injuries are. Obtain photos (with informed consent) or document her refusal if the woman declines photos. Pictures or diagrams can be worth a thousand words. Figure 9.2 shows a sample documentation form for IPV.

Laws in many states require health care providers to alert the police to any injuries that involve knives, firearms, or other deadly weapons or that present life-threatening emergencies. If assessment reveals suspicion or actual indication of abuse, nurses can explain to the woman that they are required by law to report it.

Nursing Diagnosis

When violence is suspected or validated, the nurse needs to formulate nursing diagnoses based on the completed assessment. Possible nursing diagnoses related to violence against women might include the following:

- Deficient knowledge related to understanding the cycle of violence and availability of resources
- Anxiety related to threat to self-concept, situational crisis of abuse
- Situational low self-esteem related to negative family interactions
- Powerlessness related to lifestyle of helplessness
- Compromised individual and family coping related to abusive patterns

Interventions

The response of nurses to battered women can have a profound effect on their willingness to open up or seek help. Some responses to assist successful communication in these circumstances could include:

- Listening—“I hear and understand what you are saying.” Being listened to can be an empowering experience for a woman who has been abused.
- Communicating belief—“That must have been very frightening for you.”
- Validating the decision to disclose—“It must have been difficult for you to talk about this today.”
- Emphasizing the unacceptability of this violence—“You don’t deserve to be treated this way.”

BOX 9.3

DANGER ASSESSMENT TOOL

Several risk factors have been associated with increased risk of homicides (murders) of women and men in violent relationships. No one can predict what will happen in your case, but we would like you to be aware of the danger of homicide in situations of abuse and for you to see how many of the risk factors apply to your situation. (“He” refers to your husband, partner, ex-husband, ex-partner, or whoever is currently physically hurting you.)

___1. Has the physical violence increased in severity or frequency over the past year?
___2. Does he own a gun?
___3. Have you left him after living together during the past year?

___4. Is he unemployed?
___5. Has he ever used a weapon against you or threatened you with a lethal weapon?
___6. Does he threaten to kill you?
___7. Has he avoided being arrested for domestic violence?
___8. Do you have a child that is not his?
___9. Has he ever forced you to have sex when you did not wish to do so?
___10. Does he ever try to choke you?
___11. Does he use illegal drugs? By drugs, I mean "uppers" or amphetamines, "meth," speed, angel dust, cocaine, "crack," street drugs, or mixtures.
___12. Is he an alcoholic or problem drinker?
___13. Does he control most or all of your daily activities? For instance: does he tell you who you can be friends with, when you can see your family, how much money you can use, or when you can take the car?
___14. Is he violently and constantly jealous of you? (For instance, does he say "If I can't have you, no one can.")
___15. Have you ever been beaten by him while you were pregnant?
___16. Has he ever threatened or tried to commit suicide?
___17. Does he threaten to harm your children?
___18. Do you believe he is capable of killing you?
___19. Does he follow or spy on you, leave threatening notes or messages on answering machine, destroy your property, or call you when you don't want him to?
___20. Have you ever threatened or tried to commit suicide?
___ Total "Yes" Answers

Thank you. Please talk to your nurse, advocate, or counselor about what the Danger Assessment means in terms of your situation.

Source: March of Dimes Danger Assessment questionnaire. (From Campbell, J. (1986). Nursing assessment for risk of homicide with battered women. *Advances in Nursing Science*, *8*(4), 36–51.)

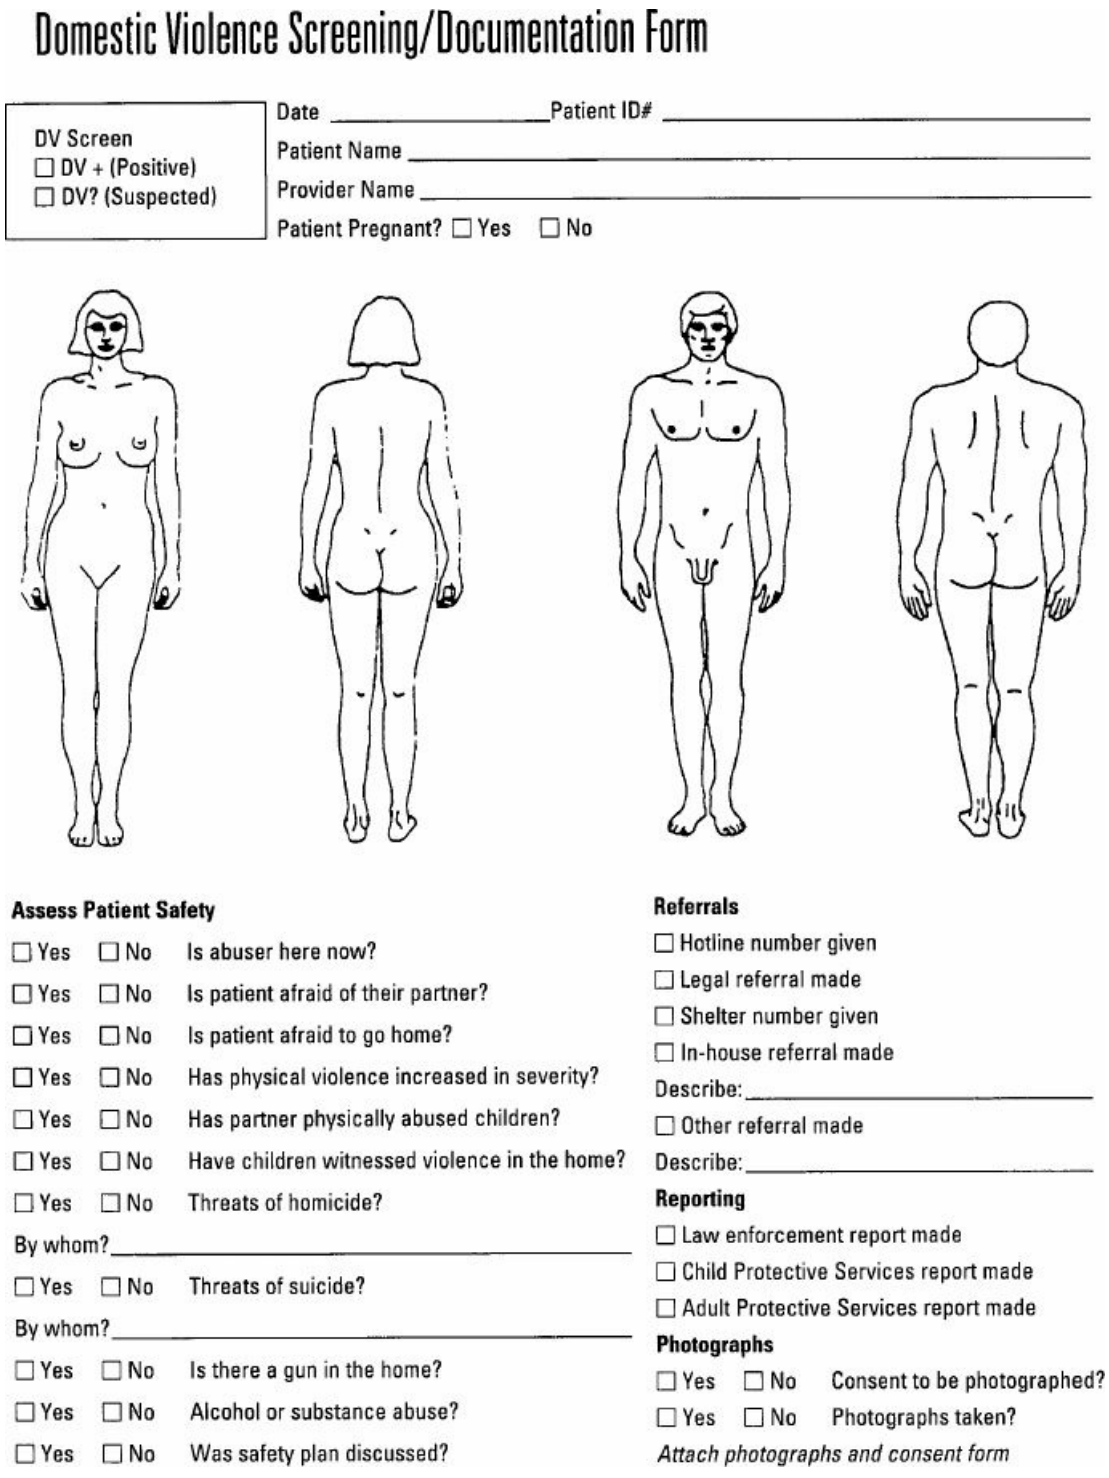
If abuse is identified, nurses can undertake interventions that can increase the woman's safety and improve her health. The goal of intervention is to enable the victim to gain control of her life. Provide sensitive, predictable care in an acceptable setting. Offer step-by-step explanations of procedures. Provide educational materials about violence. Allow the victim to actively participate in her care and have control over all health care decisions. Pace your nursing interventions and allow the woman to take the lead. Communicate support through a nonjudgmental attitude. Carefully document all of your assessment findings and nursing interventions.

Concept Mastery Alert

Priorities in Intimate Partner Violence Interventions

Although it is certainly important that the woman in an abusive situation is safe, it is most important for a woman to regain a sense of control in her life. A lack of control is what prevents a woman from escaping an abusive situation.

A public health approach to violence prevention requires input from and coordination across sectors, including health, education, social services, justice, and policy. The goal of public health is to improve the health of the entire community or society. Depending on when in the cycle of violence the nurse encounters the abused woman, goals may fall into three groups:



Domestic Violence Screening/Documentation Form

DV Screen
☐ DV + (Positive)
☐ DV? (Suspected)

Date _____ Patient ID# _____
Patient Name _____
Provider Name _____
Patient Pregnant? ☐ Yes ☐ No

Assess Patient Safety

☐ Yes ☐ No Is abuser here now?
☐ Yes ☐ No Is patient afraid of their partner?
☐ Yes ☐ No Is patient afraid to go home?
☐ Yes ☐ No Has physical violence increased in severity?
☐ Yes ☐ No Has partner physically abused children?
☐ Yes ☐ No Have children witnessed violence in the home?
☐ Yes ☐ No Threats of homicide?
By whom? _____
☐ Yes ☐ No Threats of suicide?
By whom? _____
☐ Yes ☐ No Is there a gun in the home?
☐ Yes ☐ No Alcohol or substance abuse?
☐ Yes ☐ No Was safety plan discussed?

Referrals

☐ Hotline number given
☐ Legal referral made
☐ Shelter number given
☐ In-house referral made
Describe: _____
☐ Other referral made
Describe: _____

Reporting

☐ Law enforcement report made
☐ Child Protective Services report made
☐ Adult Protective Services report made

Photographs

☐ Yes ☐ No Consent to be photographed?
☐ Yes ☐ No Photographs taken?
Attach photographs and consent form

FIGURE 9.2 Intimate partner violence documentation form. (Reprinted from *Home Healthcare Nurse, 17, Cassidy K, How to assess and intervene in domestic violence situations,* 644–72, Copyright 1999, with permission from Lippincott Williams & Wilkins.)

- *Primary prevention:* aimed at breaking the abuse cycle through community educational initiatives by nurses, physicians and nurse practitioners, law enforcement, teachers, and clergy
- *Secondary prevention:* focuses on screening high-risk individuals and dealing with victims and abusers in early stages, with the goal of preventing progression of abuse
- *Tertiary prevention:* activities are geared toward helping severely abused women and children recover and become productive members of society and rehabilitating abusers to stop the cycle of violence. These activities are typically long term and expensive.

A modified tool developed by Holtz and Furniss (1993)—the ABCDES—provides a framework for providing sensitive nursing interventions to abused women (Box 9.4). Specific nursing interventions for the abused woman include educating her about community services, providing emotional support, and offering a safety plan.

BOX 9.4

THE ABCDES OF CARING FOR ABUSED WOMEN

- **A** is reassuring the woman that she is not alone. The isolation by her abuser keeps her from knowing that others are in the same situation and that health care providers can help her.
- **B** is expressing the belief that violence against women is not acceptable in any situation and that it is not her fault. Demonstrate by your actions and words that you believe her disclosure.
- **C** is confidentiality, since the woman might believe that if the abuse is reported, the abuser will retaliate. Interview her in private, without her partner or family members being present. Assure her that you will not release her information without her permission.
- **D** is documentation, which includes the following:
  1. A clear quoted statement about the abuse in the woman's own words.
  2. Accurate descriptions of injuries and the history of them.
  3. Information on the first, the worst, and the most recent abusive incident.
  4. Photos of the injuries (with the woman's consent).
- **E** is education about the cycle of violence and that it will escalate:
  1. Educate about abuse and its health effects.
  2. Help her to understand that she is not alone.
  3. Offer appropriate community support and referrals.
  4. Display posters and brochures to foster awareness of this public health problem.
- **S** is safety, the most important aspect of the intervention, to ensure that the woman has resources and a plan of action to carry out when she decides to leave.

(2015a). *Understanding intimate partner violence: Fact sheet.* Retrieved from http://www.cdc.gov/violenceprevention/pub/ipv_factsheet.html; Human Rights Watch. (2015). *Abused and expelled.* Retrieved from http://www.hrw.org/sites/default/files/reports/morocco0214_ForUpload.pdf; Ghandour, R. M., Campbell, J. C., & Lloyd, J. (2015). Screening and counseling for intimate partner violence: A vision for the future. *Journal*

of Women's Health, *24*(1), 57–61.

EDUCATE THE WOMAN ABOUT COMMUNITY SERVICES

A wide range of support services are available to meet the needs of victims of violence. Nurses should be prepared to help the woman take advantage of these opportunities. Services will vary by community but might include psychological counseling, legal advice, social services, crisis services, support groups, hotlines, housing, vocational training, and other community-based referrals.

Give the woman information about shelters or services even if she initially rejects it. Give the woman the National Domestic Violence hotline number: (800) 799-7233. The Joint Commission on the Accreditation of Hospitals and Health care Organizations (JCAHO), American Medical Association (AMA), American College of Obstetrician Gynecologists (ACOG), and the United States Preventive Services Task Force (USPSTF) all recommend routine IVP screening, counseling, and referrals in all health care agencies (U.S. Department of Health and Human Services [USDHHS], 2015c).

PROVIDE EMOTIONAL SUPPORT

Providing reassurance and support to a victim of abuse is essential if the violence is to end. The physical, psychological, and emotional effects of IPV on women and their children can be severe and long lasting. Nurses in all clinical settings can help victims to feel a sense of personal power and provide them with a safe and supportive environment. Appropriate action can help victims to express their thoughts and feelings in constructive ways, manage stress, and move on with their lives. Appropriate interventions are:

- Strengthen the woman's sense of control over her life by:
  - Teach coping strategies to manage her stress
  - Assist with activities of daily living to improve her lifestyle
  - Allow her to make as many decisions as she can
  - Educate her about the symptoms of PTSD and their basis
- Encourage the woman to establish realistic goals for herself by:
  - Teaching problem-solving skills
  - Encouraging social activities to connect with other people
- Providing support and allow the woman to grieve for her losses by:
  - Listening to and clarifying her reactions to the traumatic event
  - Discussing shock, disbelief, anger, depression, and acceptance
- Explain to the woman that:
  - Abuse is never OK. She didn't ask for it and she doesn't deserve it
  - She is not alone and help is available
  - Abuse is a crime and she is a victim
  - Alcohol, drugs, money problems, depression, or jealousy does not cause violence, but these things can give the abuser an excuse for losing control and abusing her
  - The actions of the abuser are not her fault
  - Her history of abuse is believed
  - Making a decision to leave an abusive relationship can be very hard and takes time

OFFER A SAFETY PLAN

The choice to leave must rest with the victim. Nurses cannot choose a life for the victim; they can only offer choices. Leaving is a process, not an event. Victims may try to leave their abusers as many as seven or eight times before succeeding. Frequently, the final attempt to leave may result in the death of the victim. Women planning to leave an abusive relationship should have a safety plan, if possible (Teaching Guidelines 9.1).

Teaching Guidelines 9.1
SAFETY PLAN FOR LEAVING AN ABUSIVE RELATIONSHIP

- When leaving an abusive relationship, take the following items:
  - Driver's license or photo ID
  - Social Security number or green card/work permit
  - Birth certificates for you and your children
  - Phone numbers for social services or women's shelter
  - The deed or lease to your home or apartment
  - Any court papers or orders
  - A change of clothing for you and your children
  - Pay stubs, checkbook, credit cards, and cash
  - Health insurance cards
  - If you need to leave a domestic violence situation immediately, turn to authorities for assistance in gathering this material
- Develop a "game plan" for leaving and rehearse it
- Don't use phone cards—they leave a trail to follow

Adapted from Burnett, L. B., & Adler, J. (2015). Domestic violence. eMedicine. Retrieved from http://emedicine.medscape.com/article/805546-overview; Murray, C. E., Horton, G. E., Johnson, C. H., Notestine, L., Garr, B., Pow, A. M., et al. (2015). Domestic violence service providers' perceptions of safety planning: A focus group study. *Journal of Family Violence*, *30*(3), 381–392; Chang, J. C. (2015). Domestic violence: Epidemiology and risk factors. *Clinical Gynecology* (2nd ed., pp. 94–101), Cambridge, UK: Cambridge University Press.

Nurses need to remember that their role is that of a guide, not a savior. A woman will make the best decision she sees fit at that moment in time. A nurse may be her most effective resource in her stress-filled environment. Just allowing the woman to talk may be the most valuable intervention. The impact of the nurse's presence and support will stay with the woman, no matter what decision she makes.

SEXUAL VIOLENCE

Sexual violence is both a public health problem and a human rights violation. Sexual violence includes IPV, human trafficking, **incest**, FGC, forced prostitution, bondage, exploitation, neglect, infanticide, and sexual assault. It occurs worldwide and affects up to one-third of women over a lifetime (Bagwell-Gray et al., 2015). Once every 2 minutes, 30 times an hour, 1871 times a day, girls and women in America are raped. One in 5 women and 1 in 71 men will be sexually assaulted during their lifetime (Rape, Abuse, and Incest National Network [RAINN], 2015a).

Rape has been reported against females from age 6 months to 93 years, but it still remains one of the most underreported violent crimes in the United States. Once every 2 minutes, a woman is sexually assaulted in the United States (RAINN, 2015a). The National Center for Prevention and Control of Sexual Assault estimates that two-thirds of sexual assaults will not be reported (CDC, 2015f). Over the course of their lives, women may experience more than one type of violence.

Sexual violence can have a variety of devastating short- and long-term effects. Women can experience psychological, physical, and cognitive symptoms that affect them daily. They can include chronic pelvic pain, headaches, backache, STIs, pregnancy, anxiety, denial, fear, withdrawal, sleep disturbances, guilt, nervousness, phobias, substance abuse, depression, sexual dysfunction, and PTSD. Many contemplate suicide (CDC, 2015f). A traumatic experience not only damages a woman's sense of safety in the world, but it can also reduce her self-esteem and her ability to continue her education, to earn money and be productive, to have children and, if she has children, to nurture and protect them. Overall, sexually assaulted women exhibit lower functioning as adults afterward (MacGregor et al., 2015).

Take Note!

Sexual violence has been called a "tragedy of youth." More than half of all rapes (54%) of women occur before age 18 (Medicine Net, 2015a).

Characteristics of Assailants

Assailants, like their victims, come from all walks of life and all ethnic backgrounds; there is no typical profile. More than half are under the age of 25, and the majority are married and leading "normal" sex lives. Why do men rape? No theory provides a satisfactory explanation. So few assailants are caught and convicted that a clear profile remains elusive. What is known is that many assailants have trouble dealing with the stresses of daily life. Such men become angry and experience feelings of powerlessness. They become jealous easily; do not view women as equals; frequently are hot tempered; have a need to be reassured of their manhood; and do not handle stress in their lives well. They commit a sexual assault as an expression of power and control (Kilmartin, 2015).

Sexual Abuse

Sexual abuse occurs when a woman is forced to have sexual contact of any kind (vaginal, oral, or anal) without her consent. Current estimates indicate that one of five girls is sexually abused, and the peak ages of such abuse are from 8 to 12 years of age. At every age in the life span, females are more likely to be sexually abused by father, brother, family member, neighbor, boyfriend, husband, partner, or ex-partner than by a stranger or anonymous assailant. Sexual abuse knows no economic or cultural barriers (de Jong et al., 2015). Marriage does not constitute a tacit agreement for a spouse to inflict one's demands on the other without permission.

Childhood sexual abuse is any type of sexual exploitation that involves a child younger than 18 years old. It might include disrobing, nudity, masturbation, fondling, digital penetration, forced performance of sexual acts on the perpetrator,

and intercourse (Dutton, 2015). Childhood sexual abuse has a lifelong impact on its survivors. There is strong evidence that sexual assault in childhood or adolescence is a serious risk factor for mental illness (Brooker & Durmaz, 2015). Women who were sexually abused during childhood are at a heightened risk for repeat abuse. This is because the early abuse lowers their self-esteem and their ability to protect themselves and set firm boundaries. Childhood sexual abuse is a trauma that influences the way victims form relationships, deal with adversity, cope with daily problems, relate to their children and peers, protect their health, and live. See Evidence-Based Practice 9.2 for study regarding childhood sexual abuse. Studies have shown that the more victimization a woman experiences, the more likely it is she will be revictimized (Brenner & Ben-Amitay, 2015).

Interventions for sexually abused children or women should include referral for mental health counseling. Follow up for any medical problems (e.g., genitourinary complaints) should be arranged with the child's or woman's primary care physician or nurse practitioner. If the community has an abuse referral center, refer the victim there for follow-up care according to local protocol.

The medical consequences of sexual abuse require the prophylaxis and treatment of STIs, emergency contraception, and treatment of any injuries that resulted from the abuse. Victims with postassault bleeding require an emergent evaluation and may need emergency treatment by a gynecologist for repair of genital injury. The psychosocial aspects of sexual abuse must also be addressed because appropriate therapeutic follow-up is essential to the victim's future emotional well-being.

EVIDENCE-BASED PRACTICE 9.2

SIBLING SEXUAL ABUSE: AN EXPLORATORY STUDY OF LONG-TERM CONSEQUENCES FOR SELF-ESTEEM AND COUNSELING CONSIDERATIONS

Today, health care providers recognize childhood sexual abuse within the family as a significant and widespread problem with consequences lasting long into adulthood. Despite this progression, the research related to interfamilial incest conducted by researchers has focused primarily on father to daughter incest, largely ignoring the experience of sibling sexual assault, although it is more common than parental incest. Clearly, sibling incest is a pandemic problem that requires more attention from health care providers.

STUDY

This study addresses experiencing sibling sexual abuse as a child and how it inversely affects the level of self-esteem in adulthood. One hundred college students were used as the sample size; 67% were female and 33% were male with a diverse cultural representation. The age of the students ranged from 20 to 59 years old. A survey with two sections was used. The first section addressed recollection of the prevalence and severity of sibling abuse; the second section of the survey addressed self-esteem using the Rosenberg Self-Esteem Scale. Reliability and validity of this tool reflected a Cronbach alpha coefficient of 0.82.

Findings

This study supported the likelihood that sibling sexual abuse could be the most

common form of child sexual abuse in the United States. In spite of the apparent prevalence of this, it is disturbing how little has been done to address the complexity surrounding this form of abuse. Both survivors and offenders of sibling sexual abuse experience the lasting impact of the abuse as they become adults in their social interactions, school, work, and family life. In addition to a low self-esteem, other mental health issues experienced include symptoms of PTSD, anxiety disorders, depression, eating disorders, angry outbursts, self-injury, somatic complaints, and suicidal ideation. Many engage in at-risk behaviors such as unprotected sex, self-medication with drugs and alcohol, and dating violence. Clearly, ignoring the problem of sibling sexual abuse has a negative effect on a sense of well-being as these children become adults.

Nursing Implications

One of the most important aspects is to establish trust with these clients and create a safe environment. An important role for nurses is in primary prevention of sibling sexual abuse through educating parents. When parents understand how to promote positive parent–child relationships and sibling interactions, the risk of abuse in the entire family tends to be reduced. Nurses can take a lead role through promotion of structured parent education programs within their communities and referrals to national networks such as Family Support America.

Adopted from Morrill, M. (2014). Sibling sexual abuse: An exploratory study of long term consequences for self-esteem and counseling considerations. *Journal of Family Violence*. *29*(2), 205–213.

Incest

Incest is defined as sexual activity between persons so closely related that marriage between them is legally or culturally prohibited (Dorland, 2015). The exact incidence of child sexual victimization is unknown. Such sexual abuse is not only a crime but also a symptom of acute and irreversible family dysfunction. Childhood incest abuse involves any kind of sexual exploitation between a child and another person that violates the social taboos of family roles; children cannot yet understand these activities and cannot give informed consent. Adult women with a history of incest exhibit a clinical syndrome that includes low self-esteem, difficulty with intimate relationships, sexual dysfunction, flashbacks and nightmares, repeated victimization, as well as suicidality, depressive symptomatology, eating disorders, and substance abuse (Harkins, 2015). Survivors of incest are often tricked, coerced, or manipulated. All adults appear to be powerful to children. Perpetrators might threaten victims so that they are afraid to disclose the abuse or might tell them the abuse is their fault. Often these threats serve to silence victims.

Incestuous relationships in the home endanger not only the child's intellectual and moral development, but also the health of the child. Many children do not ask for help because they do not want to expose their "secret." For this reason, just the tip of the iceberg is statistically visible: serious injuries, internal damage, STIs, or pregnancy. Incest can have serious long-term effects on its victims, which may include eating disorders, sexual problems in adult life, difficulty in interpersonal relationships, anxiety, PTSD, intense guilt and shame, low self-esteem, depression, and self-destructive behavior (National Center for Victims of Crime [NCVC], 2015a).

Whether an incest victim endured an isolated incident of abuse or ongoing

assaults over an extended period, recovery can be painful and difficult. The recovery process begins with admission of abuse and the recognition that help and services are needed. Resources for incest victims include books, self-help groups, workshops, therapy programs, and possibly legal remedies. In addition to listening to and believing incest victims, nurses need to search for ways to prevent future generations from enduring such abuse and from continuing the cycle of abuse in their own family and relationships. Nurses have the ability and the responsibility to function within an interdisciplinary system responsible for the assessment and ongoing treatment of incestuous families. Nurses can fulfill their roles as advocates for children, while at the same time adding necessary referrals to social services and legal authorities. Forming this partnership with the social service and judicial communities will help protect the child from future abuse and ensure the child a safe environment in which to grow and develop.

Take Note!

Childhood sexual abuse is a trauma that can affect every aspect of the victim's life.

Rape

Rape is an expression of violence, not a sexual act. Rape distorts one of the most intimate forms of human interaction. It is not an act of lust or an overzealous release of passion: it is a violent, aggressive assault on the victim's body and integrity. Those who rape do so for a number of reasons, but they basically involve the motives of anger, power, eroticized cruelty, and opportunistic mating (Keygnaert, Vettenburg, & Temmerman, 2015). Rape is a legal rather than a medical term. It denotes penile penetration of the vagina, mouth, or rectum of the female or male without consent. It may or may not include the use of a weapon. **Statutory rape** is sexual activity between an adult and a person under the age of 18 and is considered to have occurred even if the underage person was willing (RAINN, 2015b). Nine out of every 10 rape victims are female (Alexander et al., 2014). Enforcement of laws, education, and community empowerment are all needed to prevent rape.

Consider This

At 53 years old, I stood and looked at myself in the mirror. The image staring back at me was one of a frightened, middle-aged, cowardly woman hiding her past. I had been sexually abused by my father for many years as a child and never told anyone. My mother knew of the abuse but felt helpless to make it stop. I married right out of high school to escape and felt I lived a "happy normal life" with my husband and three children. My children have left home and live away, and my husband recently died of a sudden heart attack. I am now experiencing dreams and thoughts about my past abuse and feeling afraid again.

Thoughts: This woman suppressed her abusive past for most of her life and now her painful experience has surfaced. What can be done to reach out to her at this point? Did her health care providers miss the "red flags" that are common to women with a history of childhood sexual abuse all those years?

Many people believe that rape usually occurs on a dark night when a stranger

assaults a provocatively dressed, promiscuous woman. They believe that rapists are sex-starved people seeking sexual gratification. Rape myths are destructive beliefs about sexual aggression (i.e., its scope, causes, context, and consequences) that serve to deny, downplay, or justify sexually aggressive behavior that men commit against women. A rape victim's recovery is frequently complicated by the public's failure to believe the victim and restore justice (Klaus, Buczkowski, & Wiktorska, 2015). Rape myths serve to blame victims and exonerate perpetrators. Such myths and the facts are presented in Table 9.3.

Acquaintance Rape

In **acquaintance rape**, someone is forced to have sex by a person he or she knows. Rape by a coworker, a teacher, a husband's friend, or a boss is considered acquaintance rape. **Date rape**, an assault that occurs within a dating relationship or marriage without consent of one of the participants, is a form of acquaintance rape. Acquaintance and date rapes commonly occur on college campuses. One in four college women has been raped—that is, has been forced, physically or verbally, actively or implicitly, to engage in sexual activity (Wilson & Miller, 2015).

TABLE 9.3 FOUR PHASES OF RAPE RECOVERY

Phase	Survivor's Response
Acute phase (disorganization)	Shock, fear, disbelief, anger, shame, guilt, feelings of uncleanliness; insomnia, nightmares, and sobbing
Outward adjustment phase (denial)	Appears outwardly composed and returns to work or school; refuses to discuss the assault and denies need for counseling
Reorganization	Denial and suppression do not work, and the survivor attempts to make life adjustments by moving or changing jobs and uses emotional distancing to cope
Integration and recovery	Survivor begins to feel safe and starts to trust others. She may become an advocate for other rape victims

Adapted from National Center for Victims of Crime [NCVC]. (2015b). *The trauma of victimization*. Retrieved from http://victimsofcrime.org/help-for-crime-victims/get-help-bulletins-for-crime-victims/trauma-of-victimization#ptsd; Rape, Abuse, and Incest National Network [RAINN]. (2015d). *Recovery from sexual assault*. Retrieved from http://www.rainn.org/get-information/sexual-assault-recovery; The Advocacy Center. (2015). The path toward recovery for survivors of sexual violence. Retrieved from http://advocacycenter.syr.edu/students/path-of-recovery/

These forms of rape are physically and emotionally devastating for the victims. Research has indicated that the survivors of acquaintance rape report similar levels of depression, anxiety, complications in subsequent relationships, and difficulty attaining prerape levels of sexual satisfaction to those reported by survivors of stranger rape. Acquaintance rape remains a controversial topic because there is lack of agreement on the definition of consent. Despite the violation and reality of physical and emotional trauma, victims of acquaintance assault often do not identify their experience as sexual assault. Instead of focusing on the violation of the sexual assault, victims of acquaintance rape often blame themselves for the assault (RAINN, 2015c).

Although acquaintance rape and date rape do not always involve drugs, a rapist might use alcohol or other drugs to sedate his victim. In 1996 the federal government passed a law making it a felony to give an unsuspecting person a "date rape drug" with the intent of raping him or her. Even with penalties of large fines and up to 20 years in prison, the use of date rape drugs is growing (USDHHS, 2015a). Date rape drugs are also known as "club drugs" because they are often used at dance clubs, fraternity parties, and all-night raves. The most common is Rohypnol (also known as "roofies," "forget pills," "mind erasers," and the "drop drug"). It comes in the form of a liquid or pill that quickly dissolves in liquid with no odor, taste, or color. This drug is 10 times as strong as diazepam (Valium). The effects can be felt within 30 minutes and produces memory loss for up to 8 hours. Gamma hydroxybutyrate (GHB; called "liquid ecstasy" or "easy lay") produces euphoria, an out-of-body high, sleepiness, increased sex drive, and memory loss. GHB takes effect in about 15 minutes and can last 3 to 4 hours. It comes in a white powder or liquid and may cause unconsciousness, depression, and coma. The third date rape drug, ketamine (known as "Special K," "vitamin K," or "super acid"), acts on the central nervous system very quickly to separate perception and sensation. Combining ketamine with other drugs can be fatal. Date rape drugs can be very dangerous, and women can protect themselves against them in a variety of ways (Teaching Guidelines 9.2).

Teaching Guidelines 9.2

PROTECTING YOURSELF AGAINST DATE RAPE DRUGS

- Avoid parties where alcohol is being served.
- Never leave a drink of any kind unattended.
- Don't accept a drink from someone else.
- Accept drinks from a bartender or in a closed container only.
- If a drink is left unattended, pour it out, don't drink it
- Don't drink anything that tastes or smells strange
- Don't drink from a punch bowl or a keg.
- If you think someone drugged you, call 911.

TABLE 9.4 RISK FACTORS FOR INTIMATE PARTNER VIOLENCE IN MEN

Individual Factors	Relationship Factors	Community Factors	Societal Factors
Young age	Martial conflict	Weak sanctions against IPV	Traditional gender norms
Heavy drinking	Economic stress	Poverty	Social norms supportive of violence
Personality disorders	Dysfunctional family	Low social capital	
Depression	Marital instability		
Low academic achievement	Male dominance in family		
Witnessing violence as a child	Cohabitation		
Low income and/or unemployment	Having outside sexual partners		
Experiencing violence as a child			
Desire for power and control in all relationships			
Anger and hostility	Taking aggression out on others while growing up

Rape Recovery

Rape survivors take a long time to heal from their traumatic experience. Some women never heal and never get professional counseling, but most can cope. Rape is viewed as a situational crisis that the survivor is unprepared to handle because it is an unforeseen event. Survivors typically go through four phases of recovery following rape (Table 9.4).

A significant proportion of women who are raped also experience symptoms of PTSD. PTSD develops when an event outside the range of normal human experience occurs that produces marked distress in the person. Symptoms of PTSD are divided into three groups:

- **Intrusion** (re-experiencing the trauma, including nightmares, flashbacks, recurrent thoughts)
- **Avoidance** (avoiding trauma-related stimuli, social withdrawal, emotional numbing)
- **Hyperarousal** (increased emotional arousal, exaggerated startle response, irritability)

Not every traumatized female develops full-blown or even minor PTSD. Symptoms usually begin within 3 months of the incident, but occasionally may only emerge years later. They must last more than a month to be considered PTSD. The condition varies from person to person. Some women recover within months, while others have symptoms for much longer. In some people, the condition becomes chronic (Darnell et al., 2015; Friedman, 2015).

Nursing Management of Rape Victims

Health care providers, along with sexual assault nurse examiners (SANE), can make a difference in the lives of survivors by understanding the facts, the effects this violence can have on mental and physical health, where to find information for

themselves and their clients, and how to properly care for a survivor. A SANE is a registered nurse specially trained to conduct sexual assault evidentiary exams for rape victims. In addition to the collection of forensic evidence, they also provide access to crisis intervention, STI testing, and emergency contraception (International Association of Forensic Nurses, 2015).

Research has found that rape survivors undergo a profound and complex trauma. Exposure therapy has been used to help victims confront their trauma-related memories, feelings, and stimuli that evoke fear and anxiety (Nacasch, Rachamim, & Foa, 2015). The survivor should be provided with a safe and comfortable environment for a forensic examination. Nursing care of the rape survivor should focus on providing supportive care, collecting and documenting evidence, assessing for STIs, preventing pregnancy, and assessing for PTSD. Once initial treatment and evidence collection have been completed, follow-up care should include counseling, medical treatment, and crisis intervention. There is mounting evidence that early intervention and immediate counseling speed a rape survivor's recovery. By early intervention, it means interventions implemented in the initials hours, days, or weeks after the traumatic event (Bryant, 2015). Nursing Care Plan 9.1 (at the end of the chapter) highlights a sample plan of care for a victim of rape.

Take Note!

Many rape survivors seek treatment in the hospital emergency department if no rape crisis center is available. Unfortunately, many emergency department doctors and nurses have little training in how to treat rape survivors or in collecting evidence. To make matters worse, if they have to wait for hours in public waiting rooms, survivors may leave the hospital, never to receive treatment or supply the evidence needed to arrest and convict their assailants.

PROVIDING SUPPORTIVE CARE

Establishing a therapeutic and trusting relationship will help the survivor describe her experience. Take the woman to a secure, isolated area away from family, friends, and other clients and staff so she can be open and honest when asked about the assault. Provide a change of clothes, access to a shower and toiletries, and a private waiting area for family and friends.

COLLECTING AND DOCUMENTING EVIDENCE

The victim should be instructed to bring all clothing, especially undergarments, worn at the time of the assault to the medical facility. The victim should not shower or bathe before presenting for care. Typically a specially trained nurse will collect the evidence from the victim.

ASSESSING FOR SEXUALLY TRANSMITTED INFECTIONS

As part of the assessment, a pelvic examination will be done to collect vaginal secretions to rule out any STIs. This examination is very emotionally stressful for most women and should be carried out very gently and sensitively.

PREVENTING PREGNANCY

An essential element in the care of rape survivors involves offering them pregnancy prevention. After unprotected intercourse, including rape, pregnancy can be prevented by using an emergency contraceptive pill, sometimes called postcoital contraception. Emergency contraceptive pills involve high doses of the same oral

contraceptives that millions of women take every day. The emergency regimen consists of one dose taken within 72 to 120 hours of the unprotected intercourse. Emergency contraception works by preventing ovulation, fertilization, or implantation. It does not disrupt an established pregnancy and should not be confused with mifepristone (RU-486), a drug approved by the Food and Drug Administration for abortion in the first 49 days of gestation. Emergency contraception is most effective if it is taken within 12 hours of the rape; it becomes less effective with every 12 hours of delay thereafter.

ASSESSING FOR POSTTRAUMATIC STRESS DISORDER

Nurses can begin to assess the extent to which a survivor is suffering from PTSD by asking the following questions:

- To assess the presence of intrusive thoughts:
  - Do upsetting thoughts and nightmares of the trauma bother you?
  - Do you feel as though you are actually reliving the trauma?
  - Does it upset you to be exposed to anything that reminds you of that event?
- To assess the presence of avoidance reactions:
  - Do you find yourself trying to avoid thinking about the trauma?
  - Do you stay away from situations that remind you of the event?
  - Do you have trouble recalling exactly what happened?
  - Do you feel numb emotionally?
- To assess the presence of physical symptoms:
  - Are you having trouble sleeping?
  - Have you felt irritable or experienced outbursts of anger?
  - Do you have heart palpitations and sweating?
  - Do you have muscle aches and pains all over? (NCVC, 2015b).

With a growing body of knowledge about rape-related PTSD, help is available through most rape crisis and trauma centers. Support groups have been established where survivors can meet regularly to share experiences to help relieve the symptoms of PTSD. For some survivors, medication prescribed along with therapy is the best combination to relieve the pain. Just as in the treatment of any other illness, at the first opportunity, the woman should be encouraged to talk about the traumatic experience. This ventilating provides a chance to receive needed support and comfort, as well as an opportunity to begin making sense of the experience. To diminish symptoms of PTSD, survivors must work on two fronts: coming to terms with the past and alleviating stress in the present (Bryant, 2015).

In order to have a better understanding of the aftermath of criminal victimization such as sexual assault, nurses must begin to accept the reality that crime is random, senseless, and can happen to anyone regardless of the precautions that are taken to prevent it. Nurses must also understand that a victim's life is turned upside down when he or she becomes a victim of crime. In order to help victims to trust society again and regain a sense of balance and self-worth, nurses must educate all those who come in contact with victims and survivors to be sensitive to their needs.

Female Genital Cutting

FGC, also referred to as female genital mutilation (FGM) or female circumcision, is defined as a procedure involving any injury of the external female genitalia for

cultural or nontherapeutic reasons. It confers severe health consequences for girls and women. The international community views this practice as a human rights violation (Gayle & Rymer, 2015). It is the surgical removal of a portion or portions of the genitalia of female infants, girls, and women, including the clitoris (type I), clitoris and labia minora (type II), and clitoris, labia minora, labia majora, and then suturing of the remaining tissue, known as fibulation, to leave only a small opening for urination, menstruation, intercourse, and childbirth (type III). There is a type IV, which encompasses all other mutilations of the female genital area such as pricking, piercing, cutting, cauterizing, and scraping of the vaginal tissue, incisions to the clitoris and vagina, and burning, scarring, or cauterizing of tissue with the aim of tightening or narrowing the vagina (Nour, 2015).

FGC is a worldwide practice that affects millions of women and girls. According to the World Health Organization (WHO) (2015b) and UNICEF, 140 million women are victims of FGC with about 130 million girls between infancy and age 15 undergoing FGC every year. Countries where this is practiced include 30 African countries and parts of the Middle East and Asia. Prevalence in countries such as Sudan and Egypt has been estimated as high as 99% (Johnsdotter, 2015). The exact origins of FGC are not known. Although FGC may be interwoven into the culture, it is not mandated by any religion. This practice predates both Islam and Christianity (Gruenbaum & Wirtz, 2015). In some cultures, it is associated with feminine beauty and often signifies a rite of passage from childhood to adulthood. Female cutting is performed to decrease a woman's sexual desires and to ensure her chastity until marriage and receipt of a dowry from the prospective groom (Farage et al., 2015). Ultimately, the reality of being ostracized by the community and the possibility of being ineligible to marry create enormous social pressure to have FGC carried out, pressure that outweighs the known physical and emotional damage of this practice (Nour, 2015).

Complications vary, depending on the type of cutting and the way it was performed. It is frequently performed without anesthesia under nonsterile conditions. Cutting tools can be anything from razors blades to knives to pieces of glass or tin can lids. Complications can include infertility, dysmenorrhea, dyspareunia, sexual dysfunction, infection, hemorrhage after the procedure, vaginal stenosis, chronic vaginitis, pelvic inflammatory disease, chronic urinary tract infections, incontinence, genital fistulas, recurrent abscesses, transmission of HIV and hepatitis during the procedure, severe pain and shock after the procedure, difficulty walking or using stairs due to severe scarring, urinary retention, inability to experience orgasm, and difficulty in giving birth. Long-term complications related to FGC include chronic pain, dyspareunia, and difficult childbirth. The most common long-term complication is the formation of inclusion clitoral dermoid cysts and labial fusion. These become large as a grapefruit and can lead to difficulty in walking, sitting and can cause psychological distress from the deformity. The psychological effects range from eating disorders, insomnia, depression, PTSD, and negative effects on the women's self-esteem and identity (Creighton, 2015).

As immigration to the United States increases, nurses are increasingly likely to encounter women affected by FGC and its complications. The psychological pressure and trauma of being torn between two cultures and feeling different may lie heavily on the women in a new setting where FGC is foreign and banned. Nurses need updated education regarding women with FGC so that appropriate care for this

population can be provided for this very sensitive health care problem. Well-informed nurses are the best tool for providing culturally sensitive care to this population. Nurses are in a unique position to contact and educate women who have been cut or are at risk for mutilation. To advocate for these women, a thorough understanding of the practice of FGC, its cultural overtones, religious implications, and psychosocial effects is needed.

Take Note!

From a Western perspective, FGC is hard to comprehend. Because it is not talked about openly in communities that practice it, women who have undergone it accept it without question and assume it is done to all girls (Gruenbaum & Wirtz, 2015).

Background

Reasons for performing the ritual reflect the ideology and cultural values of each community that practices it. Some consider it a rite of passage into womanhood; others use it as a means of preserving virginity until marriage. In cultures where it is practiced, it is an important part of culturally defined gender identity. In any case, all the reasons are cultural and traditional and are not rooted in any religious texts (Research Action and Information Network for the Bodily Integrity of Women [RAINBO], 2015). Since FGC has no health benefits and often leaves women with lifelong physical and emotional trauma, there is a human rights justification to end the practice. International pressure to end FGC has been mounting since 1997, when the WHO, UNICEF, and UNFPA issued a joint statement to call on governments to ban the practice (Borsand et al., 2015). Box 9.5 lists types of FGC procedures.

BOX 9.5

FOUR MAJOR TYPES OF FEMALE GENITAL MUTILATION PROCEDURES

Type I: Excision of the prepuce with excision of part or the entire clitoris
Type II: Excision of the clitoris and part or all of the labia minora
Type III (Infibulation): Excision of all or part of the external genitalia and stitching/narrowing of the vaginal opening
Type IV: Pricking, piercing, or incision of the clitoris or labia
- Stretching of the clitoris and/or labia
- Cauterizing by burning the clitoris and surrounding tissues
- Scraping or cutting the vaginal orifice
- Introduction of a corrosive substance into the vagina
- Placing herbs into the vagina to narrow it

Female genital cutting: Impact on women's health. In *Seminars in Reproductive Medicine*. *33*(1), 41–46; and Research Action and Information Network for the Bodily Integrity of Women [RAINBO]. (2015). *Caring for women with circumcision: Fact sheet for physicians.* Retrieved from http://www.rainbo.org/factsheet.html

Nursing Management of Female Genital Cutting Client

Because of increasing migration, nurses throughout the world are increasingly exposed to women who have experienced these procedures and thus need to know about its impact on women's reproductive health. Helping women who have had an FGC procedure requires good communication skills and often an interpreter, since many may not speak English. As nurses, we are educated to provide comprehensive, culturally sensitive care regardless of our client's circumstances. Nurses must keep in mind that FGC is considered normal in many cultures and to not have it done would be unthinkable. Nurses have the opportunity to educate clients by providing accurate information and positive health care experiences. Make sure that you are comfortable with your own feelings about this practice before dealing with clients. Some guidelines are as follows:

- Let the client know you are concerned and interested and want to help.
- Speak clearly and slowly, using simple, accurate terms.
- Use the term or name for this practice that the recipient uses, not "FGC."
- Use pictures and diagrams to help the woman understand what you are saying.
- Be patient in allowing the client to answer questions.
- Include men in any education, as they are influential in this practice.
- Repeat back your understanding of the client's statements.
- Always look and talk directly to the client, not the interpreter.
- Place no judgment on the cultural practice.
- Maintain respect for older women who have experienced FGC.
- Encourage the client to express herself freely.
- Maintain strict confidentiality.
- Provide culturally attuned care to all women.

In short, FGC is a form of violence against women, and it is only through education and empowerment of women that real changes in this practice can be made. Because this practice often defines a woman and becomes a part of her identity, nurses must understand this to be able to assist women who have had this done to them. Only through intense education will the next generation of girls be saved from this practice.

Human Trafficking

The United Nations defines human trafficking as the recruitment, transportation, transfer, harboring or receipt of persons, by means of the threat or use of force, of abduction, of fraud, or deception to achieve the consent of a person having control over another person, for the purpose of exploitation (United Nations Office on Drugs and Crime [UNODC], 2015).

A girl who was just 14 years old was held captive in a tiny trailer room, where she was forced to have sex with as many as 30 men a day. On her nightstand was a teddy bear that reminded her of her childhood in Mexico from where she was abducted and forced into sexual slavery.

This scenario describes human trafficking, the enslavement of immigrants for profit in America. Within our borders, thousands of foreign nationals and US citizens, many of them children, are forced or coerced into sex work or various forms of labor every year (Weitzer, 2015). Human trafficking is both a global problem and a domestic problem. The United States is a major receiver of trafficked persons. Human trafficking is a modern form of slavery that affects nearly 1 million

people worldwide and approximately 20,000 persons in the United States annually (U.S. Department of State, 2015). Women and children are the primary victims of human trafficking, many in the sex trade as described above and others through forced-labor domestic servitude. Poverty and lack of economic opportunity make women and children potential victims of traffickers associated with international criminal organizations. They are vulnerable to false promises of job opportunities in other countries. Many of those who accept these offers from what appear to be legitimate sources find themselves in situations where their documents are destroyed, they or their families threatened with harm, or they are bonded by a debt that they have no chance of repaying

Trafficking persons is hugely profitable: one estimate places global profits at approximately $35 billion annually. Among illegal enterprises, trafficking is second only to drug dealing and is tied with the illegal arms industry in its ability to generate dollars (Aronowitz & Koning, 2015).

The United States is a profitable destination country for traffickers, and these profits contribute to the development of organized criminal enterprises worldwide. According to findings of the (Victims of Trafficking and Violence Protection Act of 2000):

- Victims are primarily women and children who lack education, employment, and economic opportunities in their own countries.
- Traffickers promise victims employment as nannies, maids, dancers, factory workers, sales clerks, or models in the United States.
- Traffickers transport the victims from their counties to unfamiliar destinations away from their support systems.
- Once they are here, traffickers coerce them, using rape, torture, starvation, imprisonment, threats, or physical force, into prostitution, pornography, the sex trade, forced labor, or involuntary servitude.

These victims are exposed to serious and numerous health risks such as rape; physical injury such as cigarette burns, fractures, bruises; torture; HIV/AIDS; STIs; cervical cancer; violence; hazardous work environments; poor nutrition; and drug and alcohol addiction (Greenbaum et al., 2015). Health care is one of the most pressing needs of these victims, but no comprehensive care is available to undocumented immigrants. Nurses and other health care providers who encounter victims of trafficking often do not realize it, and opportunities to intervene are lost. Although no one sign can demonstrate with certainty when someone is being trafficked, clinicians should be aware of several indicators. It is important to be alert for trafficking victims in any setting and to recognize cues (Box 9.6).

Nursing interventions in the case of trafficking victims would include the following:

- Building trust is the number-one priority
- Take the time to listen and develop rapport
- Screen in a private place to ensure confidentiality and safety
- Reassure the potential victim
- One-on-one interactions are ideal
- Specifically ask about the client's safety
- Offer reworded stories
- Stay calm and on an even keel

• Understand the risk these victims are taking by disclosing their plight
• ALWAYS document your suspicion in your notes, at the very least
• Call the human trafficking hotline for guidance: 1-866-US-TIPLINE

BOX 9.6

IDENTIFYING VICTIMS OF HUMAN TRAFFICKING

Look beneath the surface and ask yourself: Is this person
• A female or a child in poor health?
• Foreign-born and doesn't speak English?
• Lacking immigration documents?
• Giving an inconsistent explanation of injury?
• Reluctant to give any information about self, injury, home, or work?
• Fearful of authority Figure or "sponsor" if present? ("Sponsor" might not leave victim alone with health care provider.)
• Living with the employer?

Sample questions to ask the potential victim of human trafficking:
• Can you leave your job or situation if you wish?
• Can you come and go as you please?
• Have you been threatened if you try to leave?
• Has anyone threatened your family with harm if you leave?
• What are your working and living conditions?
• Do you have to ask permission to go to the bathroom, eat, or sleep?
• Is there a lock on your door so you cannot get out?
• What brought you to the United States? Are your plans the same now?
• Are you free to leave your current work or home situation?
• Who has your immigration papers? Why don't you have them?
• Are you paid for the work you do?
• Are there times you feel afraid?
• How can your situation be changed?

Adapted from United Nations Office on Drugs and Crime [UNODC]. (2015). *Human trafficking*. Retrieved from http://www.unodc.org/unodc/en/human-trafficking/what-is-human-trafficking.html; Sanchez, R., & Stark, S. (2014). The hard truth about human trafficking. *Nursing Management*, *45*(1), 18–23; Weitzer, R. (2015). Human trafficking and contemporary slavery. *Annual Review of Sociology*, *41*(1). Retrieved from http://www.annualreviews.org/doi/abs/10.1146/annurev-soc-073014–112506

Human trafficking is a violation of human rights. Few crimes are more repugnant than the sex trafficking of helpless and innocent victims. Nurses are one of the few groups of professionals likely to interact with trafficked victims while they are still in captivity. They have the opportunity to screen, identify, intervene, and rescue these victims. If you suspect a trafficking situation, notify local law enforcement and a regional social service organization that has experience in dealing with trafficking victims. It is imperative to reach out to these victims and stop the cycle of abuse by following through on your suspicions. Nurses can also reach out within their communities to bring about awareness through community education to human trafficking to uncover the hard truth about it to our nation's blind eyes.

SUMMARY

The causes of violence against women are complex. Previously, violence against women was largely invisible, natural, and trivial. Many laughed at the notion that intimate or community violence against women should be seen as a human rights violation. Raising awareness and developing evidence-based programs, practices and policies to prevent IPV and sexual assault are essential in stopping violent behavior before it starts. Many women will experience some type of violence in their lives, and it can have a debilitating effect on their health and future relationships. Nurses have the skills, professional experience, and perspective to be an important part of comprehensive violence prevention efforts in communities. Violence is a preventable public health problem if multiple sectors understand patterns of violence and implement prevention strategies to reduce it (Copelon, 2015).

Violence frequently leaves a "legacy of pain" to future generations. Nurses can empower women and encourage them to move forward and take control of their lives. When women live in peace and security, free from violence, they have an enormous potential to contribute to their own communities and to the national and global society. Nurses can play an important role in working toward the creation of a violence-free community, but they must first become informed. Nurses must insist that health care agencies that employ them accept this responsibility and work together to reach out to those being abused. The time is ripe for nurses to act and ensure serious inroads are made in improving the health and well-being of all women across the globe.

Violence against women is not normal, legal, or acceptable and it should never be tolerated or justified. It can and must be stopped by the entire world community. Early education and prevention provide the best hope for creating healthy futures and fostering a global society without violence.

NURSING CARE PLAN 9.1

Overview of the Woman Who is a Victim of Rape

Lucia, a 20-year-old college junior, was admitted to the emergency room after police found her when a passerby called 911 to report an assault. She stated, "I was raped a few hours ago while I was walking home through the park." Assessment reveals the following: numerous cuts and bruises of varying sizes on her face, arms, and legs; lip swollen and cut; right eye swollen and bruised; jacket and shirt ripped and bloodied; hair matted with grass and debris; vital signs within acceptable parameters; client tearful, clutching her clothing, and trembling; perineal bruising and tearing.

NURSING DIAGNOSIS: Rape-trauma syndrome related to report of recent sexual assault

Outcome Identification and Evaluation

Client will demonstrate adequate coping skills related to effects of rape as evidenced by her ability to discuss the event, verbalize her feelings and fears, and exhibit appropriate actions to return to her precrisis level of functioning.

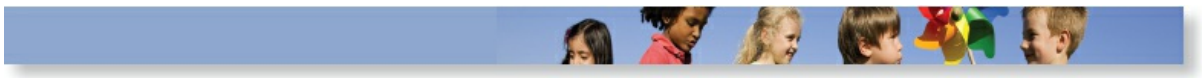
Interventions: ***Promoting Adequate Coping Skills***

• Stay with the client to promote feelings of safety.

• Explain the procedures to be completed based on facility's policy to help alleviate client's fear of the

unknown.

- Assist with physical examination for specimen collection to obtain evidence for legal proceedings.
- Administer prophylactic medication as ordered to prevent pregnancy and STIs.
- Provide care to wounds as ordered to prevent infection.
- Assist client with hygiene measures as necessary to promote self-esteem.
- Allow client to describe the events as much as possible to encourage ventilation of feelings about the incident; engage in active listening and offer nonjudgmental support to facilitate coping and demonstrate understanding of the client's situation and feelings.
- Help the client identify positive coping skills and personal strengths used in the past to aid in effective decision making.
- Assist client in developing additional coping strategies and teach client relaxation techniques to help deal with the current crisis and anxiety.
- Contact the rape counselor in the facility to help the client deal with the crisis.
- Arrange for follow-up visit with rape counselor to provide continued care and to promote continuity of care.
- Encourage the client to contact a close friend, partner, or family member to accompany her home to provide support.
- Provide the client with the telephone number of a counseling service or community support groups to help her cope and obtain ongoing support.
- Provide written instructions related to follow-up appointments, care, and testing to ensure adequate understanding.



KEY CONCEPTS

- Violence against women is a major public health and social problem because it violates a woman's very being and causes numerous mental and physical health sequelae.
- Every woman has the potential to become a victim of violence.
- Several Healthy People 2020 objectives focus on reducing the rate of physical assaults and the number of rapes and attempted rapes.
- Abuse may be mental, physical, or sexual in nature or a combination of all of these.
- The cycle of violence includes three phases: tension building, acute battering, and honeymoon.
- Many women experience PTSD after being sexually assaulted. PTSD can inhibit a survivor from adapting or coping in a healthy manner.
- Pregnancy can precipitate violence toward the woman or escalate it.
- FGC is practiced worldwide and nurses in the United States need to become knowledgeable about it and place no judgment on this cultural practice.
- Human trafficking is a violation against human rights, and nurses who suspect it should report it to stop the cycle of abuse against young children and women.
- The nurse's role in dealing with survivors of violence is to establish rapport; open up lines of communication; apply the nursing process to assess and screen all clients in all settings; and implement and intervene as appropriate.

CHAPTER WORKSHEET

MULTIPLE-CHOICE QUESTIONS

1. The primary goal of intervention in working with abused women is to:
   a. Set up an appointment with a mental health counselor for the victim
   b. Convince them to set up a safety plan to use when they leave
   c. Help them to develop courage and financial support to leave the abuser
   d. Empower them and improve their self-esteem to regain control of their lives
2. The first phase of the abuse cycle is characterized by:
   a. The woman provoking the abuser to bring about battering
   b. Tension building and verbal or minor battery
   c. A honeymoon period that lulls the victim into forgetting
   d. An acute episode of physical battering
3. Women recovering from abusive relationships need to learn ways to improve their:
   a. Educational level by getting a college degree
   b. Earning power so they can move to a better neighborhood
   c. Self-esteem and communication skills to increase assertiveness
   d. Relationship skills so they will be better prepared to deal with their partners
4. Which of the following statements might empower abuse victims to take action?
   a. “You deserve better than this.”
   b. “Your children deserve to grow up in a two-parent family.”
   c. “Try to figure out what you do to trigger his abuse and stop it.”
   d. “Give your partner more time to come to his senses about this.”
5. If a woman thinks she is being stalked when driving, a good safety measure is to:
   a. Drive to a local police or fire department
   b. Take short cuts through back streets to lose them
   c. Wave a handgun to intimidate them
   d. Roll down her window and confront them
6. Nurses play an important role in screening and assessment of any client abuse/violence. Which of the following statements is correct?
   a. Most clients are extremely reluctant to come forth with private matters.
   b. Any intimate partner violence questions should be asked in the presence of both partners.
   c. To invite disclosure, assure the woman that you won’t document her statements.
   d. The best statement to make to the abused victim is: “You don’t deserve this.”
7. What should the nurse do if a victim of intimate partner violence chooses not to disclose information about her abusive relationship during your interview?

a. Confront the victim with the physical evidence and telltale signs of abuse
b. Contact family members to tell you about their abusive relationship
c. Call the local police department to inquire about domestic disturbance calls
d. Respect the client's right of self-determination and provide her with resources

CRITICAL THINKING EXERCISE

1. Mrs. Boggs has three children under the age of 5 and is 6 months pregnant with her fourth child. She has made repeated unscheduled visits to your clinic with vague somatic complaints regarding the children as well as herself, but has missed several scheduled prenatal appointments. On occasion she has worn sunglasses to cover bruises around her eyes. As a nurse you sense there is something else bothering her, but she doesn't seem to want to discuss it with you. She appears sad and the children cling to her.
   a. Outline your conversation when you broach the subject of abuse with Mrs. Boggs.
   b. What is your role as a nurse in caring for a family in which you suspect abuse is occurring?
   c. What ethical/legal considerations are important in planning care for this family?

STUDY ACTIVITIES

1. Visit the BellaOnline Domestic Violence web site for victims of violence. Discuss what you discovered on this site and your reactions to it.
2. Research the statistics about violence against women in your state. Are law enforcement and community interventions reducing the incidence of sexual assault and intimate partner violence?
3. Attend a dorm orientation at a local college to hear about measures in place to protect women's safety on campus. Find out the number of sexual assaults reported and what strategies the college uses to reduce this number.
4. Volunteer to spend a weekend evening at the local sheriff's department 911 hotline desk to observe the number and nature of calls received reporting domestic violence. Interview the dispatch operator about the frequency and trends of these calls.
5. Identify three community resources that could be useful to a victim of violence. Identify their sources of funding and the services they provide.

BRINGING IT ALL TOGETHER: A CASE STUDY

A 23-year-old pregnant female presents to the public health maternity clinic for the third time in a month with a myriad of vague complaints including insomnia, diffuse body aches and pains, poor appetite, fatigue, and constipation. This is her first pregnancy, and it was unplanned. Her recent OB examination and laboratory survey are within normal limits. Her past medical history is remarkable for anxiety and depression. According to the client, she does not drink or smoke. She does not work outside of the home.

ASSESSMENT

On physical examination the nurse notes a well-dressed, pleasant, but anxious young female. Her husband of a year usually accompanies her to the office visits, but is absent today. She tends to avoid eye contact with the nurse when asked questions about her symptoms. Her vital signs and fetal heart rate are all within the normal range. On further examination, the nurse notices several bruises on her upper arms and thighs. When questioned about these marks, the client looks away.

QUESTIONS

1. Based on her frequent visits and diversity of symptoms with no abnormal findings, what might the nurse suspect?
2. What makes this woman vulnerable to IPV?
3. If she is experiencing abuse, what are the health consequences of it?

PLAN

1. What is the next step for the nurse in managing this client?
2. What information does the nurse need to know prior to questioning this client?
3. What important resource for abused clients is vital to inform her about for help?
4. What message does the nurse need to convey to any abused client?

Unit 3
Pregnancy

10

Fetal Development and Genetics

WOW

Words of Wisdom

Being a nurse without awe is like food without spice. Nurses only have to witness the miracle of life to find their lost awe.

KEY TERMS

allele
blastocyst
embryonic stage
fertilization
fetal stage
genes
genetic counseling
genetics
genome
genomics
genotype
heterozygous

homozygous
karyotype
mosaicism
monosomy
morula
mutation
phenotype
placenta
preembryonic stage
teratogen
trisomy
trophoblast
umbilical cord
zona pellucida
zygote

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Characterize the process of fertilization, implantation, and cell differentiation.
2. Examine the functions of the placenta, umbilical cord, and amniotic fluid.
3. Outline normal fetal development from conception through birth.
4. Compare the various inheritance patterns, including nontraditional patterns of inheritance.
5. Analyze examples of ethical and legal issues surrounding genetic testing.
6. Research the role of the nurse in genetic counseling and genetic-related activities.

Robert and Kate Shafer **have just received the good news that Kate's pregnancy test is positive. It had been a long and anxious 3 years of trying to start a family. Although both are elated about the prospect of becoming parents, they are concerned about the possibility of a genetic problem because Kate is 38 years old. What might be their first step in looking into their genetic concern? As a nurse, what might raise concerns for you?**

INTRODUCTION

Human reproduction is one of the most intimate spheres of an individual's life. For conception to occur, a healthy ovum from the woman is released from the ovary, passes into an open fallopian tube, and starts its journey downward. Sperm from the male is deposited into the vagina and swims approximately 7 inches to meet the ovum at the outermost portion of the fallopian tube, the area where **fertilization** takes place. This process occurs in about an hour (Solomon, 2015). When one spermatozoon penetrates the ovum's thick outer membrane, pregnancy begins. All

this activity takes place within a 5-hour time span.

Nurses caring for the childbearing family need to have a basic understanding of conception and prenatal development so they can identify problems or variations and can initiate appropriate interventions should any problems occur. This chapter presents an overview of fetal development, beginning with conception. It also discusses hereditary influences on fetal development and the nurse's role in **genetic counseling**.

FETAL DEVELOPMENT

Fetal development during pregnancy is measured in number of weeks after fertilization. The duration of pregnancy is about 40 weeks from the time of fertilization. This equates to 9 calendar months or approximately 266 to 280 calendar days. The three stages of fetal development during pregnancy are:

1. **Preembryonic stage**: fertilization through the second week
2. **Embryonic stage**: end of the second week through the eighth week
3. **Fetal stage**: end of the eighth week until birth

Fetal circulation is a significant aspect of fetal development that spans all three stages.

Preembryonic Stage

The preembryonic stage begins with fertilization, also called *conception.* Fertilization is the union of ovum and sperm, which is the starting point of pregnancy. Fertilization typically occurs around 2 weeks after the last normal menstrual period in a 28-day cycle (Mader & Windelspecht, 2015). Fertilization requires a timely interaction between the release of the mature ovum at ovulation and the ejaculation of enough healthy, mobile sperm to survive the hostile vaginal environment through which they must travel to meet the ovum. All things considered, the act of conception is difficult at best. To say merely that it occurs when the sperm unites with the ovum is overly simple because this union requires an intricate interplay of hormonal preparation and overcoming an overwhelming number of natural barriers. A human being is truly an amazing outcome of this elaborate process.

Prior to fertilization, the ovum and the spermatozoon undergo the process of meiosis. The primary oocyte completes its first meiotic division before ovulation. The secondary oocyte begins its second meiotic division just before ovulation. Primary and secondary spermatocytes undergo meiotic division while still in the testes (Fig. 10.1).

Although more than 200 million sperm/mL are contained in the ejaculated semen, only one is able to enter the ovum to fertilize it. All others are blocked by the clear protein layer called the **zona pellucida**. The zona pellucida disappears in about 5 days. Once the sperm reaches the plasma membrane, the ovum resumes meiosis and forms a nucleus with half the number of chromosomes (23). When the nucleus from the ovum and the nucleus of the sperm make contact, they lose their respective nuclear membranes and combine their maternal and paternal chromosomes. Because each nucleus contains a haploid number of chromosomes (23), this union restores the diploid number (46). The resulting **zygote** begins the process of a new life. The genetic information from both ovum and sperm establishes the unique

physical characteristics of the individual. Sex determination is also determined at fertilization and depends on whether the ovum is fertilized by a Y-bearing sperm or an X-bearing sperm. Approximately half of sperm carry the XX chromosome and the other half carries XY. An XX zygote will become a female and an XY zygote will become a male (Fig. 10.2). That is why it is scientifically correct to say that the sex of the infant is determined by the father and not by the mother.

Fertilization takes place in the outer third of the ampulla of the fallopian tube. When the ovum is fertilized by the sperm (now called a zygote), a great deal of activity immediately takes place. Mitosis, or *cleavage,* occurs as the zygote is slowly transported into the uterine cavity by tubal muscular movements (Fig. 10.3). After a series of four cleavages, the 16 cells appear as a solid ball of cells, or **morula**, meaning "little mulberry." The morula reaches the uterine cavity about 72 hours after fertilization. As fluid, which provides nutrients, from the uterine cavity enters the morula, the **blastocyst** is formed (Mader & Windelspecht, 2015).

With additional cell division, the morula divides into specialized cells that will later form fetal structures. Within the morula, an off-center, fluid-filled space appears, transforming it into a hollow ball of cells called a blastocyst (Fig. 10.4). The inner surface of the blastocyst will form the embryo and amnion. The outer layer of cells surrounding the blastocyst cavity is called a **trophoblast**. Eventually, the trophoblast develops into one of the embryonic membranes, the chorion, and helps to form the **placenta**.

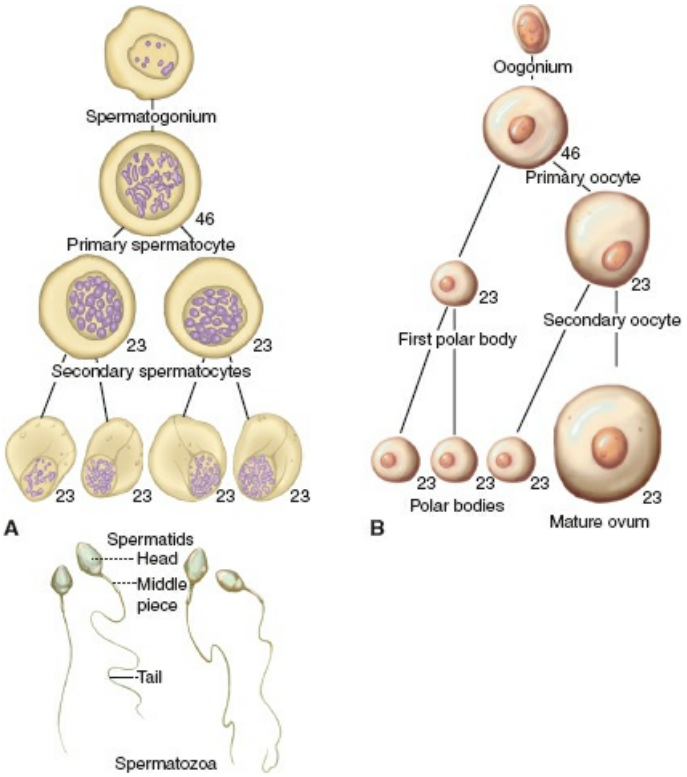

FIGURE 10.1 The formation of gametes by the process of meiosis is known as gametogenesis. A. Spermatogenesis. One spermatogonium gives rise to four spermatozoa. B. Oogenesis. From each oogonium, one mature ovum and three abortive cells are produced. The chromosomes are reduced to one-half the number characteristic for the general body cells of the species. In humans, the number in the body cells is 46, and that in the mature spermatozoon and secondary oocyte is 23.

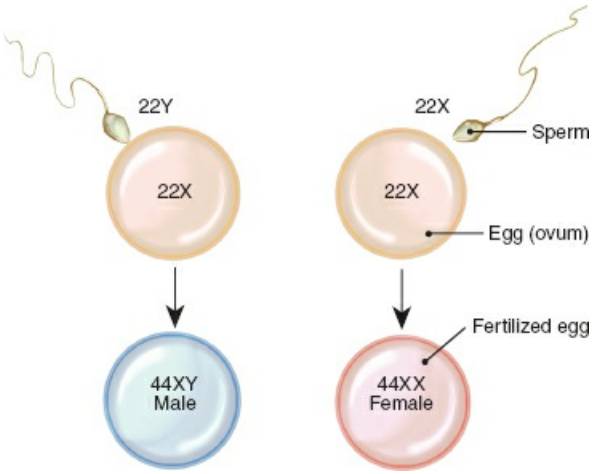

FIGURE 10.2 **Inheritance of gender. Each ovum contains 22 autosomes and an X chromosome. Each spermatozoon (sperm) contains 22 autosomes and either an X chromosome or a Y chromosome. The gender of the zygote is determined at the time of fertilization by the combination of the sex chromosomes of the sperm (either X or Y) and the ovum (X).**

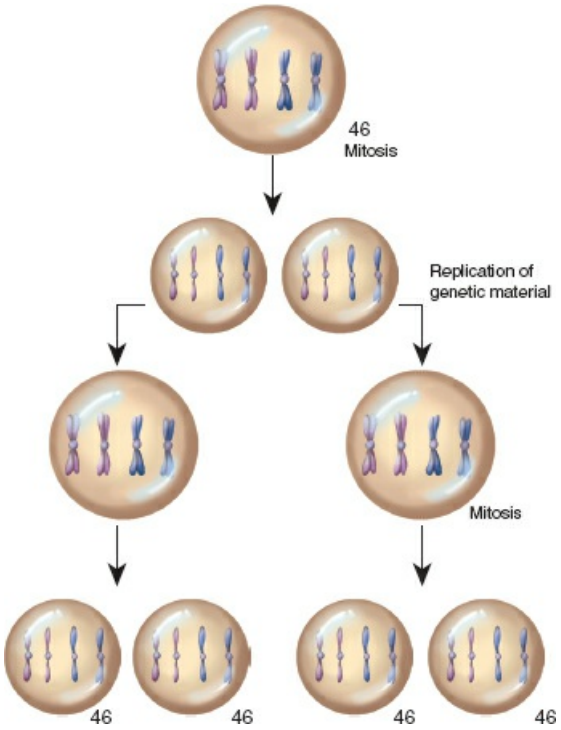

FIGURE 10.3 **Mitosis of the stoma cells.**

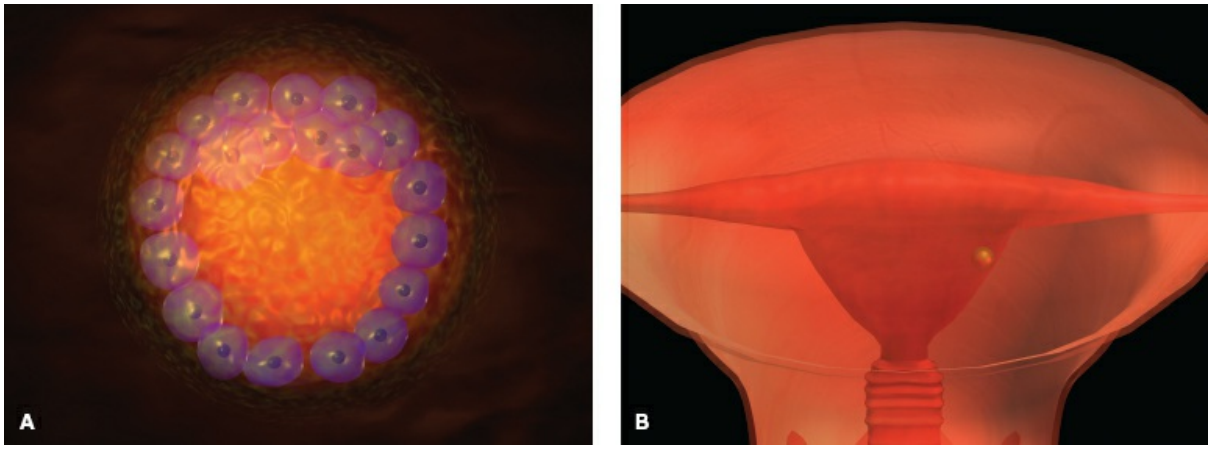

FIGURE 10.4 A. Fertilized human egg (zygote) having reached the blastocyst stage. Zygote contains 20 to 30 eggs and a fluid-filled blastocele is beginning to form. B. Implantation. All rights reserved.***

At this time, the developing blastocyst needs more food and oxygen to keep growing. The trophoblast attaches itself to the surface of the endometrium for further nourishment. Normally, implantation occurs in the upper uterus (fundus), where a rich blood supply is available. This area also contains strong muscular fibers, which clamp down on blood vessels after the placenta separates from the inner wall of the uterus. Additionally, the lining is thickest here so the placenta cannot attach so strongly that it remains attached after birth. The process of attachment and placental formation is termed implantation. This involves a complex interaction between the trophoblasts and the maternal decidua. From a medical perspective, a pregnancy has not occurred until successful implantation has taken place (Cunningham et al., 2014). Figure 10.5 shows the process of fertilization and implantation.

Concurrent with the development of the trophoblast and implantation, further differentiation of the inner cell mass occurs. Some of the cells become the embryo itself, and others give rise to the membranes that surround and protect it. The three embryonic layers of cells formed are:

1. Ectoderm—forms the central nervous system, special senses, skin, and glands
2. Mesoderm—forms the skeletal, urinary, circulatory, and reproductive organs
3. Endoderm—forms the respiratory system, liver, pancreas, and digestive system

These three layers are formed at the same time as the embryonic membranes, and all tissues, organs, and organ systems develop from these three primary germ cell layers (Jones & Lopez, 2014). Box 10.1 summarizes preembryonic development.

Despite the intense and dramatic activities going on internally to create a human life, many women are unaware that pregnancy has begun. Several weeks will pass before even one of the presumptive signs of pregnancy—missing the first menstrual period—will take place.

Embryonic Stage

The **embryonic stage** of development begins at day 15 after conception and continues through week 8. Basic structures of all major body organs and the main

external features are completed during this time period. Table 10.1 and Figure 10.6 summarize embryonic development.

The embryonic membranes (Fig. 10.7) begin to form around the time of implantation. The chorion consists of trophoblast cells and a mesodermal lining. It has fingerlike projections called *chorionic villi* on its surface. The amnion originates from the ectoderm germ layer during the early stages of embryonic development. It is a thin protective membrane that contains amniotic fluid. As the embryo grows, the amnion (inner layer) expands until it touches the chorion (outer layer). These two fetal membranes form the fluid-filled amniotic sac, or bag of waters, that protects the floating embryo (Cunningham et al., 2014).

BOX 10.1

SUMMARY OF PREEMBRYONIC DEVELOPMENT

- Fertilization takes place in ampulla of the fallopian tube.
- Union of sperm and ovum forms a *zygote* (46 chromosomes).
- Cleavage cell division continues to form a *morula* (mass of 16 cells).
- The inner cell mass is called *blastocyst,* which forms the embryo and amnion.
- The outer cell mass is called *trophoblast,* which forms the placenta and chorion.
- Implantation occurs 7 to 10 days after conception in the endometrium.

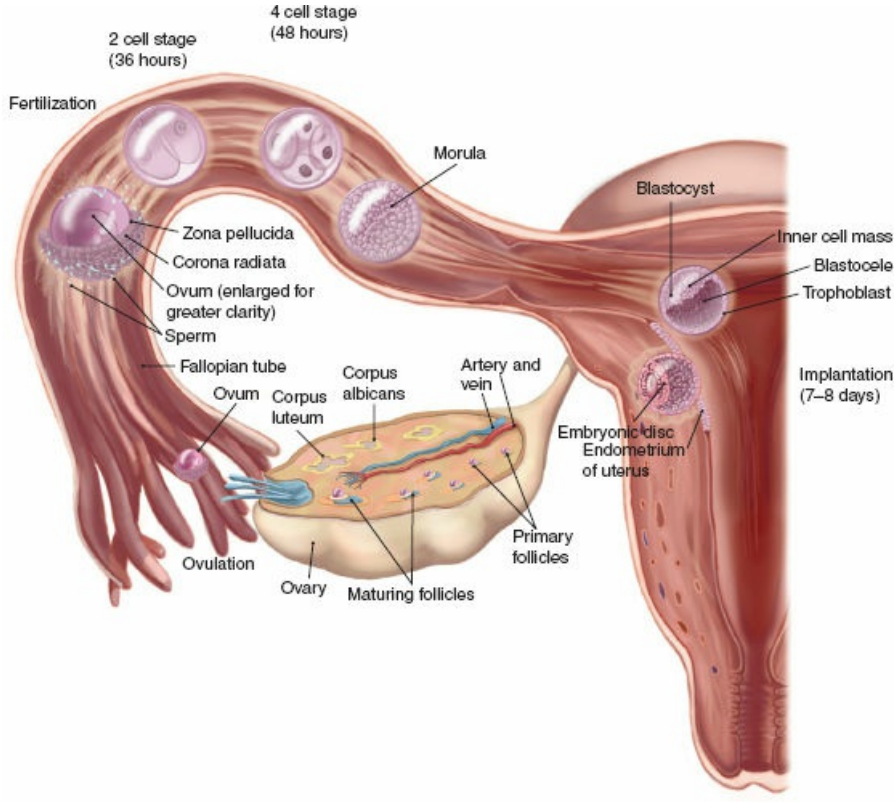

FIGURE 10.5 Fertilization and tubal transport of the zygote. From fertilization to implantation, the zygote travels through the fallopian tube, experiencing rapid mitotic division (cleavage). During the journey toward the uterus the zygote evolves through several stages, including morula and blastocyst.

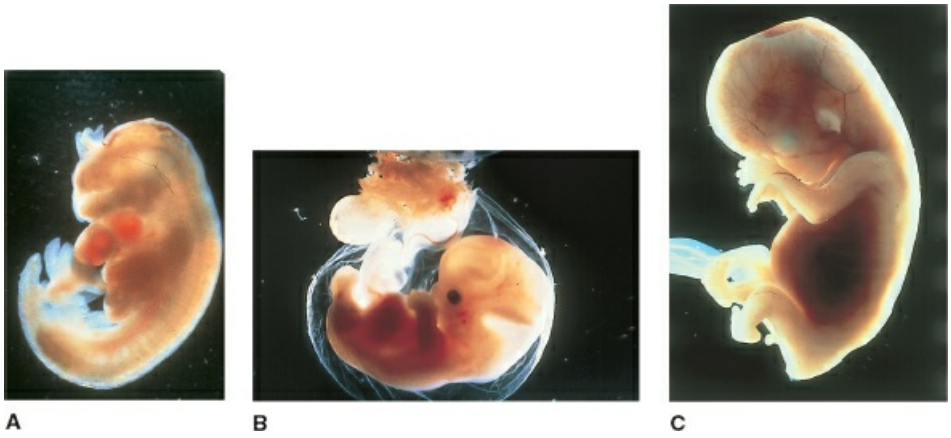

FIGURE 10.6 **Embryonic development. A. 4-week embryo. B. 5-week embryo. C. 6-week embryo.**

Amniotic fluid surrounds the embryo and increases in volume as the pregnancy progresses, reaching approximately 1 L at term. Amniotic fluid is derived from two sources: fluid transported from the maternal blood across the amnion and fetal urine. Its volume changes constantly as the fetus swallows and voids. Sufficient amounts of amniotic fluid help maintain a constant body temperature for the fetus, permit symmetric growth and development, cushion the fetus from trauma, allow the **umbilical cord** to be relatively free from compression, and promote fetal movement to enhance musculoskeletal development. Amniotic fluid is composed of 98% water and 2% organic matter. It is slightly alkaline and contains albumin, urea, bile pigments, renin, glucose, hormones, uric acid, creatinine, bilirubin, lecithin, sphingomyelin, epithelial cells, vernix, and fine hair called lanugo. The composition of amniotic fluid changes with gestation. Adequate amniotic fluid volume is necessary for proper fetal growth and development. (Magann & Ross, 2014).

TABLE 10.1 EMBRYONIC AND FETAL DEVELOPMENT

WEEK 3

Beginning development of brain, spinal cord, and heart
Beginning development of the gastrointestinal tract
Neural tube forms, which later becomes the spinal cord
Leg and arm buds appear and grow out from body

WEEK 4

Brain differentiates
Limb buds grow and develop more
Stomach, pancreas, and liver begin to form

4 weeks

WEEK 5

Heart now beats at a regular rhythm
Beginning structures of eyes and ears
Some cranial nerves are visible
Muscles innervated

WEEK 6

Beginning formation of lungs
Fetal circulation established
Liver produces RBCs
Further development of the brain
Primitive skeleton forms
Central nervous system forms
Brain waves detectable

WEEK 7

Straightening of trunk
Nipples and hair follicles form
Elbows and toes visible
Arms and legs move
Diaphragm formed
Fetal heartbeat can be heard
Mouth with lips and early tooth buds

WEEK 8

Rotation of intestines
Facial features continue to develop
Heart development complete
Resembles a human being (Mattson & Smith, 2015).

8 weeks

WEEKS 9–12

Sexual differentiation continues
Buds for all 20 temporary teeth laid down
Digestive system shows activity
Head comprises nearly half the fetus size
Face and neck are well formed
Urogenital tract completes development
Red blood cells are produced in the liver
Urine begins to be produced and excreted
Fetal gender can be determined by week 12
Limbs are long and thin; digits are well formed

12 weeks

WEEKS 13–16

A fine hair develops on the head called lanugo
Fetal skin is almost transparent
Bones become harder
Head still dominant
Fetus makes active movement
Sucking motions are made with the mouth
Amniotic fluid is swallowed
Fingernails and toenails present
Weight quadruples
Fetal movement (also known as quickening) detected by mother

16 weeks

WEEKS 17–20

Rapid brain growth occurs
Fetal heart tones can be heard with stethoscope
Kidneys continue to secret urine into amniotic fluid
Vernix caseosa, a white greasy film, covers the fetus
Eyebrows and head hair appear
Sebaceous glands appear
Brown fat deposited to help maintain temperature
Nails are present on both fingers and toes
Muscles are well developed

20 weeks

WEEKS 21–24

Eyebrows and eyelashes are well formed
Fetus has a hand grasp and startle reflex
Alveoli forming in lungs
Body is lean but fairly well proportioned
Skin is translucent and red
Lungs begin to produce surfactant

25 weeks

WEEKS 25–28

Fetus reaches a length of 15 inches
Rapid brain development
Eyelids open and close
Nervous system controls some functions
Fingerprints are set
Blood formation shifts from spleen to bone marrow
Fetus usually assumes head-down position

28 weeks

WEEKS 29–32

Rapid increase in amount of body fat
Increased central nervous system control over body functions
Rhythmic breathing movements occur
Lungs are not fully mature
Fetus stores iron, calcium, and phosphorus

32 weeks

WEEKS 33–38

Testes are in scrotum of male fetus
Lanugo begins to disappear
Increase in body fat
Fingernails reach the ends of fingertips
Small breast buds are present on both sexes
Mother supplies fetus with antibodies against disease
Fetus is considered full term at 38 weeks
Fetus fills uterus (El-Mazny, 2014)

37 weeks

The volume of amniotic fluid is important in determining fetal well-being. It gradually fluctuates throughout the pregnancy. Alterations in amniotic fluid volume can be associated with problems in the fetus. Too little amniotic fluid (<500 mL at term), termed *oligohydramnios,* is associated with uteroplacental insufficiency, fetal renal abnormalities, and a higher risk of surgical births and low birth weight infants. Too much amniotic fluid (>2000 mL at term), termed *polyhydramnios,* is associated with maternal diabetes, neural tube defects, chromosomal deviations, and malformations of the central nervous system and/or gastrointestinal tract that prevent normal swallowing of amniotic fluid by the fetus. Polyhydramnios may threaten premature rupture of membranes due to uterine overdistention (Moore, 2015).

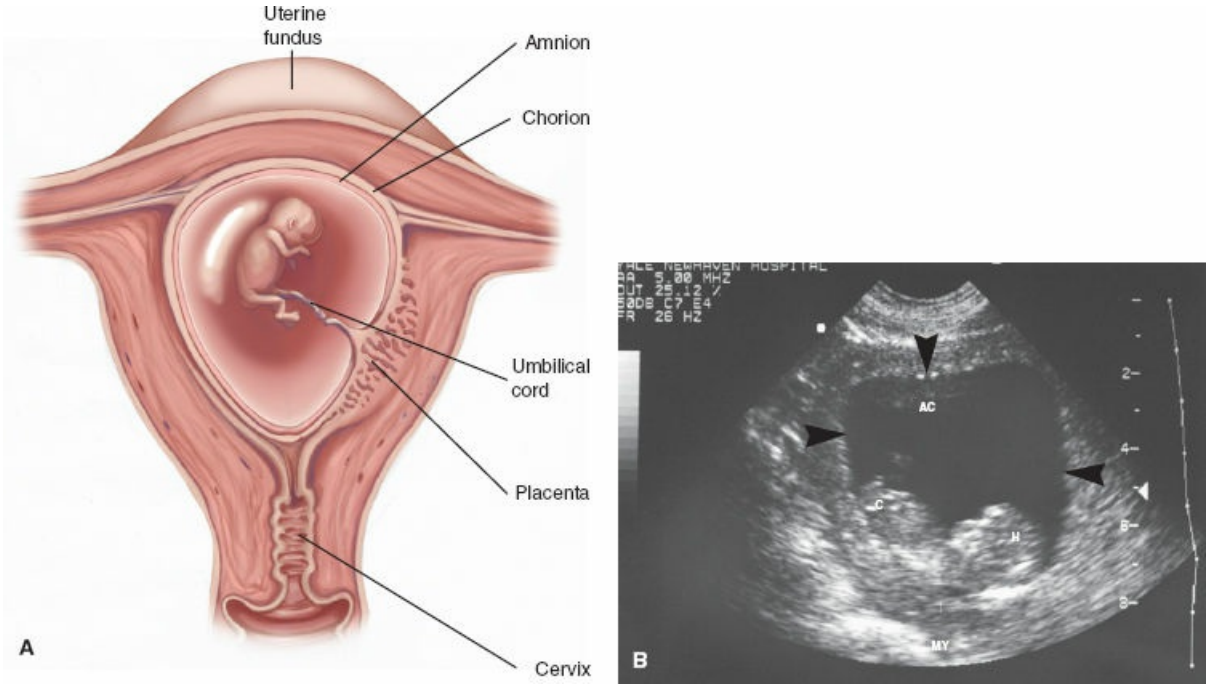

FIGURE 10.7 A. The embryo is floating in amniotic fluid, surrounded by the protective fetal membranes (amnion and chorion). B. Longitudinal sonogram of a pregnant uterus at 11 weeks showing the intrauterine gestational sac (black arrowheads) and the amniotic cavity (AC) filled with amniotic fluid; the fetus is seen in longitudinal section with the head (H) and coccyx (C) well displayed. The myometrium (MY) of the uterus can be identified. (*Figure B is courtesy of L Scoutt.*)

While the placenta is developing (end of the second week), the umbilical cord is also formed from the amnion. It is the lifeline from the mother to the growing embryo. It contains one large vein and two small arteries. Wharton's jelly (a specialized connective tissue) surrounds these three blood vessels in the umbilical cord to prevent compression, which would cut off fetal blood and nutrient supply. The cord reaches its maximum length by 30 weeks of gestation. Its length is determined by **genetics** and intrauterine space and fetal activity, which places tension on the cord. At term, the average umbilical cord is 22 inches long and about 1 inch wide (King et al., 2015).

The precursor cells of the placenta—the trophoblasts—first appear 4 days after **fertilization** as the outer layer of cells of the blastocyst. These early blastocyst trophoblasts differentiate into all the cells that form the placenta. When fully developed, the placenta serves as the interface between the mother and the developing fetus. As early as 3 days after conception, the trophoblasts make human chorionic gonadotropin (hCG), a hormone that ensures that the endometrium will be receptive to the implanting embryo. During the next few weeks the placenta begins to make hormones that control the basic physiology of the mother in such a way that the fetus is supplied with the nutrients and oxygen needed for growth. The placenta also protects the fetus from immune attack by the mother, removes waste products from the fetus, induces the mother to bring more food to the placenta and, near the time of childbirth, produces hormones that ready fetal organs for life outside the uterus. Placenta function depends on the maternal blood pressure supplying circulation. If there is an interference with blood flow to the placenta, it cannot carry out its functions to the embryo or fetus (Mattson & Smith, 2015).

Theoretically, at no time during pregnancy does the mother's blood mix with fetal blood because there is no direct contact between their bloods; layers of fetal tissue always separate the maternal blood and the fetal blood. These fetal tissues are called the *placental barrier*. Materials can be interchanged only through diffusion. The maternal uterine arteries deliver the nutrients to the placenta, which in turn provides nutrients to the developing fetus; the mother's uterine veins carry fetal waste products away. The structure of the placenta is usually completed by week 12.

The placenta is not only a transfer organ but a hormone factory as well. Placental hormones have profound effects on maternal metabolism, initially building up her energy reserves and then releasing these to support fetal growth in later pregnancy and lactation postnatally. Several hormones are produced that are necessary for normal pregnancy:

- hCG—preserves the corpus luteum and its progesterone production so that the endometrial lining of the uterus is maintained; this is the basis for pregnancy tests
- Human placental lactogen (hPL)—modulates fetal and maternal metabolism, participates in the development of maternal breasts for lactation, and decreases maternal insulin sensitivity to increase its availability for fetal nutrition
- Estrogen (estriol)—causes enlargement of a woman's breasts, uterus, and external genitalia; stimulates myometrial contractility
- Progesterone (progestin)—maintains the endometrium, decreases the contractility of the uterus, stimulates maternal metabolism and breast development, provides nourishment for the early conceptus
- Relaxin—acts synergistically with progesterone to maintain pregnancy, causes relaxation of the pelvic ligaments, softens the cervix in preparation for birth (Freemark, 2015).

The placenta acts as a pass-through between the mother and fetus, not a barrier. Almost everything the mother ingests (food, alcohol, drugs) passes through to the developing conceptus. This is why it is so important to advise pregnant women not to use unprescribed drugs, alcohol, and tobacco, because they can be harmful to the conceptus.

During the embryonic stage, the conceptus grows rapidly as all organs and structures are forming. During this critical period of differentiation the growing embryo is most susceptible to damage from external sources, including **teratogens** (substances that cause birth defects, such as alcohol and drugs), infections (such as rubella or cytomegalovirus), radiation, and nutritional deficiencies.

Fetal Stage

The average pregnancy lasts 280 days from the first day of the last menstrual period. The fetal stage is the time from the end of the eighth week until birth. It is the longest period of prenatal development. During this stage, the conceptus is mature enough to be called a fetus. Although all major systems are present in their basic form, dramatic growth and refinement of all organ systems take place during the fetal period (see Table 10.1). Figure 10.8 depicts a 12- to 15-week-old fetus.

Fetal Circulation

Fetal circulation differs from adult circulation due to the presence of certain vessels and shunts. These shunts will close after birth and most of the vessels will be seen as remnants in the adult circulation. The function of these shunts is to direct oxygen-rich venous blood to the systemic circulation and to ensure that oxygen-depleted venous blood bypasses the underdeveloped pulmonary circulation. The lungs finish their development after birth. Prior to birth, the lungs function is taken over by the placenta during fetal life (Finnemore & Groves, 2015). The circulation through the fetus during uterine life differs from that of a child or an adult. In the extrauterine world, oxygenation occurs in the lungs and oxygenated blood returns via the pulmonary veins to the left side of the heart to be ejected by the left ventricle into the systemic circulation. In contrast, fetal circulation oxygenation occurs in the placenta, and the fetal lungs are nonfunctional as far as the transfer of oxygen and carbon dioxide is concerned. For oxygenated blood derived from the placenta to reach the fetus's systemic circulation, it has to travel through a series of shunts to accomplish this.

FIGURE 10.8 Fetal development: 12- to 15-week fetus.

Thus, fetal circulation involves the circulation of blood from the placenta to and through the fetus, and back to the placenta. A properly functioning fetal circulation system is essential to sustain the fetus. Before it develops, nutrients and oxygen diffuse through the extraembryonic coelom and the yolk sac from the placenta. As the embryo grows, its nutrient needs increase and the amount of tissue easily reached by diffusion increases. Thus, the circulation must develop quickly and accurately (Jones & Lopez, 2014).

The circulatory system of the fetus functions much differently from that of a newborn. The most significant difference is that oxygen is received from the placenta during fetal life and via the lungs after birth. In addition, the fetal liver does not perform the metabolic functions that it will after birth because the mother's body performs these functions. Three shunts also are present during fetal life:

1. Ductus venosus—connects the umbilical vein to the inferior vena cava
2. Ductus arteriosus—connects the main pulmonary artery to the aorta
3. Foramen ovale—anatomic opening between the right and left atrium

Take Note!

Fetal circulation functions to carry highly oxygenated blood to vital areas (e.g., heart, brain) while first shunting it away from less important ones (e.g., lungs, liver). The placenta essentially takes over the functions of the lungs and liver during fetal life. As a result, large volumes of oxygenated blood are not needed.

The oxygenated blood is carried from the placenta to the fetus via the umbilical vein. About half of this blood passes through the hepatic capillaries and the rest flows through the ductus venosus into the inferior vena cava. Blood from the vena cava is mostly deflected through the foramen ovale into the left atrium, then to the left ventricle, into the ascending aorta, and on to the head and upper body. This allows the fetal coronary circulation and the brain to receive the blood with the highest level of oxygenation.

Deoxygenated blood from the superior vena cava flows into the right atrium, the right ventricle, and then the pulmonary artery. Because of high pulmonary vascular resistance, only a small percentage (5% to 10%) of the blood in the pulmonary artery flows to the lungs; the majority is shunted through the patent ductus arteriosus and then to the descending aorta (American Heart Association, 2015). The fetal lungs are essentially nonfunctional because they are filled with fluid, making them resistant to incoming blood flow. They receive only enough blood for proper nourishment. Finally, two umbilical arteries carry the unoxygenated blood from the descending aorta back to the placenta.

At birth, a dramatic change in the fetal circulatory pattern occurs. The foramen ovale, ductus arteriosus, ductus venosus, and umbilical vessels are no longer needed. With the newborn's first breath, the lungs inflate, which leads to an increase in blood flow to the lungs from the right ventricle. This increase raises the pressure in the left atrium, causing a one-way flap on the left side of the foramen ovale, called the septum primum, to press against the opening, creating a functional separation between the two atria. Blood flow to the lungs increases because blood entering the right atrium can no longer bypass the right ventricle. As a result, the right ventricle pumps blood into the pulmonary artery and on to the lungs. Typically the foramen ovale is functionally closed within 1 to 2 hours after birth. It is physiologically closed by 1 month with deposits of fibrin to seal the shunt. Permanent closure occurs by the sixth month of life.

The ductus venosus, which links the inferior vena cava with the umbilical vein, usually closes with the clamping of the umbilical cord and inhibition of blood flow through the umbilical vein. This fetal structure closes by the end of the first week. The ductus arteriosus constricts partly in response to the higher arterial oxygen levels that occur after the first few breaths. This closure prevents blood from the aorta from entering the pulmonary artery. Functional closure of the ductus arteriosus in a term infant usually occurs within the first 72 hours after birth. Permanent closure occurs at 3 to 4 weeks of age. Frequently a functional or innocent murmur is auscultated by the nursery nurse when there are delayed fetal shunt closures, but they usually are not associated with a heart lesion (Lawford & Tulloh, 2015). All of these changes at birth leave the newborn with the typical adult pattern of circulation with right ventricle output equaling that of the left. Figure 10.9 shows fetal circulation. Go to thePoint for a web link to a video depicting fetal circulation.

GENETICS

Genetics is the study of heredity and its variation (Nussbaum, McInnes, & Willard, 2016). **Genomics**, a relatively new science, is the study of all genes and includes interactions among genes as well as interactions between genes and the

environment. Genomics plays a role in complex conditions such as heart disease and diabetes. Another emerging area of research is that of pharmacogenomics, the study of genetic and genomic influences on pharmacodynamics and pharmacotherapeutics. It aims to use an individual's genetic information in order to treat diseases more efficiently and minimize adverse events (Meyer zu Schwabedissen, 2015). An individual's genetics influences wellness and health issues throughout that person's lifespan. The challenge for health care providers is to find the link between the client's genetic makeup and diseases (Brazeau, 2015).

According to the Centers for Disease Control and Prevention (CDC), birth defects occur in about 3% of all infants born in the United States, or 1 in every 33 infants. Every 5 minutes an infant is born with a birth defect in the United States with nearly 120,000 infants affected annually (Centers for Disease Control and Prevention, 2015). Traditionally, genetics has been associated with making decisions about childbearing and caring for children with genetic disorders. Recently, genetic and technologic advances are expanding our understanding of how genetic changes affect human diseases such as diabetes, cancer, Alzheimer's disease, and other multifactorial diseases that are prevalent in adults. Today's genetic technologies are not yet a crystal ball for seeing a child's future, but scientists are closer to routinely glimpsing at the genetic blueprints of a fetus just months after sperm meets egg (Kumar, Kingsley, & DiStefano, 2015). Newborn screening is perhaps the most widely used application of genetics in perinatal and neonatal care. Our ability to diagnose genetic conditions is more advanced than our ability to cure or treat the disorders. However, accurate diagnosis has led to improved treatment and outcomes for those affected with these disorders.

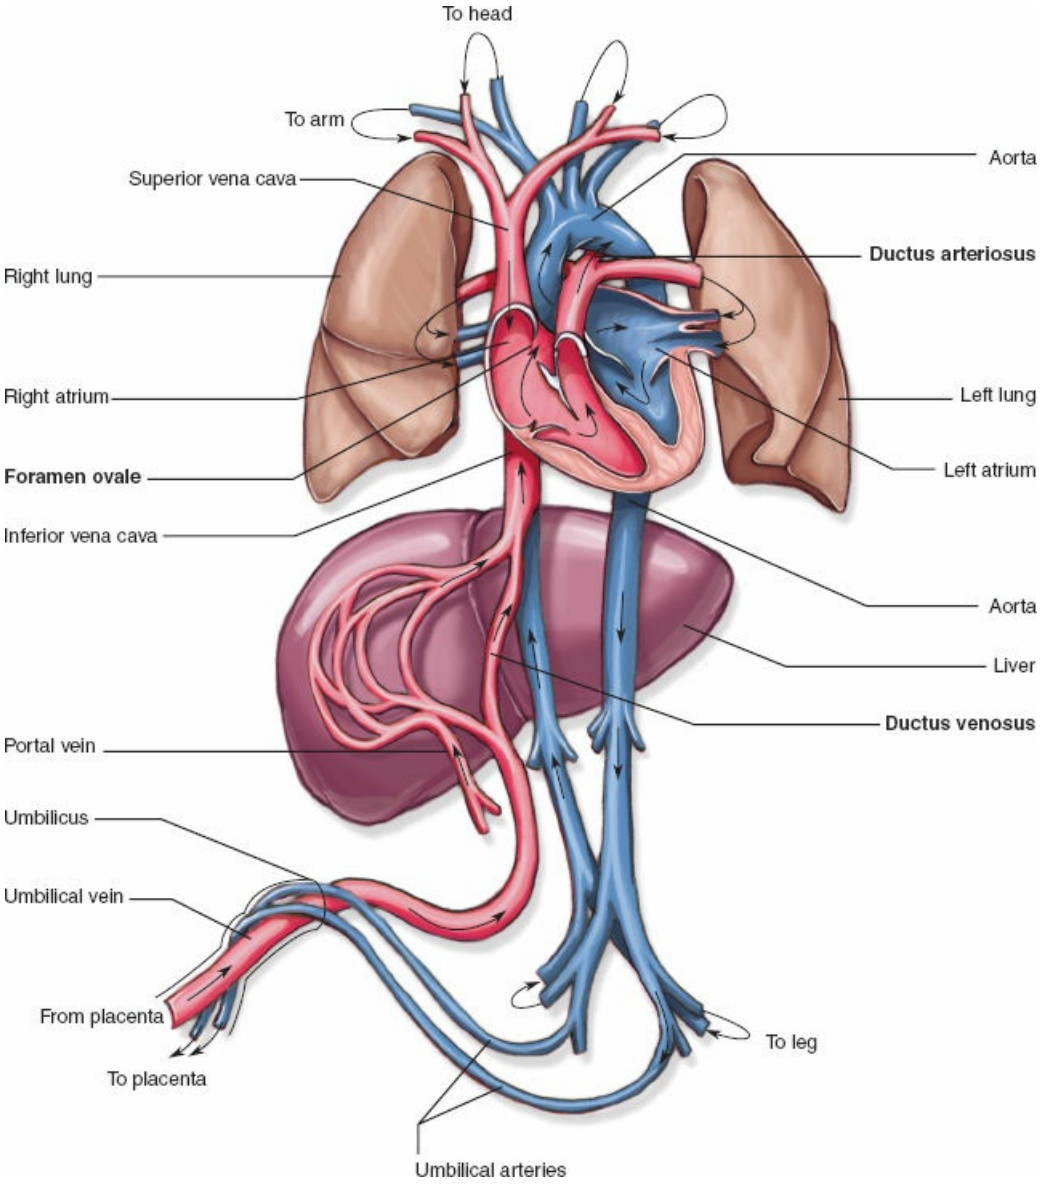

FIGURE 10.9 **Fetal circulation. Arrows indicate the path of blood. The umbilical vein carries oxygen-rich blood from the placenta to the liver and through the ductus venosus. From there it is carried to the inferior vena cava to the right atrium of the heart. Some of the blood is shunted through the foramen ovale to the left side of the heart, where it is routed to the brain and upper extremities. The rest of the blood travels down to the right ventricle and through the pulmonary artery. A small portion of the blood travels to the nonfunctioning lungs, while the remaining blood is shunted through the ductus arteriosus into the aorta to supply the rest of the body.**

Take Note!

Genetic science has the potential to revolutionize health care with regard to national screening programs, predisposition testing, detection of genetic disorders, and pharmacogenetics.

Genetics has been a part of perinatal care for decades. Rapid development and implementation of advanced genetics technology in prenatal settings includes the ability to screen for and diagnose a broader range of diseases and conditions of the fetus in early gestational ages. Ultrasounds and maternal serum screening have become routine elements of prenatal care. Preconception carrier screening for conditions such as Tay–Sachs disease has been in place among high-risk populations

such as Ashkenazi Jews. Amniocentesis and chorionic villus sampling are diagnostic tests that may confirm a genetic anomaly in a developing fetus, but they are all invasive procedures. A fetal nuchal translucency test, as seen on ultrasound, may be suggestive of the presence of trisomy 21 or Down syndrome if increased nuchal thickness is found (Lichtenbelt et al., 2015).

Today, nurses are required to have basic skills and knowledge in genetics, genetic testing, and genetic counseling so they can assume new roles and provide information and support to women, children, and families. Roles for maternity nurses in genetic health care have expanded significantly as genetics education and counseling has become standard of care. Today, nurses may provide preconception counseling for women at risk for the transmission of a genetic disorder. In addition, they may provide prenatal care for women with genetically linked disorders that require specialized care or participate in screening infants for birth defects and genetic disorders. Nurses employed in prenatal settings need to have accurate information they can provide to women so they understand the benefits and limitations of screening. Timely presentation of information and identification of available resources will help nurses minimize a couple's confusion and provide support for women as they proceed with pregnancy screening. Nurses at all levels should be participating in risk assessment for genetic conditions and disorders, explaining genetic risk and genetic testing, and supporting informed health decisions and opportunities for early intervention (Seven et al., 2015).

It is very clear that genomics will have a profound effect on health and illness at all levels. Modern technology makes it possible to screen for and diagnose conditions prior to birth, such as open neural tube defects, chromosomal aneuploids (i.e., trisomy 13, 18, and 21), congenital defects, and a myriad of single gene inheritable disorders (i.e., Tay-Sachs disease, cystic fibrosis, Huntington's disease, Duchenne muscular dystrophy, and hemophilia) (Lewis, 2015). In the future, as the era of personalized health care moves forward, nurses will be responsible for ensuring that our practice includes the scientific principles, ethical standards, and professional accountability of genetics and genomics practice. Nurses are increasingly incorporating genetics into their practice as they gain the knowledge and skills necessary to do so. The strength of the nursing voice in genetics and genomic research will be the link to the bedside and the commitment to ensure that new knowledge is translated into competent, safe, effective evidence-based client care (Latendresse & Deneris, 2015).

Advances in Genetics

Recent advances in genetic knowledge and technology have affected all areas of health. These advances have increased the number of health interventions that can be undertaken with regard to genetic disorders. For example, genetic diagnosis is now possible before conception (see Evidence-Based Practice 10.1). Genetic testing can identify presymptomatic conditions in children and adults, and provide carrier screening, prenatal diagnostic testing, newborn screening, confirmation of a diagnosis, forensic and identity testing, preimplantation genetic diagnosis and pharmacogenetic testing, which provides information on how an individual will respond to certain medications based on genetic variability (National Human Genome Research Institute [NHGRI], 2015a; National Institutes of Health (NIH),

2016). Over 2,000 genetic tests are available for diseases such as Duchenne muscular dystrophy/Becker muscular dystrophy, cystic fibrosis, and sickle cell disease (NIH, 2013). Gene therapy can be used to replace or repair defective or missing genes with normal ones. It is a promising treatment option for many inherited and incurable diseases; however, it currently remains an experimental treatment option (GHR, 2015). Hundreds of clinical trials are underway to test gene therapy but currently it is only available in the research setting (GHR, 2015).

The Human Genome Project (HGP) and continued research by the National Human Genome Research Institute has helped foster much of this progress. The **genome** of an organism is its entire hereditary information encoded in the DNA. The HGP, in an international effort to produce a comprehensive sequence of the human genome, was coordinated by the U.S. Department of Energy and the National Institutes of Health. It began in October 1990 and was completed in May 2003. Its goals included:

- Identify all of the approximately 20,500 genes in human DNA.
- Determine the sequences of the 3 billion chemical base pairs that make up human DNA.
- Store this information in databases to make it accessible for further study.
- Improve tools for data analysis.
- Transfer related technologies to the private sector.
- Address the ethical, legal, and social implications of this discovery (U.S. Department of Energy Genome Programs, 2014).

The HGP has led to the discovery of the genetic basis for hundreds of disorders and has advanced our understanding of basic genetic processes at the molecular level. A link to additional information about the HGP is available at thePoint.

One goal of the HGP was to translate the findings into new and more effective strategies for the prevention, diagnosis, and treatment of genetic diseases and disorders.

Current and potential applications for the HGP to health care include rapid and more specific diagnosis of disease, with hundreds of genetic tests available in research or clinical practice; earlier detection of genetic predisposition to disease; less emphasis on treating the symptoms of a disease and more emphasis on looking at the fundamental causes of the disease; new classes of drugs; avoiding environmental conditions that may trigger disease; and repair or replacement of defective genes through gene therapy (U.S. Department of Energy Genome Programs, 2015). This new genetic knowledge and technology, along with the commercialization of this knowledge, will change both professional and parental understanding of genetic disorders.

EVIDENCE-BASED PRACTICE 10.1

THE EVIDENCE BASE REGARDING THE EXPERIENCES OF AND ATTITUDES TO PREIMPLANTATION GENETIC DIAGNOSIS IN PROSPECTIVE PARENTS

STUDY

Technology now allows scientists to know the sequence of people's genomes and to act on this knowledge. Preimplantation genetic diagnosis was developed for IVF couples

with a family history of genetic disease. It involves obtaining cells from a developing embryo in culture, which is then subjected to genetic diagnostic analysis. The resulting information is used to guide which embryos are transferred into the uterus. Previous research has suggested that couples wishing to avoid having a child with an inherited genetic condition favor preimplantation genetic testing to prevent the need for pregnancy termination following a prenatal diagnosis of an affected fetus. The purpose of this study was to understand the experiences of couples who have used or considered this technique.

Findings

A systematic review was conducted using nine studies that met the inclusion criteria. Results of the studies were analyzed and synthesized with three main themes emerging: 1) motivating factors; 2) emotional labor; 3) choices and uncertainty. The review identified an emotional and difficult journey for couples pursing preimplantation genetic diagnosis. While this technique gave them hope to prevent transmission of a genetic disease, both the decision-making and uncertainty were challenging. Lack of information was a major barrier to accessing this reproductive option.

Nursing Implications

Based on the findings, more education is needed for nurses regarding various reproductive screening tests that are available for couples with a family history of a genetic disease or at risk for them. Being aware of the spectrum of genetic disorders and linking them with the appropriate genetic tests when counseling couples would assist them greatly. The nurse needs to know which genetic problems this option would help. They might include autosomal recessive diseases in which both parents are known carriers, such as cystic fibrosis, Tay–Sachs disease, or sickle cell disease; autosomal dominant diseases, such as Huntington's disease; genetic mutations with important consequences, such as BRCA gene (breast cancer); and X linked diseases, such as hemophilia. With greater understanding and current knowledge of the various options available for couples, nurses can improve communication and provide psychological support to couples.

Source: Cunningham, J., Goldsmith, L., & Skirton, H. (2015). The evidence base regarding the experiences of and attitudes to preimplantation genetic diagnosis in prospective parents. *Midwifery*, *31*(2), 288–296.

The potential benefits of these discoveries are vast, but so is the potential for misuse. These advances challenge all health care professionals to consider the many ethical, legal, and social ramifications of genetics in human lives. In the near future, risk profiling based on an individual's unique genetic makeup will be used to tailor prevention, treatment, and ongoing management of health conditions. This profiling will raise issues associated with privacy and confidentiality related to workplace discrimination and access to health insurance. Issues of autonomy are equally problematic as society considers how to address the injustices that will inevitably surface when disease risk can be determined years in advance of its occurrence. Nurses will play an important role in developing policies and providing direction and support in this arena, and to do so they will need a basic understanding of genetics, including inheritance and inheritance patterns. Visit thePoint for links to websites sharing additional information on the ethical, social, and legal issues

surrounding human genetic research and advances.

Inheritance

The nucleus within the cell is the controlling factor in all cellular activities because it contains chromosomes, long continuous strands of deoxyribonucleic acid (DNA) that carry genetic information. Each chromosome is made up of genes. **Genes** are individual units of heredity of all traits and are organized into long segments of DNA that occupy a specific location on a chromosome and determine a particular characteristic in an organism.

DNA stores genetic information and encodes the instructions for synthesizing specific proteins needed to maintain life. DNA is double-stranded and takes the form of a double helix. The side pieces of the double helix are made up of a sugar, deoxyribose, and a phosphate, occurring in alternating groups. The cross connections or rungs of the ladder are attached to the sides and are made up of four nitrogenous bases: adenine, cytosine, thymine, and guanine. The sequence of the base pairs as they form each rung of the ladder is referred to as the genetic code (Fig. 10.10) (Travers & Muskhelishvili, 2015).

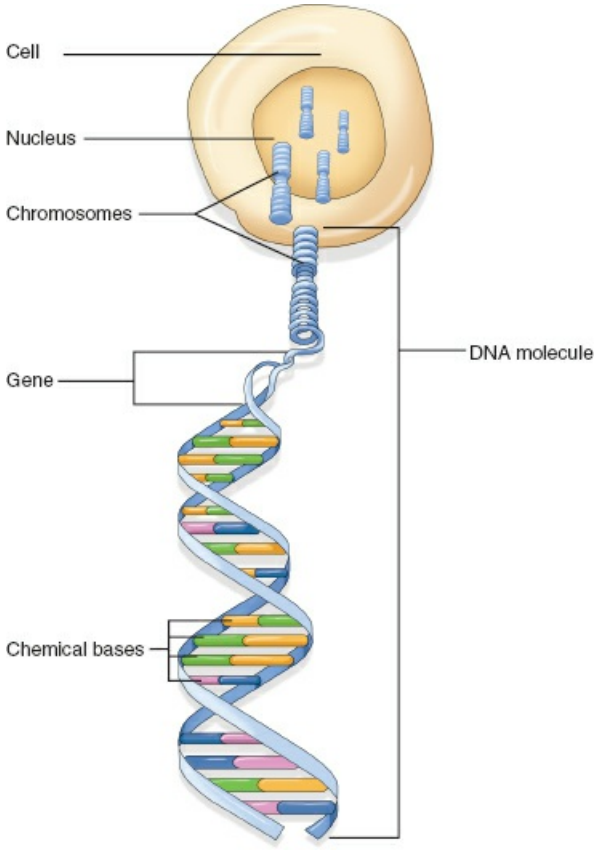

FIGURE 10.10 DNA is made up of four chemical bases. Tightly coiled strands of DNA are packaged in units called chromosomes, housed in the cell's nucleus. Working subunits of DNA are known as genes. (From the National Institutes of Health and National Cancer Institute. [1995]. Understanding gene testing [NIH Pub. No. 96–3905]. Washington, DC: U.S. Department of Human Services.)

Each gene has a segment of DNA with a specific set of instructions for making proteins needed by body cells for proper functioning. Genes control the types of

proteins made and the rate at which they are produced (Snustad, 2015). Any change in gene structure or location leads to a **mutation**, which may alter the type and amount of protein produced (Fig. 10.11). Genes never act in isolation; they always interact with other genes and the environment. They are arranged in a specific linear formation along a chromosome.

The **genotype**, the specific genetic makeup of an individual, usually in the form of DNA, is the internally coded inheritable information. It refers to the particular **allele**, which is one of two or more alternative versions of gene at a given position or locus on a chromosome that imparts the same characteristic of that gene. For instance, each human has a gene that controls height, but there are variations of these genes, which are alleles, in accordance with the specific height for which the gene codes. A gene that controls eye color may have an allele that can produce blue eyes or an allele that produces brown eyes. The genotype, together with environmental variation that influences the individual, determines the **phenotype**, or the observed, outward characteristics of an individual. A human inherits two genes, one from each parent. Therefore, one allele comes from the mother and one from the father. These alleles may be the same for the characteristic (**homozygous**) or different (**heterozygous**). For example, WW stands for homozygous dominant; ww stands for homozygous recessive. Heterozygous would be indicated as Ww. If the two alleles differ, such as Ww, the dominant one will usually be expressed in the phenotype of the individual.

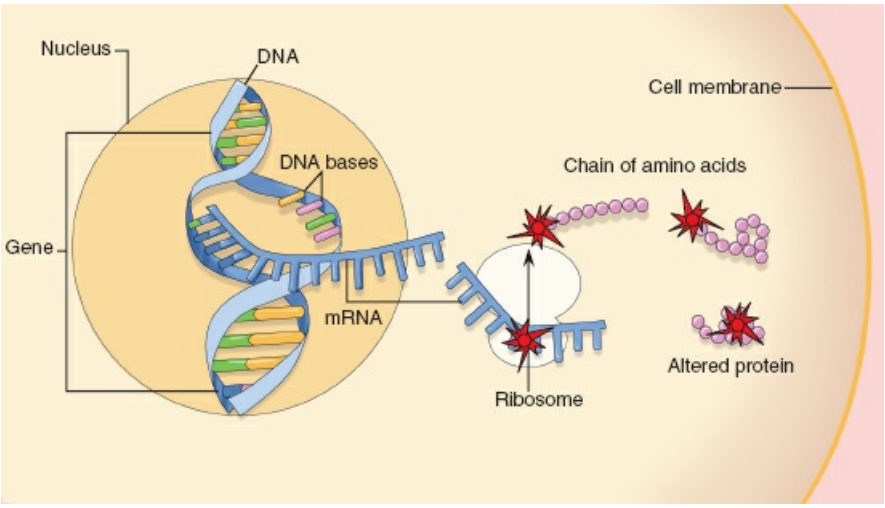

FIGURE 10.11 When a gene contains a mutation, the protein encoded by that gene will be abnormal. Some protein changes are insignificant, while others are disabling. (From the National Institutes of Health and National Cancer Institute. [1995]. *Understanding gene testing [NIH Pub. No. 96–3905]*. Washington, DC: U.S. Department of Human Services.)

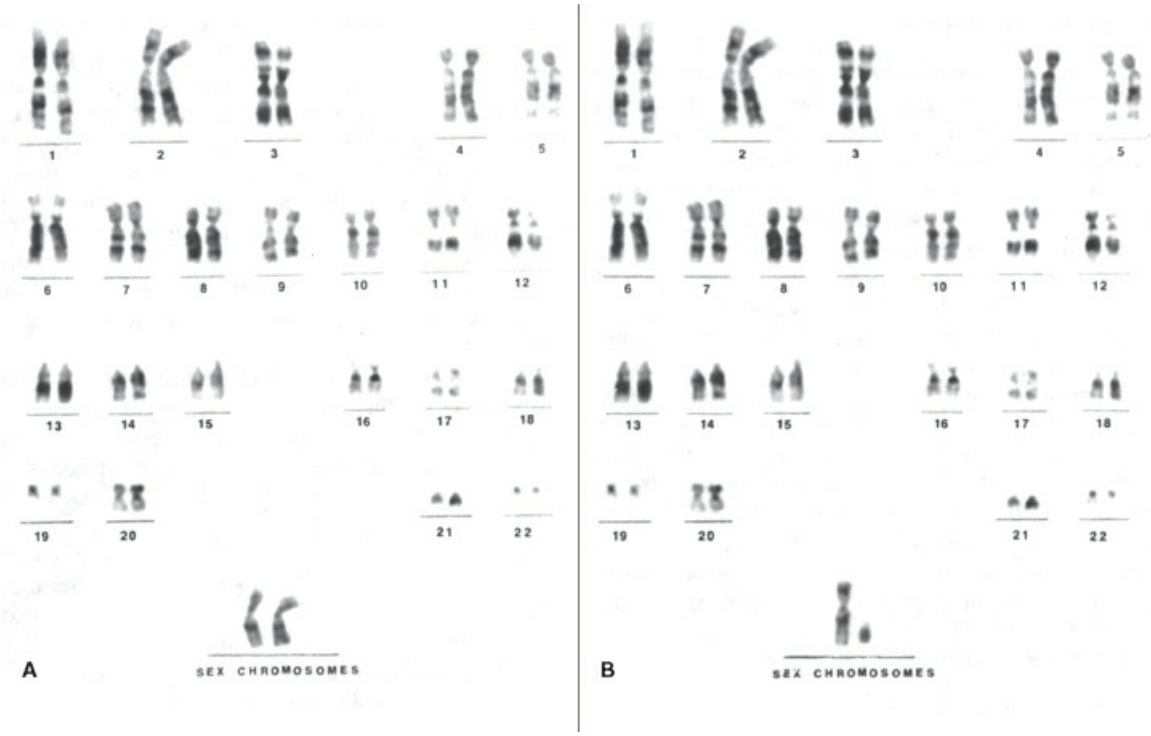

FIGURE 10.12 Karyotype pattern. A. Normal female karyotype. B. Normal male karyotype.

Human beings typically have 46 chromosomes. This includes 22 pairs of non-sex chromosomes or autosomes and 1 pair of sex chromosomes (two X chromosomes in females, and an X chromosome and a Y chromosome in males). Offspring receive one chromosome of each of the 23 pairs from each parent.

The pictorial analysis of the number, form, and size of an individual's chromosomes is termed the **karyotype**. This analysis commonly uses white blood cells and fetal cells in amniotic fluid. The chromosomes are numbered from the largest to the smallest, 1 to 22, and the sex chromosomes are designated by the letter X or Y. A female karyotype is designated as 46, XX and a male karyotype is designated as 46, XY. Figure 10.12 illustrates an example of a karyotyping pattern.

Regulation and expression of the thousands of human genes is very complex and is the result of many intricate interactions within each cell. Alterations in gene structure, function, transcription, translation, and protein synthesis can influence an individual's health (Jones & Lopez, 2014). Gene mutations are a permanent change in the sequence of DNA. Some mutations have no significant effect, whereas others can have a tremendous impact on the health of the individual. Several genetic disorders can result from these mutations, such as cystic fibrosis, sickle cell disease, phenylketonuria, or hemophilia.

Patterns of Inheritance for Genetic Disorders

Patterns of inheritance demonstrate how genetic abnormalities can be passed on to offspring. Although diagnosis of a genetic disorder is usually based on clinical signs and symptoms or on laboratory confirmation of an altered gene associated with the disorder, accurate diagnosis can be aided by the recognition of the pattern of inheritance within a family. In addition, nurses must understand the patterns of inheritance so they can teach and counsel families about the risks of genetic

disorders occurring in future pregnancies. Some genetic disorders occur in multiple family members, while others may occur in only a single family member. A genetic disorder is caused by completely or partially altered genetic material, whereas a familial disorder is more common in relatives of the affected individual but may be caused by environmental influences and not genetic alterations. For a more detailed discussion of specific types of genetic disorders, see Chapter 49.

Mendelian or Monogenic Laws of Inheritance

Principles of inheritance of single-gene disorders are the same principles that govern the inheritance of other traits, such as eye and hair color. These are known as Mendel's laws of inheritance, named for Gregory Mendel, an Austrian naturalist who conducted genetic research. These patterns occur because a single gene is defective and the disorders that result are referred to as monogenic or, sometimes, Mendelian disorders. If the defect occurs on the autosome, the genetic disorder is termed autosomal; if the defect is on the X chromosome, the genetic disorder is termed X-linked. The defect also can be classified as dominant or recessive. Monogenic disorders include autosomal dominant, autosomal recessive, X-linked dominant and X-linked recessive patterns.

AUTOSOMAL DOMINANT INHERITANCE DISORDERS

Autosomal dominant inherited disorders occur when a single gene in the heterozygous state is capable of producing the phenotype. In other words, the abnormal or mutant gene overshadows the normal gene and the person will demonstrate signs and symptoms of the disorder. The affected person generally has one affected parent. However, there are varying degrees of presentation among individuals in a family. For example, a parent with a mild form of the disorder could have a child with a more severe form (termed *variable expression*). In some autosomal dominant disorders there may be no history of an affected family member. This can be due to the child representing a new mutation or the result of incomplete or reduced penetrance, which means that a person with the genetic mutation does not develop phenotypic features of the disorder. Incomplete or reduced penetrance may result from a combination of genetic, environmental, and lifestyle factors, age, and gender.

Offspring of an affected parent will have a 50% chance of inheriting two normal genes (disorder free) and a 50% chance of inheriting one normal and one abnormal gene (and, thus, the disorder) (Fig. 10.13) (NIH, 2013). Females and males are equally affected by autosomal dominant disorders and an affected male can pass the disorder on to his son (NIH, 2013). This male-to-male transmission is important in distinguishing autosomal dominant inheritance from X-linked inheritance. Common types of genetic disorders that follow the autosomal dominant pattern of inheritance include neurofibromatosis (genetic disorders affecting the development and growth of neural cells and tissues), Huntington's disease (a genetic disorder affecting the nervous system characterized by abnormal involuntary movements and progressive dementia), achondroplasia (a genetic disorder resulting in disordered growth and abnormal body proportion), and polycystic kidney disease (a genetic disorder involving the growth of multiple, bilateral, grapelike clusters of fluid-filled cysts in the kidneys that eventually compress and replace functioning renal tissue).

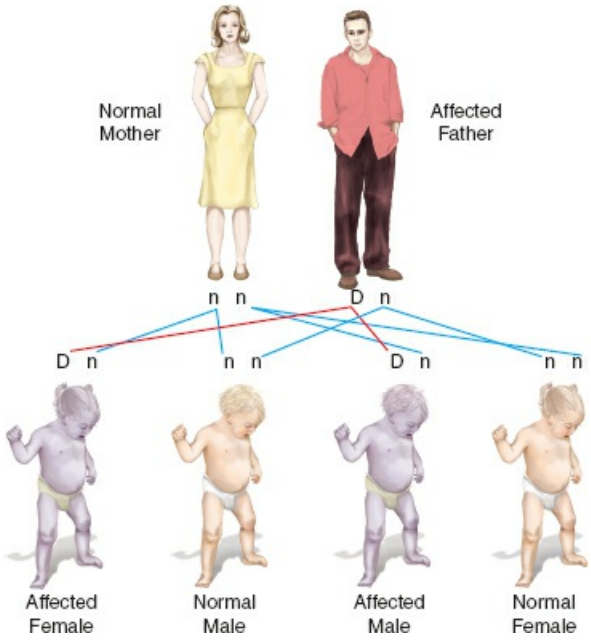

FIGURE 10.13 **Autosomal dominant inheritance.**

AUTOSOMAL RECESSIVE INHERITANCE DISORDERS

Autosomal recessive inherited disorders occur when two copies of the mutant or abnormal gene in the homozygous state are necessary to produce the phenotype. In other words, two abnormal genes are needed for the individual to demonstrate signs and symptoms of the disorder. Both parents of the affected person must be heterozygous carriers of the gene (clinically normal but carriers of the gene). Offspring of two carriers of the abnormal gene have a 25% chance of inheriting two normal genes; a 50% chance of inheriting one normal gene and one abnormal gene (carrier); and a 25% chance of inheriting two abnormal genes (and, thus, the disorder) (Fig. 10.14) (NIH, 2013). Affected people are usually present in only one generation of the family. Females and males are equally affected and a male can pass the disorder on to his son. The chance that any two parents will both be carriers of the mutant gene is increased if the couple has consanguinity (relationship by blood or common ancestry) (NIH, 2013). Common types of genetic disorders that follow the autosomal recessive inheritance pattern include cystic fibrosis (a genetic disorder involving generalized dysfunction of the exocrine glands), phenylketonuria (a disorder involving a deficiency in a liver enzyme that leads to the inability to process the essential amino acid phenylalanine), Tay–Sachs disease (a disorder due to insufficient activity of the enzyme hexosaminidase, which is necessary for the breakdown of certain fatty substances in the brain and nerve cells), and sickle cell disease (a genetic disorder in which the red blood cells carry an ineffective type of hemoglobin instead of the normal adult hemoglobin).

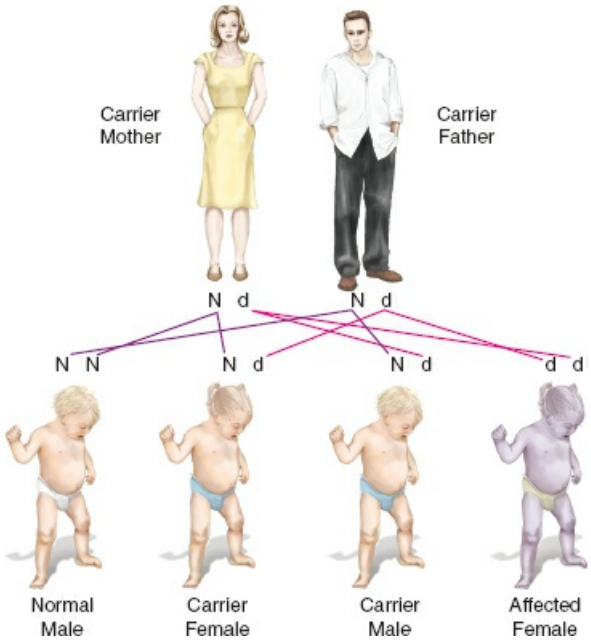

FIGURE 10.14 **Autosomal recessive inheritance.**

X-LINKED INHERITANCE DISORDERS

X-linked inherited disorders are those associated with altered genes present on the X chromosome. They differ from autosomal disorders. If a male inherits an X-linked altered gene, he will express the condition. This is because a male has only one X chromosome, therefore all the genes on his X chromosome will be expressed (the Y chromosome carries no normal allele to compensate for the altered gene). Because females inherit two X chromosomes, they can be either heterozygous or homozygous for any allele. Therefore, X-linked disorders in females are expressed similarly to autosomal disorders.

X-LINKED RECESSIVE INHERITANCE

Most X-linked disorders demonstrate a recessive pattern of inheritance (Snustad, 2015). There are more affected males than females because all the genes on a man's X chromosome will be expressed since a male has only one X chromosome (Snustad, 2015). On the other hand, a female will usually need two abnormal X chromosomes to exhibit the disease, and one normal and one abnormal X chromosome to be a carrier of the disease. There is no male-to-male transmission (since no X chromosome from the male is transmitted to male offspring), but any man who is affected with an X-linked recessive disorder will have carrier daughters. If a woman is a carrier, there is a 25% chance she will have an affected son, a 25% chance that her daughter will be a carrier, a 25% chance that she will have an unaffected son, and a 25% chance her daughter will be a noncarrier (Fig. 10.15) (Conley, 2014). Common types of genetic disorders that follow X-linked recessive inheritance patterns include hemophilia, color blindness, and Duchenne muscular dystrophy (NIH, 2013).

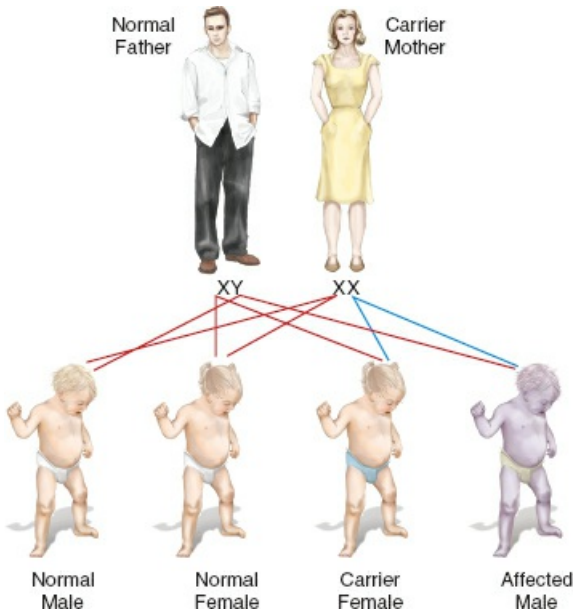

FIGURE 10.15 X-linked recessive inheritance.

X-LINKED DOMINANT INHERITANCE

X-linked dominant inheritance occurs when a male has an abnormal X chromosome or a female has one abnormal X chromosome. All of the daughters and none of the sons of an affected male will inherit the condition, while both male and female offspring of an affected woman have a 50% chance of inheriting the condition (Fig. 10.16) (NIH, 2013). Males are more severely affected than females. Many X-linked dominant disorders have lethal results in males (Slavotinek & Ali, 2015). In females, even though the gene is dominant, having a second normal X gene offsets the effects of the dominant gene to some extent resulting in decreasing severity of the disorder. X-linked dominant disorders are rare; examples include hypophosphatemic (vitamin D–resistant) rickets and fragile X syndrome. Fragile X syndrome causes a range of developmental problems including learning disabilities and cognitive impairment (Van Esch, 2014). A characteristic of X-linked dominant inheritance is that fathers cannot pass X-linked traits to their sons (no male-to-male transmission) (GHR, 2015).

Multifactorial Inheritance Disorders

Many of the common congenital malformations, such as cleft lip, cleft palate, spina bifida, pyloric stenosis, clubfoot, congenital hip dysplasia, and cardiac defects, are attributed to multifactorial inheritance (Snustad, 2015). These conditions are thought to be caused by multiple gene and environmental factors. That is, a combination of genes from both parents, along with unknown environmental factors, produces the trait or condition. An individual may inherit a predisposition to a particular anomaly or disease. The anomalies or diseases vary in severity, and often a sex bias is present. For example, pyloric stenosis is seen more often in males, while congenital hip dysplasia is much more likely to occur in females. Multifactorial conditions tend to run in families, but the pattern of inheritance is not as predictable as with single-gene disorders. The chance of recurrence is also less than in single-gene disorders, but the degree of risk is related to the number of genes in common with the affected individual. The closer the degree of relationship,

the more genes an individual has in common with the affected family member, resulting in a higher chance the individual's offspring will have a similar defect. In multifactorial inheritance the likelihood that both identical twins will be affected is not 100%, indicating that there are nongenetic factors involved.

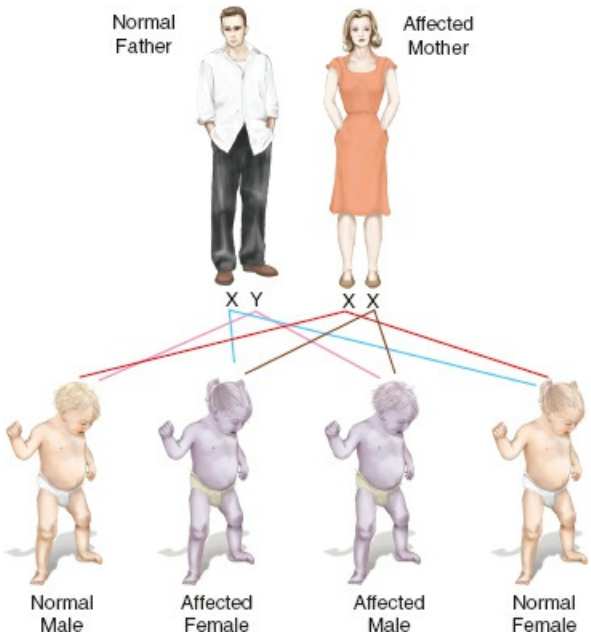

FIGURE 10.16 X-linked dominant inheritance.

Nontraditional Inheritance Patterns

Molecular studies have revealed that some genetic disorders are inherited in ways that do not follow the typical patterns of dominant, recessive, X-linked, or multifactorial inheritance. Examples of nontraditional inheritance patterns include mitochondrial inheritance and genomic imprinting. As the science of molecular genetics advances and more is learned about inheritance patterns, other nontraditional patterns of inheritance may be discovered or found to be relatively common.

MITOCHONDRIAL INHERITANCE

Certain diseases result from mutations in the mitochondrial DNA. Mitochondria (the part of the cell responsible for energy production) are inherited almost exclusively from the mother. Therefore, mitochondrial inheritance is usually passed from the mother to the offspring, regardless of the offspring's sex (differentiating mitochondrial inheritance from X-linked recessive inheritance). These mutations are often deletions and abnormalities and are often seen in one or more organs, such as the brain, eye, and skeletal muscle. They are often associated with energy deficits in cells with high energy requirements, such as nerve and muscle cells. These disorders tend to be progressive and the age of onset can vary from infancy to adulthood. There is an extreme amount of variability in symptoms within a family. Examples of disorders that follow mitochondrial inheritance include Kearns–Sayre syndrome (a neuromuscular disorder) and Leber's hereditary optic neuropathy (which causes progressive visual impairment).

GENOMIC IMPRINTING

Another nontraditional inheritance pattern results from a process called genomic imprinting. Genomic imprinting plays a critical role in fetal growth and development and placental functioning. It is a phenomenon by which the expression of a gene is determined by its parental origin. In genomic imprinting both the maternal and paternal alleles are present, but only one is expressed; the other is inactive. Genomic imprinting does not alter the genetic sequence itself, but affects the phenotype observed. In these cases, the altered genes in a certain region of the genome have very different expressions depending on whether they were inherited from the mother or the father. Several human syndromes are known to be associated with defects in gene imprinting. Disorders that result from a disruption of imprinting usually involve a growth phenotype and include varying degrees of developmental problems. Common examples include Prader–Willi syndrome (a condition resulting in severe hypotonia and hyperphagia, leading to obesity and intellectual disability), Angelman syndrome (a neurodevelopmental disorder associated with intellectual disability, jerky movements, and seizures), and Beckwith–Wiedemann syndrome (characterized by somatic overgrowth, congenital malformations, and a predisposition to embryonic neoplasia).

Chromosomal Abnormalities

In some cases of genetic disorders, the abnormality occurs due to problems with the chromosomes. Chromosomal abnormalities do not follow straightforward patterns of inheritance. Although some chromosomal disorders can be inherited, most others occur due to random events during the formation of reproductive cells or in early fetal development. Most chromosomal abnormalities occur due to an error in the egg or sperm. Therefore, the abnormality is present in every cell of the body. Some abnormalities can happen after fertilization, during mitotic cell division, and result in mosaicism. **Mosaicism** or the mosaic form is when the chromosomal abnormalities do not show up in every cell; only some cells or tissues carry the abnormality. In mosaic forms of the disorder the symptoms are usually less severe than if all the cells were abnormal.

Chromosomal abnormalities occur in about 1 in 150 live-born infants (March of Dimes, 2015). Congenital anomalies and intellectual disability are often associated with chromosomal abnormalities (Bacino & Lee, 2016). These abnormalities occur on autosomal or non-sex chromosomes as well as sex chromosomes and can result from abnormalities of either chromosome number or chromosome structure.

As mentioned, a karyotype is a pictorial analysis of chromosomes. It depicts a systematic arrangement of chromosomes of a single cell by pairs (see Fig. 10.12). Karyotyping is often used in prenatal testing to diagnose or predict genetic diseases.

Abnormalities of Chromosome Number

Chromosomal abnormalities of number often result due to nondisjunction (failure of separation of the chromosome pair during cell division, meiosis, or mitosis). Few chromosomal numerical abnormalities are compatible with full-term development and most result in spontaneous abortion (Snustad, 2015).

There are some numerical abnormalities that do support development to term because the chromosome on which the abnormality is present carries relatively few

genes (such as chromosome 13, 18, 21, or X). Two common abnormalities of chromosome number are monosomy and trisomy. In **monosomy**, there is only one copy of a particular chromosome instead of the usual pair (an entire single chromosome is missing). In these cases, all fetuses spontaneously abort in early pregnancy. Survival is seen only in mosaic forms of these disorders. In **trisomy**, there are three of a particular chromosome instead of the usual two (an entire single chromosome is added). The most common trisomies include trisomy 21 (Down syndrome), trisomy 18, and trisomy 13. Figure 10.17 shows the karyotype of a child with Down syndrome. (See Chapter 49 for a detailed discussion of these disorders.) Trisomies may be present in every cell or may present in the mosaic form.

Abnormalities of Chromosome Structure

Abnormalities of chromosome structure usually occur when there is a breakage and loss of a portion of one or more chromosomes, and during the repair process the broken ends are rejoined incorrectly. Structural abnormalities usually lead to having too much or too little genetic material. Altered chromosome structure can take on several forms. Deletions occur when a portion of the chromosome is missing or deleted, resulting in a loss of that portion of the chromosome. Duplications are seen when a portion of the chromosome is duplicated and an extra chromosomal segment is present. Clinical findings vary depending on how much chromosomal material is involved. Inversions occur when a portion of the chromosome breaks off at two points and is turned upside down and reattached; therefore, the genetic material is inverted. With inversion, there is no loss or gain of chromosomal material and carriers are phenotypically normal, but they do have an increased risk for miscarriage and having chromosomally abnormal offspring (GHR, 2015). Ring chromosomes are seen when a portion of a chromosome has broken off in two places and formed a circle or ring. The most clinically significant structural abnormality is a translocation. This occurs when a portion of one chromosome is transferred to another chromosome and an abnormal rearrangement is present.

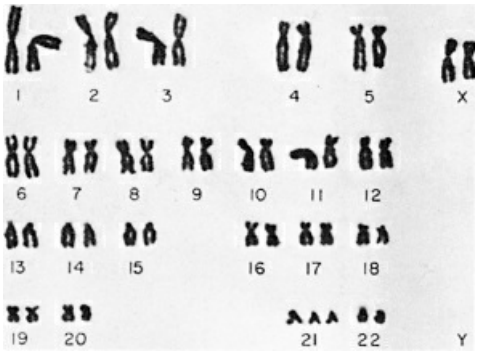

FIGURE 10.17 Karyotype of a child with Down syndrome.

Structural abnormalities can be balanced or unbalanced. Balanced abnormalities involve the rearrangement of genetic material with neither an overall gain nor loss. Individuals who inherit a balanced structural abnormality are usually phenotypically normal but are at a higher risk for miscarriages and having chromosomally abnormal offspring. Examples of structural rearrangements that can be balanced include inversions, translocation, and ring chromosomes. Unbalanced structural abnormalities are similar to numerical abnormalities because genetic

material is either gained or lost. Unbalanced structural abnormalities can encompass several genes and result in severe clinical consequences.

Sex Chromosome Abnormalities

Chromosomal abnormalities can also involve sex chromosomes. These cases are usually less severe in their clinical effects than autosomal chromosomal abnormalities. Sex chromosome abnormalities are gender-specific and involve a missing or extra sex chromosome. They affect sexual development and may cause infertility, growth abnormalities, and possibly behavioral and learning problems (Chen, 2015). However, many affected people lead essentially normal lives. Examples are Turner syndrome in females and Klinefelter syndrome in males. (See Chapter 49 for a more detailed discussion of these disorders.)

GENETIC EVALUATION AND COUNSELING

Genetic counseling is a communication and educational process where the genetic influence of health is explained along with information regarding a specific genetic disorder, its transmission, inheritance, and options available in management and family planning (Nussbaum et al., 2016). There are a variety of reasons a person should be referred for genetic counseling (Box 10.2). In many cases, geneticists and genetic counselors provide information to families regarding genetic diseases. However, an experienced family physician, pediatrician, or nurse who has received special training in genetics may also provide the information. A genetic consultation involves evaluation of an individual or a family. Its purpose is to confirm, diagnose, or rule out genetic conditions; identify medical management issues; calculate and communicate genetic risks to a family; discuss ethical and legal issues; and assist in providing and arranging psychosocial support. Genetic counselors serve as educators and resource persons for other health care providers and the general public. Nurses have long been on the forefront of genetic counseling for their clients. The knowledge gained from the Human Genome Project is transforming the health care model, with implications for nurses in genetic counseling, practice and research (International Society of Nurses in Genetics [ISONG], 2014).

BOX 10.2

THOSE WHO MAY BENEFIT FROM GENETIC COUNSELING

- Maternal age 35 years or older when the baby is born
- Paternal age 50 years or older
- Previous child, parents, or close relatives with an inherited disease, congenital anomalies, metabolic disorders, developmental disorders, or chromosomal abnormalities
- Consanguinity or incest
- Pregnancy screening abnormality, including alpha-fetoprotein, triple/quadruple screen, amniocentesis, or ultrasound
- Stillborn with congenital anomalies
- Two or more pregnancy losses
- Exposure to drugs, medications, radiation, chemicals, or infection

- Teratogen exposure or risk
- Concerns about genetic defects that occur frequently in their ethnic or racial group (e.g., those of African descent are most at risk for having a child with sickle cell anemia)
- Abnormal newborn screening
- Couples with a family history of X-linked disorders
- Carriers of autosomal recessive or dominant diseases
- Child born with one or more major malformations in a major organ system
- Child with abnormalities of growth
- Child with developmental delay, intellectual disability, blindness, or deafness

(2015b). *Frequently asked questions about genetic counseling.* Retrieved from http://www.genome.gov/19016905; Lewis, R. (2015). *Human genetics: Concepts and applications* (11th ed.). New York: McGraw-Hill Companies, Incorporated.

The ideal time for genetic counseling is before conception. Preconception counseling allows couples to identify and reduce potential pregnancy risks, plan for known risks, and establish early prenatal care. Unfortunately, many women delay seeking prenatal care until their second or third trimester, after the crucial time of organogenesis. Therefore, it is important that preconception counseling is offered to all women as they seek health care throughout their childbearing years, especially if they are contemplating pregnancy. This requires health care providers to take an active role. Consideration of genetics is rapidly becoming a part of routine health care, and all nurses need to be up to date and confident in their understanding of this topic.

Consider This

As I waited for the genetic counselor to come into the room, my mind was filled with numerous fears and questions. What does an inconclusive amniocentesis really mean? What if this pregnancy produced an abnormal baby? How would I cope with a special child in my life? If only I had gone to the midwife sooner when I thought I was pregnant, but still in denial. Why did I wait so long to admit this pregnancy and get prenatal care? If only I had started to take my folic acid pills when prescribed. Why didn't I research my family's history to know of any hidden genetic conditions? What about my sister with a Down syndrome child? What must I have been thinking? I guess I could play the "what-if" game forever and never come up with answers. It was too late to do anything about this pregnancy because I was in my last trimester. I started to pray silently when the counselor opened the door. . . .

Thoughts: This woman is reviewing the last several months, looking for answers to her greatest fears. Inconclusive screenings can introduce emotional torment for many women as they wait for validating results. Are these common thoughts and fears for many women facing potential genetic disorders? What supportive interventions might the nurse offer?

Preconception counseling plays a key role in preparing for a pregnancy. In couples with a history of recurrent early pregnancy loss, counseling is of particular importance because women are invariably more distressed and require reassurance to avoid future pregnancy losses. Several interventions ranging from genetic testing

to lifestyle changes and medications may have a positive effect on the chances of a successful pregnancy. Early pregnancy monitoring and support increases the chance of a live birth and helps to predict potential future pregnancy complications. Recent research suggests that events that occur in the uterine decidua, even before a woman knows she is pregnant, may have a significant impact on fetal growth and the outcome of pregnancy. With this in mind, shifting future research and clinical practice to focus on the periconceptual period and the very early stages of pregnancy should offer significant benefits to the health of both the mother and her infant. The overall aim should be to effectively use every pregnancy as the health care opportunity of two lifetimes (Lopes, de Omena Bomfim, & Floria-Santos, 2015).

Preconception screening and counseling can raise serious ethical and moral issues for a couple. The results of prenatal genetic testing can lead to the decision to terminate a pregnancy, even if the results are not conclusive but indicate a strong possibility that the child will have an abnormality. The severity of the abnormality may not be known, and some may find the decision to terminate unethical. Another difficult situation that provides an example of the ethical and moral issues surrounding genetic screening and counseling involves disorders that affect only one gender of offspring. A mother may find she is a carrier of a gene for a disorder for which there is no prenatal screening test available. In these cases the couple may decide to terminate any pregnancy where the fetus is the affected sex, even though there is a 50% chance that the child will not inherit the disorder. In these situations, the choice is the couple's and information and support must be provided in a nondirective, nonjudgmental manner.

Genetic counseling is particularly important if a congenital anomaly or genetic disease has been diagnosed prenatally or when a child is born with a life-threatening congenital anomaly or genetic disease. In these cases families need information urgently so they can make immediate decisions. If a diagnosis with genetic implications is made later in life, if a couple with a family history of a genetic disorder or a previous child with a genetic disorder is planning a family, or if there is suspected teratogen exposure, urgency of information is not such an issue. In these situations, the family needs to take in all the information and explore their options. This may occur during several meetings over a longer period of time.

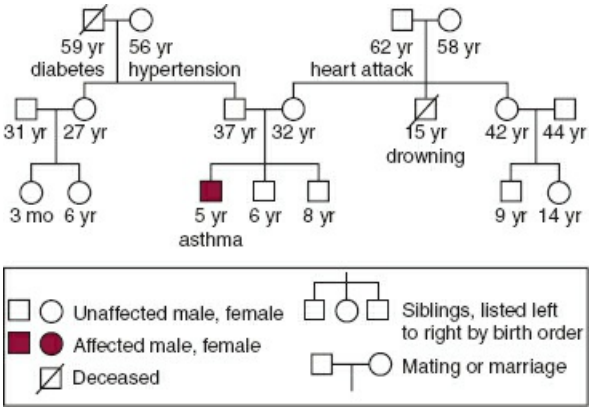

FIGURE 10.18 A pedigree is a diagram made using symbols that demonstrates the links between family members and focuses on medical and health information for each relative.

Genetic counseling involves extensive information gathering about birth history,

past medical history, and current health status as well as a family history of congenital anomalies, mental retardation, genetic diseases, reproductive history, general health, and causes of death. A detailed family history is imperative and in most cases will include the development of a pedigree, which is like a family tree (Fig. 10.18). Information is ideally gathered on three generations, but if the family history is complicated, information from more distant relatives may be needed. Families receiving genetic counseling should be told that this information will be necessary so that they can discuss these sensitive issues with family members in advance. When necessary, medical records may be requested for family members, especially those who have a genetic disorder, to help ensure accuracy of the information. Sometimes the process of preparing a pedigree may reveal information that is not known by all family members, such as an adoption, a child conceived through in vitro fertilization, or a husband not being the father of a baby. Therefore, it is extremely important to take steps to maintain confidentiality. After careful analysis of the data obtained, referral to a genetic counselor when indicated is appropriate.

Medical genetic knowledge has increased dramatically over the past few decades. This has greatly expanded the role of the genetic counselor. It is possible not only to detect specific diseases with genetic mutations, but also to test for a genetic predisposition to various diseases or conditions and certain physical characteristics. This leads to complex ethical, moral, and social issues. Health care providers need to maintain privacy and confidentiality and administer care in a nondiscriminatory manner while maintaining sensitivity to cultural differences. It is essential to respect the individual's autonomy and present information in a nondirective manner.

Nursing Roles and Responsibilities

The nurse is likely to interact with the client in a variety of ways related to genetics —taking a family history, scheduling genetic testing, explaining the purposes of all screening and diagnostic tests, answering questions, and addressing concerns raised by family members. Nurses are often the first health care providers to encounter women with preconception and prenatal issues. Nurses play an important role in beginning the preconception counseling process and referring women and their partners for further genetic testing when indicated.

An accurate and thorough family history is an essential part of preconception counseling. Nurses in any practice setting can obtain a client's history during the initial encounter. The purpose is to gather client and family information that may provide clues as to whether the client has a genetic trait, inherited condition, or inherited predisposition (ISONG, 2014). At a basic level, all nurses should be able to take a family medical history to help identify those at risk for genetic conditions, and then initiate a referral when appropriate. (Box 10.3) presents examples of focused assessment questions that can be used. Based on the information gathered during the history, the nurse must decide whether a referral to a genetic specialist is necessary or whether further evaluation is needed. Families identified with genetic issues need unique clinical care including management of acute illnesses, screening for long-term complications, discussion of the etiology of the condition, connections to social supports, and clarification of the recurrence risks and prenatal testing and treatment options (ISONG, 2014). Prenatal testing to assess for genetic risks and

defects might be used to identify genetic disorders. These tests are described in Common Laboratory and Diagnostic Tests 10.1.

BOX 10.3

FOCUSED HEALTH ASSESSMENT: GENETIC HISTORY

What was the cause and age of death for deceased family members?
Does any consanguinity exist between relatives?
Do any serious illnesses or chronic conditions exist? If so, what was the age of onset?
Do any female family members have a history of miscarriages, stillbirths, or diabetes?
Do any female members have a history of alcohol or drug use during pregnancy?
What were the ages of female members during childbearing, especially if older than 35?
Do any family members have mental retardation or developmental delays?
Do any family members have a known or suspected metabolic disorder such as PKU?
Do any family members have an affective disorder such as bipolar disorder?
Have any close relatives been diagnosed with any type of cancer?
What is your ethnic background (explore as related to certain disorders)?
Do any family members have a known or suspected chromosomal disorder?
Do any family members have a progressive neurologic disorder?

Remember Robert and Kate Shafer? Based on the information gathered from their genetic history, they were referred to a genetic specialist. What prenatal tests might be ordered to assess their risk for genetic disorders? What would be the nurse's role related to genetic counseling?

Nurses working with families involved with genetic counseling typically have certain responsibilities. These include:

- Using interviewing and active listening skills to identify genetic concerns
- Knowing basic genetic terminology and inheritance patterns
- Explaining basic concepts of probability and disorder susceptibility
- Safeguarding the privacy and confidentiality of clients' genetic information
- Providing complete informed consent to facilitate decisions about genetic testing
- Discussing costs of genetic services and the benefits and risks of using health insurance to pay for genetic services, including potential risks of discrimination
- Recognizing and defining ethical, legal, and social issues
- Providing accurate information about the risks and benefits of genetic testing
- Providing culturally appropriate methods to convey genetic information

- Monitoring clients' emotional reactions after receiving genetic analysis
- Providing information on appropriate local support groups
- Knowing their own limitations and making appropriate referrals (Sermon & Viville, 2014)

Talking with families who have recently been diagnosed with a genetic disorder or who have had a child born with congenital anomalies is very difficult. Many times the nurse may be the one who has first contact with these parents and will be the one to provide follow-up care.

COMMON LABORATORY AND DIAGNOSTIC TESTS 10.1

PRENATAL TESTS TO ASSESS RISK FOR GENETIC DISORDERS

Test	Description	Indication	Timing
Alpha-fetoprotein	A sample of the woman's blood is drawn to evaluate plasma protein that is produced by the fetal liver, yolk sac, and GI tract, and crosses from the amniotic fluid into the maternal blood	Increased levels might indicate a neural tube defect, Turner syndrome, tetralogy of Fallot, multiple gestation, omphalocele gastroschisis, or hydrocephaly. Decreased levels might indicate Down syndrome or trisomy 18	Typically performed between 15 and 18 weeks' gestation
Amniocentesis	Amniotic fluid aspirated from the amniotic sac; safety concerns include infection, pregnancy loss, and fetal needle injuries	To perform chromosome analysis, alpha-fetoprotein, DNA markers, viral studies, karyotyping, and identify inborn errors of metabolism	Usually performed between 15 and 20 weeks' gestation to allow for adequate amniotic fluid volume to accumulate; results take 2–4 weeks
Chorionic villus sampling	Removal of small tissue specimen from the fetal portion of the placenta, which reflects the fetal genetic makeup; main complications include severe transverse limb defects and spontaneous pregnancy loss	To detect fetal karyotype, sickle cell anemia, phenylketonuria, Down syndrome, Duchenne muscular dystrophy, and numerous other genetic disorders	Typically performed between 10 and 12 weeks' gestation, with results available in less than 1 week
Percutaneous umbilical blood sampling	Insertion of a needle directly into a fetal umbilical vessel under ultrasound guidance; two potential complications: fetal hemorrhage and risk of infection	Used for prenatal diagnosis of inherited blood disorders such as hemophilia A, karyotyping, detection of fetal infection, determination of acid–base status, and assessment and treatment of isoimmunization	Generally performed after 16 weeks' gestation
Fetal nuchal translucency (FNT)	An intravaginal ultrasound that measures fluid collection in the subcutaneous space between the skin and the cervical spine of the fetus	To identify fetal anomalies; abnormal fluid collection can be associated with genetic disorders (trisomies 13, 18, and 21), Turner syndrome, cardiac deformities, and/or physical anomalies. When the FNT is greater than 2.5 mm, the measurement is considered abnormal	Performed between 10 and 14 weeks' gestation
Level II ultrasound/fetal scan	Use of high-frequency sound waves to visualize the fetus	Enables evaluation of structural changes to be identified early	Typically performed after 18 weeks' gestation
Triple and quad screening tests	Triple screening includes alpha-fetoprotein, estriol, and beta-hCG; quad screening includes alpha-fetoprotein, estriol, beat-hCG, and inhibin A	To identify risk for Down syndrome, neural tube defects, and other chromosomal disorders. Elevated hCG combined with lower-than-normal estriol and MSAFP levels indicate increased risk for Down syndrome or other trisomy condition.	Performed between 15 and 18 weeks' gestation
Preimplantation genetic diagnosis	Genetic testing of embryos produced through in vitro fertilization (IVF)	Identifies embryos carrying specific genetic alterations that can cause disease, and transfer those without genetic alterations into the woman's uterus to start a pregnancy; prevents inheritable genetic disease before implantation	Usually on day 3 after egg retrieval and 2 days after fertilization, a single blastomere is removed from the developing embryo to be evaluated
Cell-free fetal DNA (CffDNA)	A noninvasive prenatal test using maternal plasma which hold a mixture of maternal and fetal DNA after 4 weeks' gestation	Determines fetal sex in pregnancies at risk of sex-linked conditions; RhD genotyping in pregnancies at risk of hemolytic disease of the newborn and fetal chromosomal abnormalities such as Down syndrome.	A maternal blood sample is taken and next generation sequencing is used to analyze the cffDNA at approximately 10 weeks' gestation.

Davis Company..

Genetic disorders are significant, life-changing, and possibly life-threatening situations. The information is highly technical and the field is undergoing significant technologic advances. Nurses need an understanding of who will benefit from genetic counseling and must be able to discuss the role of the genetic counselor with families. The nurse wants to ensure that families at risk are aware that genetic counseling is available before they attempt to have another baby.

Based on the results of their genetic tests, Robert and Kate are placed at moderate risk for having an infant with an autosomal recessive genetic

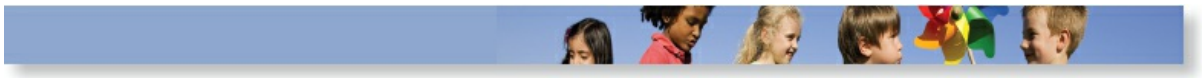
disorder. The couple asks the nurse what all of this means. What information should the nurse provide about concepts of probability and disorder susceptibility for this couple? How can the nurse help this couple to make knowledgeable decisions concerning their reproductive future?

Nurses play an essential role in providing emotional support to the family through this challenging time. Genetics permeates all aspects of health care. Today, everyone is embracing quality and evidence-based care. Nurses who have an understanding of genetics and genomics will possess the foundation to provide quality, evidence-based care especially with follow-up counseling after the couple or family has been to the genetic specialist (Verklan & Walden, 2015).

Take Note!

Nurses need to be actively engaged with clients and their families and help them consider the facts, values, and context in which they are making decisions. Nurses need to be open and honest with families as they discuss these sensitive and emotionally laden choices.

The nurse is in an ideal position to help families review what has been discussed during the genetic counseling sessions and to answer any additional questions they might have. Referral to appropriate agencies, support groups, and resources, such as a social worker, a chaplain, or an ethicist, is another key role when caring for families with suspected or diagnosed genetic disorders. Couples need unique clinical care which includes screening for genetic disorders, discussion of the etiology of a potential condition, connections to social supports, and clarification of the recurrence risks and prenatal testing and treatment options. Nurses need to be involved in all aspects of this care.



KEY CONCEPTS

- Fertilization, which takes place in the outer third of the ampulla of the fallopian tube, leads to the formation of a zygote. The zygote undergoes cleavage, eventually implanting in the endometrium about 7 to 10 days after conception.
- Three embryonic layers of cells are formed and include the ectoderm, which forms the central nervous system, special senses, skin, and glands; the mesoderm, which forms the skeletal, urinary, circulatory, and reproductive systems; and the endoderm, which forms the respiratory system, liver, pancreas, and digestive system.
- Amniotic fluid surrounds the embryo and increases in volume as the pregnancy progresses, reaching approximately 1 L in volume by term.
- At no time during pregnancy is there any direct connection between the blood of the fetus and the blood of the mother, so there is no mixing of blood. A specialized connective tissue known as Wharton's jelly surrounds the three blood vessels in the umbilical cord to prevent compression, which would choke off the blood supply and nutrients to the growing life inside.

- The placenta protects the fetus from immune attack by the mother, removes waste products from the fetus, induces the mother to bring more food to the placenta and, near the time of birth, produces hormones that mature fetal organs in preparation for life outside the uterus.
- The purpose of fetal circulation is to carry highly oxygenated blood to vital areas (heart and brain) while first shunting it away from less vital ones (lungs and liver).
- Humans have 46 paired chromosomes that are found in all cells of the body, except the ovum and sperm cells, which have just 23 chromosomes. Each person has a unique genetic constitution, or genotype.
- Research from the Human Genome Project has provided a better understanding of the genetic contribution to disease.
- Genetic disorders can result from abnormalities in patterns of inheritance or chromosomal abnormalities involving chromosomal number or structure.
- Autosomal dominant inheritance occurs when a single gene in the heterozygous state is capable of producing the phenotype. Autosomal recessive inheritance occurs when two copies of the mutant or abnormal gene in the homozygous state are necessary to produce the phenotype. X-linked inheritance disorders are those associated with altered genes present on the X chromosome. They can be dominant or recessive. Multifactorial inheritance is thought to be caused by multiple genetic and environmental factors.
- In some cases of genetic disorders, a chromosomal abnormality occurs. Chromosomal abnormalities do not follow straightforward patterns of inheritance. These abnormalities occur on autosomal as well as sex chromosomes and can result from changes in the number or structure of the chromosomes.
- Genetic counseling involves evaluation of an individual or a family. Its purpose is to confirm, diagnose, or rule out genetic conditions; identify medical management issues; calculate and communicate genetic risks to a family; discuss ethical and legal issues; and assist in providing and arranging psychosocial support.
- Legal, ethical, and social issues can arise related to genetic testing and may include the privacy and confidentiality of genetic information, who should have access to personal genetic information, psychological impact and stigmatization due to individual genetic differences, use of genetic information in reproductive decision making and reproductive rights, and whether testing should be performed if no cure is available.
- Preconception screening and counseling can raise serious ethical and moral issues for a couple. The results of prenatal genetic testing can lead to the decision to terminate a pregnancy.
- Nurses play an important role in beginning the preconception counseling process and referring women and their partners for further genetic information when indicated. Many times the nurse is the one who has first contact with these women and will be the one to provide follow-up care.

- Nurses need to have a solid understanding of who will benefit from genetic counseling and be able to discuss the role of the genetic counselor with families, ensuring that families at risk are aware that genetic counseling is available before they attempt to have another baby.
- Nurses play an essential role in providing emotional support and referrals to appropriate agencies, support groups, and resources when caring for families with suspected or diagnosed genetic disorders. Nurses can assist clients with their decision making by referring them to a social worker, chaplain, or ethicist.

CHAPTER WORKSHEET

MULTIPLE-CHOICE QUESTIONS

1. After teaching a group of students about fertilization, the instructor determines that the teaching was successful when the group identifies which as the usual site of fertilization?
   a. Fundus of the uterus
   b. Endometrium of the uterus
   c. Distal portion of fallopian tube
   d. Follicular tissue of the ovary
2. A client comes to the clinic for pregnancy testing. The nurse explains that the test detects the presence of which hormone?
   a. Human placental lactogen (hPL)
   b. Human chorionic gonadotropin (hCG)
   c. Follicle stimulating hormone (FSH)
   d. Thyroid stimulating hormone (TSH)
3. The nurse is counseling a couple, one of whom is affected by an autosomal dominant disorder. They express concerns about the risk of transmitting the disorder. What is the best response by the nurse regarding the risk that their baby may have for the disease?
   a. “You have a one in four (25%) chance.”
   b. “The risk is 12.5%, or a one in eight chance.”
   c. “The chance is 100%.”
   d. “Your risk is 50%, or a one in two chance.”
4. What is the first step in determining a couple’s risk for a genetic disorder?
   a. Observing the client and family over time
   b. Conducting extensive psychological testing
   c. Obtaining a thorough family health history
   d. Completing an extensive exclusionary list
5. A nurse is working in a women’s health clinic. Which woman would genetic counseling be most appropriate for?
   a. Had her first miscarriage at 10 weeks
   b. Is 30 years old and planning to conceive
   c. Has a history with a close relative with Down syndrome
   d. Is 18 weeks pregnant with a normal triple screen result
6. Which of the following is an example of an autosomal dominant disorder?
   a. Phenylketonuria
   b. Tay–Sachs disease
   c. Polycystic kidney disease
   d. Cystic fibrosis

7. Which of the following is the major goal of genetic counseling?
   a. Diagnose and determine the role of heredity
   b. Reinforce previously presented test data
   c. Emphasize good communication skills
   d. Offer referral to community support groups

CRITICAL THINKING EXERCISE

1. Mr. and Mrs. Martin wish to start a family, but they can't agree on something important. Mr. Martin wants his wife to be tested for cystic fibrosis (CF) to see if she is a carrier. Mr. Martin had a brother with CF and watched his parents struggle with the hardship and the expense of caring for him for years, and he doesn't want to experience it in his own life. Mr. Martin has found out he is a CF carrier. Mrs. Martin doesn't want to have the test because she figures that once a baby is in their arms, they will be glad, no matter what.
   a. What information/education should this couple consider before deciding whether to have the test?
   b. How can you assist this couple in their decision-making process?
   c. What is your role in this situation if you don't agree with their decision?

STUDY ACTIVITIES

1. Obtain the video *Miracle of Life,* which shows conception and fetal development. What are your impressions? Is the title of this video realistic?
2. Select one of the websites listed in thePoint to explore the topic of genetics. Critique the information presented. Was it understandable to a layperson? What specifically did you learn? Share your findings with your classmates during a discussion group.
3. Draw your own family pedigree, identifying inheritance patterns. Share it with your family to validate its accuracy. What did you discover about your family's past health?
4. Select one of the various prenatal screening tests (alpha-fetoprotein, amniocentesis, chorionic villus sampling, or fetal nuchal translucency) and research it in depth. Role-play with another nursing student how you would explain its purpose, the procedure, and potential findings to an expectant couple at risk for a fetal abnormality.

BRINGING IT ALL TOGETHER: A CASE STUDY

Rebecca and Jon are a couple seeking genetic counseling. Rebecca, 43 years old, is 10 weeks pregnant with their first baby. The couple is concerned about the possibility of their child demonstrating trisomy 21 (Down syndrome).

Go to thePoint to find questions to consider about this case.

11

Maternal Adaptation During Pregnancy

WOW

Words of Wisdom

When a woman discovers that she is pregnant, she must remember to protect and nourish the fetus by making wise choices.

KEY TERMS

ballottement
Braxton Hicks contractions
Chadwick's sign
dietary reference intakes (DRIs)
Goodell's sign
Hegar's sign
linea nigra
physiologic anemia of pregnancy
pica
quickening
trimester

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Differentiate between subjective (presumptive), objective (probable), and diagnostic (positive) signs of pregnancy.
2. Describe maternal physiologic changes that occur during pregnancy.
3. Summarize the nutritional needs of the pregnant woman and her fetus.
4. Characterize the emotional and psychological changes that occur during pregnancy.

***Marva*, age 17, appeared at the health department clinic complaining that she had a stomach virus and needed to be seen right away. When the nurse asked her additional questions about her illness, Marva reported that she had been sick to her stomach and "beat tired" for days. She had stopped eating to avoid any more nausea and vomiting.**

INTRODUCTION

Pregnancy is a normal life event that involves considerable physical and psychological adjustments for the mother. A pregnancy is divided into three trimesters of 13 weeks each (Edelman, Kudzma, & Mandle, 2014). Within each **trimester**, numerous adaptations take place that facilitate the growth of the fetus. The most obvious are physical changes to accommodate the growing fetus, but pregnant women also undergo psychological changes as they prepare for parenthood. A thorough understanding of these numerous changes and adaptations is essential for all nurses caring for women during pregnancy.

SIGNS AND SYMPTOMS OF PREGNANCY

Traditionally, signs and symptoms of pregnancy have been grouped into the following categories: presumptive, probable, and positive (Box 11.1). The only signs that can determine a pregnancy with 100% accuracy are positive signs.

What additional information is necessary to complete the assessment of Marva, the 17-year-old with nausea and vomiting? What diagnostic tests might be done to confirm the nurse's suspicion that she is pregnant?

Subjective (Presumptive) Signs

Presumptive signs are those signs that the mother can perceive. The most obvious presumptive sign of pregnancy is the absence of menstruation. Skipping a period is not a reliable sign of pregnancy by itself, but if it is accompanied by consistent nausea, fatigue, breast tenderness, and urinary frequency, pregnancy would seem very likely.

Consider This

Jim and I decided to start our family, so I stopped taking the pill 3 months ago. One morning when I got out of bed to take the dog out, I felt queasy and light-headed. I sure hoped I wasn't coming down with the flu. By the end of the week, I was feeling really tired and started taking naps in the afternoon. In addition, I seemed to be going to the bathroom frequently, despite not drinking much fluid. When my breasts started to tingle and ache, I decided to make an appointment with my doctor to see what "illness" I had contracted.

After listening to my list of physical complaints, the office nurse asked me if I might be pregnant. My eyes opened wide: I had somehow missed the link between my symptoms and pregnancy. I started to think about when my last period was, and it had been 2 months ago. The office ran a pregnancy test and much to my surprise it was positive!

Thoughts: Many women stop contraceptives in an attempt to achieve pregnancy but miss the early signs of pregnancy. This woman was experiencing several signs of early pregnancy—urinary frequency, fatigue, morning nausea, and breast tenderness. What advice can the nurse give this woman to ease these symptoms? What additional education related to her pregnancy would be appropriate at this time?

BOX 11.1
SIGNS AND SYMPTOMS OF PREGNANCY

Presumptive (Time of Occurrence)	Probable (Time of Occurrence)	Positive (Time of Occurrence)
Fatigue (12 wks) Breast tenderness (3–4 wks) Nausea and vomiting (4–14 wks) Amenorrhea (4 wks) Urinary frequency (6–12 wks) Hyperpigmentation of the skin (16 wks) Fetal movements (quickening; 16–20 wks) Uterine enlargement (7–12 wks) Breast enlargement (6 wks)	Braxton Hicks contractions (16–28 wks) Positive pregnancy test (4–12 wks) Abdominal enlargement (14 wks) Ballottement (16–28 wks) Goodell's sign (5 wks) Chadwick's sign (6–8 wks) Hegar's sign (6–12 wks)	Ultrasound verification of embryo or fetus (4–6 wks) Fetal movement felt by experienced clinician (20 wks) Auscultation of fetal heart tones via Doppler (10–12 wks)

Adapted from Bope, E. T., & Kellerman, R. D. (2015). *Conn's current therapy 2015*. Philadelphia, PA: Saunders Elsevier; Shields, A. D. (2015). Pregnancy diagnosis. *eMedicine*. Retrieved from http://emedicine.medscape.com/article/262591-overview; Jordan, R.G., Engstrom, J., Matrfell, J., & Farley, C. L. (2014). *Prenatal and postnatal care: A woman-centered approach*. Ames, IA: Wiley-Blackwell.

Presumptive changes are the least reliable indicators of pregnancy because any one of them can be caused by conditions other than pregnancy (Shields, 2015). For example, amenorrhea can be caused by early menopause, endocrine dysfunction, malnutrition, anemia, diabetes mellitus, long-distance running, cancer, or stress. Nausea and vomiting can be caused by gastrointestinal disorders, food poisoning, acute infections, or eating disorders. Fatigue could be caused by anemia, stress, or viral infections. Breast tenderness may result from chronic cystic mastitis, premenstrual changes, or the use of oral contraceptives. Urinary frequency could have a variety of causes other than pregnancy, such as infection, cystocele, structural disorders, pelvic tumors, or emotional tension (Tharpe, Farley, & Jordan, 2016).

Objective (Probable) Signs

Physical Signs

Probable signs of pregnancy are those that can be detected on physical examination by a health care provider. Common probable signs of pregnancy include softening of the lower uterine segment or isthmus (**Hegar's sign**), softening of the cervix (**Goodell's sign**), and a bluish-purple coloration of the vaginal mucosa and cervix (**Chadwick's sign**). Other probable signs include changes in the shape and size of the uterus, abdominal enlargement, Braxton Hicks contractions, and **ballottement** (the examiner pushes against the woman's cervix during a pelvic examination and feels a rebound from the floating fetus).

Pregnancy Tests

Along with these physical signs, pregnancy tests are also considered a probable sign of pregnancy. In-home pregnancy testing became available in the United States in late 1977. In-home testing appealed to the general public because of convenience, cost, and confidentiality. Several pregnancy tests are available (Table 11.1). The tests vary in sensitivity, specificity, and accuracy and are influenced by the length of gestation, specimen concentration, presence of blood, and the presence of some drugs. Human chorionic gonadotropin (hCG) is detectable in the serum of approximately 5% of clients 8 days after conception and in more than 98% of clients by day 11 (Shields, 2015). At least 25 different home pregnancy tests are currently marketed in the United States. Most of these tests claim "99% accuracy" according to a U.S. Food and Drug Administration (FDA) guideline or make other similar statements on the packaging or product insert. The 99% accuracy statement in reference to the FDA guideline is misleading in that it has no bearing on the ability of the home pregnancy test to detect early pregnancy (Shields, 2015). The limitations of these tests must be understood so that pregnancy detection is not delayed significantly. Early pregnancy detection allows for the commencement of prenatal care, potential medication changes, and lifestyle changes to promote a healthy pregnancy.

Human chorionic gonadotropin (hCG) is a glycoprotein and the earliest biochemical marker for pregnancy. Many pregnancy tests are based on the recognition of hCG or a beta subunit of hCG. hCG levels in normal pregnancy usually double every 48 to 72 hours until they peak approximately 60 to 70 days after fertilization. At this point, they decrease to a plateau at 100 to 130 days of pregnancy. The hCG doubling time has been used as a marker by clinicians to differentiate normal from abnormal gestations. Low levels are associated with an ectopic pregnancy and higher-than-normal levels may indicate a molar pregnancy or multiple-gestational pregnancies (Zinaman, Johnson, & Marriott, 2015).

TABLE 11.1 SELECTED PREGNANCY TESTS

Type	Specimen	Example	Remarks
Agglutination inhibition tests	Urine	Pregnosticon, Gravindex	If hCG is present in urine, agglutination does not occur, which is positive for pregnancy; reliable 14–21 days after conception; 95% accurate in diagnosing pregnancy
Immuno-radiometric assay	Blood serum	Neocept, Pregnosis	Measures ability of blood sample to inhibit the binding of radiolabeled hCG to receptors; reliable 6–8 days after conception; 99% accurate in diagnosing pregnancy
Enzyme-linked immunosorbent assay (ELISA)	Blood serum or urine	Over-the-counter home/office pregnancy tests; precise	Uses an enzyme to bond with hCG in the urine if present; reliable 4 days after implantation; 99% accurate if hCG specific

Take Note!

This elevation of hCG corresponds to the morning sickness period of approximately 6 to 12 weeks during early pregnancy.

Although probable signs suggest pregnancy and are more reliable than presumptive signs, they still are not 100% reliable in confirming a pregnancy. For example, uterine tumors, polyps, infection, and pelvic congestion can cause changes to uterine shape, size, and consistency. And although pregnancy tests are used to establish the diagnosis of pregnancy when the physical signs are still inconclusive, they are not completely reliable, because conditions other than pregnancy (e.g., ovarian cancer, choriocarcinoma, hydatidiform mole) can also elevate hCG levels.

Positive Signs

Usually within 2 weeks after a missed period, enough subjective symptoms are present so that a woman can be reasonably sure she is pregnant. However, an experienced health care provider can confirm her suspicions by identifying positive signs of pregnancy that can be directly attributed to the fetus. The positive signs of pregnancy confirm that a fetus is growing in the uterus. Visualizing the fetus by ultrasound, palpating for fetal movements, and hearing a fetal heartbeat are all signs that make the pregnancy a certainty.

If the pregnancy test is positive, the clinical visit should include an estimation of gestational age so that appropriate counseling can be provided. In addition, clients should receive information about the normal signs and symptoms of early pregnancy, and should be instructed to report any concerns to the health care provider for further evaluation. Once pregnancy has been confirmed, the health care provider will set up a schedule of prenatal visits to assess the woman and her fetus throughout the entire pregnancy. Assessment and education begins at the first visits and continues throughout the pregnancy (see Chapter 12).

Remember Marva, who thought she had a stomach virus? Her pregnancy test was positive. On questioning by the nurse, she acknowledged missing two menstrual periods and being sexually active with her boyfriend without using protection. What is the nurse's role at this point with Marva?

What instructions might be given to her while she waits for her first prenatal visit?

PHYSIOLOGIC ADAPTATIONS DURING PREGNANCY

Every system of a woman's body changes during pregnancy to accommodate the needs of the growing fetus, and these changes occur with startling rapidity. The physical changes of pregnancy can be uncomfortable, although every woman reacts uniquely.

Reproductive System Adaptations

Significant changes occur throughout the woman's body during pregnancy to accommodate the growing human being within her. Many have a protective role for maternal homeostasis and are essential to meet the demands of both the mother and the fetus. Many adaptations are reversible after the woman gives birth, but some persist for life.

Uterus

The uterus grows at a steady, predictable rate during pregnancy. During the first few months of pregnancy, estrogen stimulates uterine growth, and the uterus undergoes a tremendous increase in size, weight, length, width, depth, volume, and overall capacity throughout pregnancy. The weight of the uterus increases from 70 g to about 1,100 to 1,200 g at term; its capacity increases from 10 to 5,000 mL or more at term (King et al., 2015). The uterine walls thin to 1.5 cm or less; the shape changes from pear shape to a solid globe in the first trimester, and then expands to become a hollow vessel.

Uterine growth occurs as a result of both hyperplasia and hypertrophy of the myometrial cells, which do not increase much in number but do increase in size. In early pregnancy, uterine growth is due to hyperplasia of uterine smooth muscle cells within the myometrium; however, the major component of myometrial growth occurs after mid-gestation due to smooth muscle cell hypertrophy caused by mechanical stretch of uterine tissue by the growing fetus (Osol & Moore, 2014). Blood vessels elongate, enlarge, dilate, and sprout new branches to support and nourish the growing muscle tissue, and the increase in uterine weight is accompanied by a large increase in uterine blood flow, which is necessary to perfuse the uterine muscle and accommodate the growing fetus. As pregnancy progresses, 80% to 90% of uterine blood flow goes to the placenta, with the remainder distributed between the endometrium and myometrium. During pregnancy, the diameter of the main uterine artery approximately doubles in size. This enlargement from a narrow to a larger-caliber vessel enhances the capacity of the uteroplacental vessels to accommodate the increased blood volume needed to supply the placenta (Osol & Moore, 2014).

Uterine contractility is enhanced as well. Spontaneous, irregular, and painless contractions, called **Braxton Hicks contractions**, begin during the first trimester. These contractions continue throughout pregnancy, becoming especially noticeable during the last month, when they function to thin out or efface the cervix before birth (see Chapter 12 for more information).

The lower portion of the uterus (the isthmus) does not undergo hypertrophy and becomes increasingly thinner as pregnancy progresses, thereby forming the lower uterine segment. Changes in the lower uterus occurring during the first 6 to 8 weeks of gestation produce some of the typical findings, including a positive Hegar's sign. This softening and compressibility of the lower uterine segment results in exaggerated uterine anteflexion during the early months of pregnancy, which adds to urinary frequency (Heffner & Schust, 2014).

The uterus remains in the pelvic cavity for the first 3 months of pregnancy, after which it progressively ascends into the abdomen (Fig. 11.1). As the uterus grows, it presses on the urinary bladder and causes the increased frequency of urination experienced during early pregnancy. In addition, the heavy gravid uterus in the last trimester can fall back against the inferior vena cava in the supine position, resulting in vena cava compression, which reduces venous return and decreases cardiac output and blood pressure, with increasing orthostatic stress. This occurs when the woman changes her position from recumbent to sitting to standing. This acute hemodynamic change, termed supine hypotensive syndrome, causes the woman to experience symptoms of weakness, light-headedness, nausea, dizziness, or syncope (Fig. 11.2). These changes are reversed when the woman is in the side-lying position, which displaces the uterus to the left and off the vena cava.

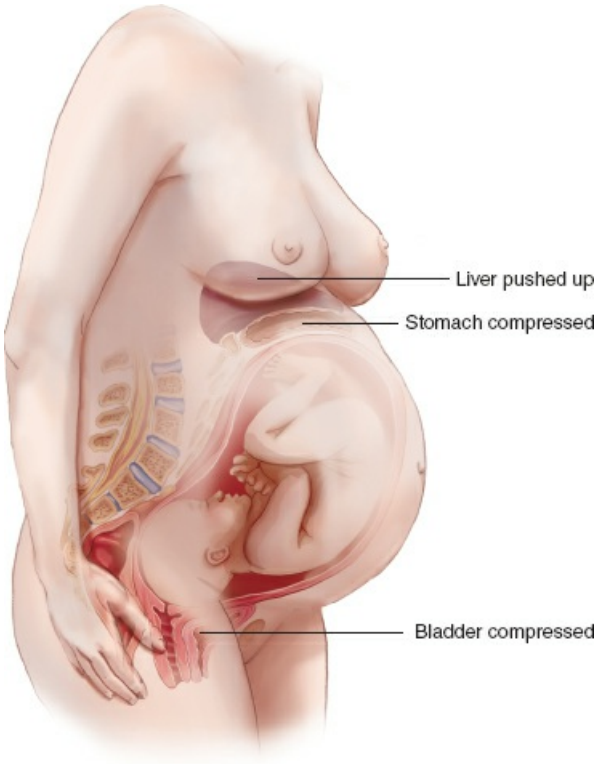

FIGURE 11.1 **The growing uterus in the abdomen.**

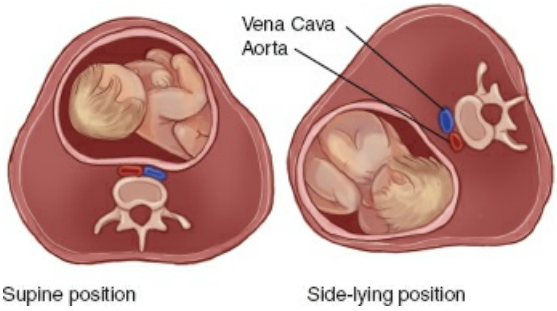

FIGURE 11.2 Supine hypotensive syndrome.

The uterus, which starts as a pear-shaped organ, becomes ovoid as length increases over width. By 20 weeks' gestation, the fundus, or top of the uterus, is at the level of the umbilicus and measures 20 cm. A monthly measurement of the height of the top of the uterus in centimeters, which corresponds to the number of gestational weeks, is commonly used to date the pregnancy.

Take Note!

Fundal height usually can be correlated with gestational weeks most accurately between 18 and 32 weeks. Obesity, hydramnios, and uterine fibroids interfere with the accuracy of this correlation.

The fundus reaches its highest level, at the xiphoid process, at approximately 36 weeks. Between 38 and 40 weeks, fundal height drops as the fetus begins to descend and engage into the pelvis. Because it pushes against the diaphragm, many women experience shortness of breath. By 40 weeks, the fetal head begins to descend and engage in the pelvis, which is termed *lightening.* For the woman who is pregnant for the first time, lightening usually occurs approximately 2 weeks before the onset of labor; for the woman who is experiencing her second or subsequent pregnancy, it usually occurs at the onset of labor. Although breathing becomes easier because of this descent, the pressure on the urinary bladder now increases and the woman now experiences urinary frequency again, as she did in the first trimester of pregnancy.

Cervix

Between weeks 6 and 8 of pregnancy, the cervix begins to soften (Goodell's sign) due to vasocongestion and the influence of estrogen. Along with the softening, the endocervical glands increase in size and number and produce more cervical mucus. Under the influence of progesterone, a thick mucus plug is formed that blocks the cervical os and protects the opening from bacterial invasion. At about the same time, increased vascularization of the cervix causes Chadwick's sign, a cyanosis or bluish purple discoloration Cervical ripening (softening, effacement, and increased distensibility) begins about 4 weeks before birth. The connective tissues of the cervix undergo biochemical modifications in preparation for labor that result in changes to its elasticity and strength. These changes are mediated through several factors, including inflammation, cervical stretch, pressure of the fetal presenting part, and release of hormones, including oxytocin, relaxin, nitric oxide, and prostaglandins (Myers et al., 2015).

Vagina

During pregnancy, vascularity increases because of the influences of estrogen,

resulting in pelvic congestion and hypertrophy of the vagina in preparation for the distention needed for birth. The vaginal mucosa thickens, the connective tissue begins to loosen, the smooth muscle begins to hypertrophy, and the vaginal vault begins to lengthen (Bope & Kellerman, 2015). Vaginal secretions become more acidic, white, and thick. Most women experience an increase in a whitish vaginal discharge, called leukorrhea, during pregnancy. This is normal except when it is accompanied by itching and irritation, possibly suggesting *Candida albicans,* a monilial vaginitis, which is a very common occurrence in this glycogen-rich environment (King et al., 2015). Symptomatic vulvovaginal candidiasis affects 15% of pregnant women (Krapf, 2015). It is a benign fungal condition that is uncomfortable for the woman and can be transmitted from an infected mother to her newborn at birth. Neonates develop an oral infection known as thrush, which presents as white patches on the mucous membranes of their mouths. It is self-limiting and is treated with local antifungal agents.

Ovaries

The increased blood supply to the ovaries causes them to enlarge until approximately the 12th to 14th week of gestation. The ovaries are not palpable after that time because the uterus fills the pelvic cavity. Ovulation ceases during pregnancy because of the elevated levels of estrogen and progesterone, which block secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior pituitary. The ovaries are very active in hormone production to support the pregnancy until about weeks 6 to 7, when the corpus luteum regresses and the placenta takes over the major production of progesterone.

Breasts

The breasts increase in fullness, become tender, and grow larger throughout pregnancy under the influence of estrogen and progesterone. The breasts become highly vascular, and veins become visible under the skin. The nipples become larger and more erect. Both the nipples and the areola become deeply pigmented, and tubercles of Montgomery (sebaceous glands) become prominent. These sebaceous glands keep the nipples lubricated for breast-feeding.

Changes that occur in the connective tissue of the breasts, along with the tremendous growth, lead to striae (stretch marks) in approximately half of all pregnant women (Jordan et al., 2014). Initially they appear as pink to purple lines on the skin, but they eventually fade to a silver color. Although they become less conspicuous in time, they never completely disappear.

Creamy, yellowish breast fluid called colostrum can be expressed by the third trimester. This fluid provides nourishment for the breast-feeding newborn during the first few days of life (see Chapters 15 and 16 for more information). Table 11.2 summarizes reproductive system adaptations.

General Body System Adaptations

In addition to changes in the reproductive system, the pregnant woman also experiences changes in virtually every other body system in response to the growing fetus.

Gastrointestinal System

The gastrointestinal system begins in the oral cavity and ends at the rectum. During pregnancy, the gums become hyperemic, swollen, and friable and tend to bleed easily. This change is influenced by estrogen and increased proliferation of blood vessels and circulation to the mouth. In addition, the saliva produced in the mouth becomes more acidic. Some women complain about excessive salivation, termed *ptyalism,* which may be caused by the decrease in unconscious swallowing by the woman when nauseated. Ptyalism typically resolves spontaneously, although in some women it endures throughout the pregnancy. Some women get temporary relief from gum chewing or sucking on hard candies (King et al., 2015). Dental plaque, calculus, and debris deposits increase during pregnancy and are all associated with gingivitis. An increased production of female hormones during pregnancy contributes to the development of gingivitis and periodontitis because vascular permeability and possible tissue edema are both increased. It is reported that as many as 50% to 70% of pregnant women will have some level of gingivitis during pregnancy as a result of hormonal changes that promote inflammation (Anil et al., 2015). Previous studies linked periodontal disease with preterm birth, preeclampsia, low–birth-weight risk, stillbirth, and early-onset neonatal sepsis, but more recent research findings indicated no reduction in preterm births with the treatment of periodontal disease during pregnancy (Trivedi, Lal, & Singhal, 2015).

TABLE 11.2 SUMMARY OF REPRODUCTIVE SYSTEM ADAPTATIONS

Reproductive Organ	Adaptations
Uterus	Size increases to 20 times that of nonpregnant size Capacity increases by 2,000 times to accommodate the developing fetus Weight increases from 2 oz to approximately 2 lb at term Uterine growth occurs as a result of both hyperplasia and hypertrophy of the myometrial cells Increased strength and elasticity allow uterus to contract and expel fetus during birth
Cervix	Increases in mass, water content, and vascularization Changes from a relatively rigid to a soft, distensible structure that allows the fetus to be expelled Under the influence of progesterone, a thick mucus plug is formed, which blocks the cervical os and protects the developing fetus from bacterial invasion
Vagina	Increased vascularity because of estrogen influences, resulting in pelvic congestion and hypertrophy Increased thickness of mucosa, along with an increase in vaginal secretions to prevent bacterial infections
Ovaries	Increased blood supply to the ovaries causes them to enlarge until approximately the 12th to 14th week of gestation. They actively produce hormones to support the pregnancy until weeks 6 to 7 when the placenta takes over the production of progesterone.
Breasts	Breast changes begin soon after conception; they increase in size and areolar pigmentation The tubercles of Montgomery enlarge and become more prominent, and the nipples become more erect The blood vessels become more prominent, and blood flow to the breast doubles

Concept Mastery Alert

Gum Fragility in Pregnancy

Bleeding of gums during pregnancy results from increased estrogen levels that cause blood vessel proliferation. This then leads to increased blood vessels in the gums and an increased chance of bleeding.

Smooth muscle relaxation and decreased peristalsis occur related to the influence of progesterone. Elevated progesterone levels cause smooth muscle relaxation, which results in delayed gastric emptying and decreased peristalsis. Transition time of food throughout the gastrointestinal tract may be so much slower that more water than normal is reabsorbed, leading to bloating and constipation. Constipation can also result from low-fiber food choices, reduced fluid intake, use of iron supplements, decreased activity level, and intestinal displacement secondary to a growing uterus. Constipation, increased venous pressure, and the pressure of the gravid uterus contribute to the formation of hemorrhoids.

The slowed gastric emptying combined with relaxation of the cardiac sphincter allows reflux, which causes heartburn. Acid indigestion or heartburn (pyrosis) seems to be a universal problem for pregnant women. It is caused by regurgitation of the stomach contents into the upper esophagus and may be associated with the generalized relaxation of the entire digestive system. Over-the-counter antacids will usually relieve the symptoms, but they should be taken with the health care provider's knowledge and only as directed.

The emptying time of the gallbladder is prolonged secondary to the smooth muscle relaxation from progesterone. Hypercholesterolemia can follow, increasing the risk of gallstone formation. Other risk factors for gallbladder disease include obesity, Hispanic ethnicity, and increasing maternal age (Heuman, Mihas, & Allen, 2015).

Nausea and vomiting, better known as morning sickness, plague about 80% of pregnant women. This condition is usually self-limiting, but the symptoms can be distressing and interfere with work, social activities, and interrupt sleep. Recently, the FDA approved doxylamine succinate 10 mg/pyridoxine hydrochloride 10 mg (Diclegis) as the first medication to specifically treat morning sickness in pregnancy (Pope, Maltepe, & Koren, 2015). Although it occurs most often in the morning, the nauseated feeling can last all day in some women. The highest incidence of morning sickness occurs between 6 and 12 weeks. The physiologic basis for morning sickness is still debatable. It has been linked to the high levels of hCG, high levels of circulating estrogens, prostaglandins, reduced stomach acidity, advancing maternal age, slowed peristalsis, genetic factors, and the lowered tone and motility of the digestive tract (King et al., 2015).

Cardiovascular System

Cardiovascular changes occur early during pregnancy to meet the demands of the enlarging uterus and the placenta for more blood and more oxygen. The changes include an increase in heart rate (25%); cardiac output increases by 30% to 50% and peaks at 25 to 30 weeks' gestation; reduced total peripheral resistance; increased blood volume; increased plasma volume which leads to physiologic anemia. Perhaps the most striking cardiac alteration occurring during pregnancy is the increase in blood volume.

BLOOD VOLUME

Blood volume increases by approximately 1,500 mL, or up to 50% above nonpregnant levels, by the 32nd week of gestation, and remains more or less constant thereafter (Foo et al., 2015). The increase is made up of 1,000 mL plasma

plus 450 mL red blood cells. It begins at weeks 10 to 12, peaks at weeks 32 to 34, and decreases slightly by week 40.

Take Note!

The rise in blood volume correlates directly with fetal weight, supporting the concept of the placenta as an arteriovenous shunt in the maternal vascular compartment.

This increase in blood volume is needed to provide adequate hydration of fetal and maternal tissues, to supply blood flow to perfuse the enlarging uterus, and to provide a reserve to compensate for blood loss at birth and during postpartum. The maternal blood volume expansion occurs at a larger proportion than the increase in red blood cell mass, which results in physiologic anemia and hemodilution. Criteria of physiologic anemia include hemoglobin 10 g or less, red blood cells 3.5 million/mm^3, and normal morphology with central pallor (Sabina et al., 2015). This increase is also necessary to meet the increased metabolic needs of the mother and to meet the need for increased perfusion of other organs, especially the woman's kidneys, because she is excreting waste products for herself and the fetus.

CARDIAC OUTPUT AND HEART RATE

Cardiac output, the product of stroke volume and heart rate, is a measure of the functional capacity of the heart. It increases from 30% to 50% over the nonpregnant rate by the 32nd week of pregnancy and declines to about a 20% increase at 40 weeks' gestation. The increase in cardiac output is associated with an increase in venous return and greater right ventricular output, especially in the left lateral position (Bope & Kellerman, 2015). Heart rate increases by 10 to 15 bpm between 14 and 20 weeks of gestation, and this persists to term. There is slight hypertrophy or enlargement of the heart during pregnancy. This is probably to accommodate the increase in blood volume and cardiac output. The heart works harder and pumps more blood to supply the oxygen needs of the fetus as well as those of the mother. Both heart rate and venous return are increased in pregnancy, contributing to the increase in cardiac output seen throughout gestation. A woman with preexisting heart disease may become symptomatic and begin to decompensate during the time the blood volume peaks. Close monitoring is warranted during 28 to 35 weeks' gestation.

BLOOD PRESSURE

Blood pressure, especially the diastolic pressure, declines slightly during pregnancy as a result of peripheral vasodilation caused by progesterone. It usually reaches a low point at midpregnancy and thereafter increases to prepregnancy levels until term. During the first trimester, blood pressure typically remains at the prepregnancy level. During the second trimester, the blood pressure decreases 5 to 10 mmHg and thereafter returns to first-trimester levels (Gaillard & Jaddoe, 2015). Any significant rise in blood pressure during pregnancy should be investigated to rule out gestational hypertension. Gestational hypertension is a clinical diagnosis defined by the new onset of hypertension (systolic of 140 mmHg or higher and/or diastolic of 90 mmHg or higher) after 20 weeks' gestation.

BLOOD COMPONENTS

The number of red blood cells also increases throughout pregnancy to a level 25% to 33% higher than nonpregnant values, depending on the amount of iron available. This increase is necessary to transport the additional oxygen required during pregnancy. Although there is an increase in red blood cells, there is a greater increase in the plasma volume as a result of hormonal factors and sodium and water retention. Because the plasma increase exceeds the increase of red blood cell production, normal hemoglobin and hematocrit values decrease. This state of hemodilution is referred to as **physiologic anemia of pregnancy**. Changes in red blood cell volume are due to increased circulating erythropoietin and accelerated red blood cell production. The rise in erythropoietin in the last two trimesters is stimulated by progesterone, prolactin, and human placental lactogen (Jones & Lopez, 2014).

Iron requirements during pregnancy increase because of the demands of the growing fetus and the increase in maternal blood volume. The fetal tissues prevail over the mother's tissues with respect to use of iron stores. With the accelerated production of red blood cells, iron is necessary for hemoglobin formation, the oxygen-carrying component of red blood cells.

Take Note!

Many women enter pregnancy with insufficient iron stores and thus need supplementation to meet the extra demands of pregnancy.

Both fibrin and plasma fibrinogen levels increase, along with various blood-clotting factors. These factors make pregnancy a hypercoagulable state. These changes, coupled with venous stasis secondary to venous pooling, which occurs during late pregnancy after long periods of standing in the upright position with the pressure exerted by the uterus on the large pelvic veins, contribute to slowed venous return, pooling, and dependent edema. These factors also increase the woman's risk for venous thrombosis (DeLoughery, 2015).

Respiratory System

The growing uterus and the increased production of the hormone progesterone cause the lungs to function differently during pregnancy. Oxygen consumption reflects the uptick of maternal metabolism by increasing between 20% and 30% by the time full term is reached. During pregnancy, the amount of space available to house the lungs decreases as the uterus puts pressure on the diaphragm and causes it to shift upward by 4 cm above its usual position. The growing uterus does change the size and shape of the thoracic cavity, but diaphragmatic excursion increases, chest circumference increases by 2 to 3 inches, and the transverse diameter increases by an inch, allowing a larger tidal volume, as evidenced by deeper breathing (tidal volume, or the volume of air inhaled, increases by 30% to 40% (from 500 to 700 mL) as the pregnancy progresses. This increase results in maternal hyperventilation and hypocapnia. As a result of these changes, the woman's breathing becomes more diaphragmatic than abdominal. Concomitant with the increase in tidal volume is a 30% to 40% increase in maternal oxygen consumption due to the increased oxygen requirements of the developing fetus, placenta, and maternal organs.

Anatomic and physiologic changes of pregnancy predispose the mother to increased morbidity and mortality and increase the risks of a less than optimal outcome for the fetus. The frequency and significance of acute and chronic respiratory conditions in pregnant women have increased in recent years. Because of these various changes, pregnant women with asthma, pneumonia, or other respiratory pathology are more susceptible to early decompensation (Mehta et al., 2015).

A pregnant woman breathes faster and more deeply because she and the fetus need more oxygen. Oxygen consumption increases during pregnancy even as airway resistance and lung compliance remain unchanged. Changes in the structures of the respiratory system take place to prepare the body for the enlarging uterus and increased lung volume (Alexander et al., 2014). As muscles and cartilage in the thoracic region relax, the chest broadens, with a conversion from abdominal breathing to thoracic breathing. This leads to a 50% increase in air volume per minute. All of these structural alterations are temporary and revert back to their prepregnant state at the end of the pregnancy.

Increased vascularity of the respiratory tract is influenced by increased estrogen levels, leading to congestion. Rising levels of sex hormones and heightened sensitivity to allergens may influence the nasal mucosa, precipitating epistaxis (nosebleed) and rhinitis. This congestion gives rise to nasal and sinus stuffiness and changes in the tone and quality of the woman's voice (Jordan et al., 2014).

Renal/Urinary System

Hormonal changes during pregnancy allow for increased blood flow to the kidneys. The renal system must handle the effects of increased maternal intravascular and extracellular volume and metabolic waste products as well as excretion of fetal wastes. The predominant structural change in the renal system during pregnancy is dilation of the renal pelvis and uterus. Changes in renal structure occur as a result of the hormonal influences of estrogen and progesterone, pressure from an enlarging uterus, and an increase in maternal blood volume. Like the heart, the kidneys work harder throughout the pregnancy. Changes in kidney function occur to accommodate a heavier workload while maintaining a stable electrolyte balance and blood pressure. As more blood flows to the kidneys, the glomerular filtration rate (GFR) increases, leading to an increase in urine flow and volume, substances delivered to the kidneys, and filtration and excretion of urea, uric acid, creatinine, water and solutes (Cox & Reid, 2015).

Anatomically, the kidneys enlarge during pregnancy. Each kidney increases in length by approximately 1 to 1.5 cm and weight as a result of hormonal effects that cause increased tone and decreased motility of the smooth muscle. The renal pelvis becomes dilated. The ureters (especially the right ureter) elongate, widen, and become more curved above the pelvic rim as early as the 10th gestational week (Thadhani & Maynard, 2015). Progesterone is thought to cause both of these changes because of its relaxing influence on smooth muscle.

Blood flow to the kidneys increases by 50% to 80% as a result of the increase in cardiac output and relaxin, which causes a decrease in both efferent and afferent resistance. This in turn leads to an increase in the GFR by as much as 40% to 60% starting during the second trimester, resulting in hyperfiltration. This elevation continues until birth. This change has important clinical implications for medication

use because renally excreted drugs may require higher doses and more frequent administration for therapeutic blood levels during pregnancy (Larson, 2015).

The activity of the kidneys normally increases when a person lies down and decreases on standing. This difference is amplified during pregnancy, which is one reason a pregnant woman feels the need to urinate frequently while trying to sleep. Late in the pregnancy, the increase in kidney activity is even greater when the woman lies on her side rather than her back. Lying on either side relieves the pressure that the enlarged uterus puts on the vena cava carrying blood from the legs. Subsequently, venous return to the heart increases, leading to increased cardiac output. Increased cardiac output results in increased renal perfusion and glomerular filtration. As a rule, all the physiologic changes maximize by the end of the second trimester and then start to return to the prepregnant level. However, changes in the anatomy take up to 3 months postpartum to subside (King et al., 2015).

Musculoskeletal System

Changes in the musculoskeletal system are progressive, resulting from the influence of hormones, fetal growth, and maternal weight gain. Pregnancy is characterized by changes in posture and gait. By the 10th to 12th week of pregnancy, the ligaments that hold the sacroiliac joints and the pubis symphysis in place begin to soften and stretch, and the articulations between the joints widen and become more movable (Bope & Kellerman, 2015). The relaxation of the joints peaks by the beginning of the third trimester. The purpose of these changes is to increase the size of the pelvic cavity and to make delivery easier.

The postural changes of pregnancy—an increased swayback and an upper spine extension to compensate for the enlarging abdomen—coupled with the loosening of the sacroiliac joints may result in lower back pain. The woman's center of gravity shifts forward, requiring a realignment of the spinal curvatures. Factors thought to contribute to these postural changes include the alteration to the center of gravity that come with pregnancy, the influence of the pregnancy-related hormone relaxin on the pelvic joints, and the increasing weight and position of the growing fetus.

An increase in the normal lumbosacral curve (lordosis) occurs and a compensatory curvature in the cervicodorsal area develops to assist her in maintaining her balance (Fig. 11.3). In addition, relaxation and increased mobility of joints occur because of the hormones progesterone and relaxin, which lead to the characteristic "waddle" gait that pregnant women demonstrate toward term. Increased weight gain can add to this discomfort by accentuating the lumbar and dorsal curves (Kouhkan et al., 2015).

Integumentary System

There are a variety of skin changes that are associated with pregnancy. Increased activity of the maternal adrenal and pituitary glands, along with a contribution for the developing fetal endocrine glands, increasing cortisone levels, accelerated metabolism, and enhanced production of progesterone and estrogenic hormones are responsible for most skin changes in pregnancy (Tyler, 2015). Up to 90% of pregnant women will show signs of hyperpigmentation during pregnancy, and it is typically generalized and mild. The skin of pregnant women undergoes hyperpigmentation primarily as a result of estrogen, progesterone, and melanocyte-stimulating hormone levels. These changes are mainly seen on the nipples, areola,

umbilicus, perineum, and axilla. Although many integumentary changes disappear after giving birth, some only fade. Many pregnant women express concern about stretch marks, skin color changes, and hair loss. Unfortunately, little is known about how to avoid these changes.

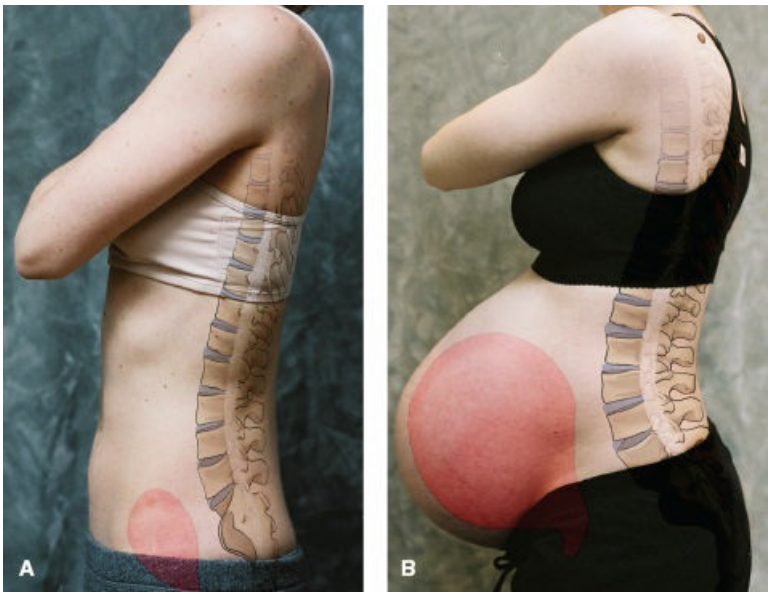

FIGURE 11.3 **Postural changes during (A) the first trimester and (B) the third trimester.**

Complexion changes are not unusual. The increased pigmentation that occurs on the breasts and genitalia also develops on the face to form the "mask of pregnancy," which is also called facial melasma. It occurs in up to 70% of pregnant women. There is a genetic predisposition toward melasma, which is exacerbated by the sun, and it tends to recur in subsequent pregnancies. This blotchy, brownish pigment covers the forehead and cheeks in dark-haired women. Most facial pigmentation fades as the hormones subside at the end of the pregnancy, but some may linger. The skin in the middle of the abdomen may develop a pigmented line called **linea nigra**, which extends from the umbilicus to the pubic area (Fig. 11.4).

FIGURE 11.4 **Linea nigra.**

Striae gravidarum, or stretch marks, are irregular reddish streaks that appear on the abdomen, breasts, and buttocks in up to 90% of pregnant women. Striae are most prominent by 6 to 7 months. They result from genetics, reduced connective tissue strength resulting from the elevated adrenal steroid levels, and stretching of the structures secondary to growth (Tyler, 2015). They are more common in younger women, women with larger infants, and women with higher body mass indices. Nonwhites and women with a history of breast or thigh striae or a family history of striae gravidarum also are at higher risk. Several creams and lotions such as cocoa butter and olive oil have been touted as being able to prevent striae gravidarum, but research currently doesn't validate these claims. A study done by Tretti Clementoni and Lavagno (2015) did find that laser treatments did improve pigmentation, volume, and textural appearance of striae gravidarum in >50% of the women enrolled in the study.

Vascular-Related Skin Changes

Vascular changes during pregnancy manifested in the integumentary system include varicosities of the legs, vulva, and perineum. Varicose veins commonly are the result of distention, instability, and poor circulation secondary to prolonged standing or sitting and the heavy gravid uterus placing pressure on the pelvic veins, preventing complete venous return. Interventions to reduce the risk of developing varicosities include:

- Elevating both legs when sitting or lying down
- Avoiding prolonged standing or sitting; changing position frequently
- Resting in the left lateral position
- Walking daily for exercise
- Avoiding tight clothing or knee-high hosiery
- Wearing support hose if varicosities are a preexisting condition to pregnancy

Another skin manifestation, believed to be secondary to vascular changes and high estrogen levels, is the appearance of small blood vessels called vascular spiders. They may appear on the neck, thorax, face, and arms. They are especially obvious in White women and typically disappear after childbirth. Palmar erythema is a well-delineated pinkish area on the palmar surface of the hands. This integumentary change is also related to elevated estrogen levels (Trupin, 2015).

Hair and Nails

Some women also notice a decline in hair growth during pregnancy. The hair follicles normally undergo a growing and resting phase. The resting phase is followed by a loss of hair; the hairs are then replaced by new ones. During pregnancy, fewer hair follicles go into the resting phase. After delivery, the body catches up with subsequent hair loss for several months. Nails typically grow faster during pregnancy. Pregnant women may experience increased brittleness, distal separation of the nail bed, whitish discoloration, and transverse grooves on the nails, but most of these conditions resolve in the postpartum period (King et al., 2015).

Endocrine System

The endocrine system undergoes many changes during pregnancy because hormonal changes are essential in meeting the needs of the growing fetus. Hormonal changes play a major role in controlling the supplies of maternal glucose, amino acids, and lipids to the fetus. Although estrogen and progesterone are the main hormones involved in pregnancy changes, other endocrine glands and hormones also change during pregnancy.

THYROID GLAND

The thyroid gland enlarges slightly and becomes more active during pregnancy as a result of increased vascularity and hyperplasia. Increased gland activity results in an increase in thyroid hormone secretion starting during the first trimester; levels taper off within a few weeks after birth and return to normal limits. Maternal thyroid hormone is transferred to the fetus beginning soon after conception and is critical for fetal brain development, neurogenesis, and organizational processes prior to 20 weeks when fetal thyroid production is low. However, even after the fetal thyroid is producing increasing amounts of hormone, much of the thyroxin (T_4) needed for development continues to be provided by the mother. Low maternal thyroid levels with thyroid insufficiency, hypothyroidism, or low or inadequate iodine intake may compromise fetal neurologic development (Pearce, 2015). With an increase in the secretion of thyroid hormones, the basal metabolic rate (the amount of oxygen consumed by the body over a unit of time in milliliters per minute) progressively increases by 25%, along with heart rate and cardiac output (Medici et al., 2015).

PITUITARY GLAND

During pregnancy, major endocrine and metabolic alterations occur due to the physiologic hormonal secretion from the placenta. The pituitary gland adapts to these changes and all secretory axes are affected. During pregnancy, the pituitary gland enlarges; it returns to normal size after birth.

The anterior lobe of the pituitary is glandular tissue and produces multiple hormones. The release of these hormones is regulated by releasing and inhibiting hormones produced by the hypothalamus. Some of these anterior pituitary hormones induce other glands to secrete their hormones. The increase in blood levels of the hormones produced by the final target glands (e.g., the ovary or thyroid) inhibits the release of anterior pituitary hormones. Changes in levels of pituitary hormones are discussed in the following paragraphs.

FSH and LH secretion are inhibited during pregnancy, probably as a result of hCG produced by the placenta and corpus luteum, and the increased secretion of prolactin by the anterior pituitary gland. Levels remain decreased until after delivery.

Thyroid-stimulating hormone (TSH) is reduced during the first trimester but usually returns to normal for the remainder of the pregnancy. Decreased TSH is thought to be one of the factors, along with elevated hCG levels, associated with morning sickness, nausea, and vomiting during the first trimester.

Growth hormone (GH) is an anabolic hormone that promotes protein synthesis. It stimulates most body cells to grow in size and divide, facilitating the use of fats for fuel and conserving glucose. During pregnancy, there is a decrease in the number of GH-producing cells and a corresponding decrease in GH blood levels. The action of human placental lactogen (hPL) is thought to decrease the need for and use of GH.

During pregnancy, prolactin is secreted in pulses and increases 10-fold to promote breast development and the lactation process. High levels of progesterone secreted by the placenta inhibit the direct influence of prolactin on the breast during pregnancy, thus suppressing lactation. At birth, as soon as the placenta is expelled and there is a drop in progesterone, lactogenesis can begin. Prolactin, released from the anterior pituitary gland in response to suckling by the newborn is the major hormonal signal responsible for stimulation in the breasts (Crowley, 2015).

Melanocyte-stimulating hormone (MSH), another anterior pituitary hormone, increases during pregnancy. For many years, its increase was thought to be responsible for many of the skin changes of pregnancy, particularly changes in skin pigmentation (e.g., darkening of the areola, melasma, and linea nigra). However, currently it is thought that the skin changes are due to estrogen (and possibly progesterone) as well as the increase in MSH.

The two hormones oxytocin and antidiuretic hormone (ADH) released by the posterior pituitary are actually synthesized in the hypothalamus. They migrate along nerve fibers to the posterior pituitary and are stored until stimulated to be released into the general circulation. Oxytocin is released by the posterior pituitary gland, and its production gradually increases as the fetus matures (Kim, Bennett, & Terzidou, 2015). Oxytocin is responsible for uterine contractions, both before and after delivery. The muscle layers of the uterus (myometrium) become more sensitive to oxytocin near term. Toward the end of a term pregnancy, levels of progesterone decline and contractions that were previously suppressed by progesterone begin to occur more frequently and with stronger intensity. This change in the hormonal levels is believed to be one of the initiators of labor.

Oxytocin is responsible for stimulating the uterine contractions that bring about delivery. Contractions lead to cervical thinning and dilation. They also exert pressure, helping the fetus to descend in the pelvis for eventual delivery. After delivery, oxytocin secretion continues, causing the myometrium to contract and helping to constrict the uterine blood vessels, decreasing the amount of vaginal bleeding after delivery. Oxytocin is also responsible for milk ejection during breast-feeding. Stimulation of the breasts through sucking or touching stimulates the secretion of oxytocin from the posterior pituitary gland. Oxytocin causes contraction of the myoepithelial cells in the lactating mammary gland.

Women experience cramping pain and discomfort following childbirth as the uterus contracts and returns to its prepregnant size. These after pains are caused by involuntary contractions and usually last for a few days after childbirth. They are more evident in women who have previously had a baby. Breastfeeding, signals the release of oxytocin, which stimulates the uterus to contract and increases the severity of after birth pains.

Vasopressin, also known as antidiuretic hormone (ADH) functions to inhibit or prevent the formation of urine via vasoconstriction, which results in increased blood pressure. Vasopressin also exhibits an antidiuretic effect and plays an important role in the regulation of water balance (Cheng, 2015).

PANCREAS

The pancreas is an exocrine organ, supplying digestive enzymes and buffers, and an endocrine organ. The endocrine pancreas consists of the islets of Langerhans, which are groups of cells scattered throughout, each containing four cell types. One of the

cell types is the beta cell, which produces insulin. Insulin lowers blood glucose by increasing the rate of glucose uptake and utilization by most body cells. The growing fetus needs significant amounts of glucose, amino acids, and lipids. Even during early pregnancy the fetus makes demands on the maternal glucose stores. Ideally, hormonal changes of pregnancy help meet fetal needs without putting the mother's metabolism out of balance.

A woman's insulin secretion works on a supply versus demand mode. As the demand to meet the needs of pregnancy increases, more insulin is secreted. Maternal insulin does not cross the placenta, so the fetus must produce his or her own supply to maintain glucose control. (Box 11.2 gives information about pregnancy, glucose, and insulin.)

Maternal glucose metabolism during pregnancy differs from the nongravid state to allow the mother to meet her own and the growing fetus's energy needs. During the first half of pregnancy, much of the maternal glucose is diverted to the growing fetus, and thus the mother's glucose levels are low. Human placental lactogen and other hormonal antagonists increase during the second half of pregnancy. Therefore, the mother must produce more insulin to overcome the resistance by these hormones. Insulin resistance (the inability of insulin to increase glucose uptake and utilization) in pregnancy is consequent to the physiologic adaptation necessary to provide glucose to the growing fetus. Disturbance in the maternal metabolism can induce structural and functional adaptations during fetal development (Nas, Breyer, & Tuu, 2015).

BOX 11.2

PREGNANCY, INSULIN, AND GLUCOSE

- During early pregnancy, maternal glucose levels decrease because of the heavy fetal demand for glucose. The fetus is also drawing amino acids and lipids from the mother, decreasing the mother's ability to synthesize glucose. Maternal glucose is diverted across the placenta to assist the growing embryo/fetus during early pregnancy, and thus levels decline in the mother. As a result, maternal glucose concentrations decline to a level that would be considered "hypoglycemic" in a nonpregnant woman.
- During early pregnancy there is also a decrease in maternal insulin production and insulin levels. The pancreas is responsible for the production of insulin, which facilitates entry of glucose into cells. Although glucose and other nutrients easily cross the placenta to the fetus, insulin does not. Therefore, the fetus must produce its own insulin to facilitate the entry of glucose into its own cells.
- After the first trimester, hPL from the placenta and steroids (cortisol) from the adrenal cortex act against insulin. hPL acts as an antagonist against maternal insulin, and thus more insulin must be secreted to counteract the increasing levels of hPL and cortisol during the last half of pregnancy.
- Prolactin, estrogen, and progesterone are also thought to oppose insulin. As a result, glucose is less likely to enter the mother's cells and is more likely to cross over the placenta to the fetus.

Adapted from Cunningham, F. G., Leveno, K. J., Bloom, S. L., Spong, C. Y., Dashe, J. S., Hoffman, B. L., et al. (2014). *William's Obstetrics* (24th ed.). New York, NY: McGraw Hill Education.

If the mother has normal beta cells of the islets of Langerhans, there is usually no problem meeting the demands for extra insulin. However, if the woman has inadequate numbers of beta cells, she may be unable to produce enough insulin and will develop glucose intolerance during pregnancy. If the woman has glucose intolerance, she is not able to meet the increasing demands and her blood glucose level increases.

ADRENAL GLANDS

Pregnancy does not cause much change in the size of the adrenal glands themselves, but there are changes in some secretions and activity. One of the key changes is the marked increase in cortisol secretion, which regulates carbohydrate and protein metabolism and is helpful in times of stress. Although pregnancy is considered a normal condition, it is a time of stress for a woman's body. The rate of secretion of cortisol by maternal adrenals is not increased in pregnancy, but the rate of clearance is decreased. Cortisol increases in response to increased estrogen levels throughout pregnancy and returns to normal levels within 6 weeks postpartum (Banerjee & Williamson, 2015). During the stress of pregnancy, cortisol:

- Helps keep up the level of glucose in the plasma by breaking down noncarbohydrate sources, such as amino and fatty acids, to make glycogen. Glycogen, stored in the liver, is easily broken down to glucose when needed so that glucose is available in times of stress
- Breaks down proteins to repair tissues and manufacture enzymes
- Has anti-insulin, anti-inflammatory, and antiallergic actions
- Is needed to make the precursors of adrenaline, which the adrenal medulla produces and secretes (Jones & Lopez, 2014)

The amount of aldosterone, also secreted by the adrenal glands, is increased during pregnancy. It normally regulates absorption of sodium from the distal tubules of the kidney. During pregnancy, progesterone allows salt to be wasted (or lost) in the urine. Aldosterone is a key regulator of electrolyte and water homeostasis and plays a central role in blood pressure regulation. Hormonal changes during pregnancy, among them increased progesterone and aldosterone production, lead to the required plasma volume expansion of the maternal body as an accommodation mechanism for fetus growth. Aldosterone is produced in increased amounts by the adrenal glands as early as 15 weeks of pregnancy (Rossier, Baker, & Studer, 2015).

PROSTAGLANDIN SECRETION DURING PREGNANCY

Prostaglandins are not protein or steroid hormones; they are chemical mediators, or local hormones. Although hormones circulate in the blood to influence distant tissues, prostaglandins act locally on adjacent cells. The fetal membranes of the amniotic sac—the amnion and chorion—are both believed to be involved in the production of prostaglandins. Various maternal and fetal tissues, as well as the amniotic fluid itself, are considered to be sources of prostaglandins, but details about their composition and sources are limited. It is widely believed that

prostaglandins play a part in softening the cervix and initiating and/or maintaining labor, but the exact mechanism is unclear. What is theorized is that when progesterone levels drop at term, an increased production of prostaglandins occurs, which facilitates uterine contractions and increases myometrial sensitivity to oxytocin that is needed for the labor process (King et al., 2015). Along with oxytocin, the influence of prostaglandins on the uterine myometrium predominates to promote uterine contractile activity.

PLACENTAL SECRETION

The placenta is an organ that serves to prevent the direct exchange between the blood of the fetus and the blood of the mother. The placenta is not only a transfer organ but a factory as well. It is capable of synthesizing enzymes and proteins, and manufactures fats and carbohydrates that serve as a source of stored energy. The placenta also functions as an endocrine gland, manufacturing and secreting hormones. The placenta has a feature possessed by no other endocrine organ—the ability to form protein and steroid hormones. Very early during pregnancy, the placenta begins to produce the following hormones:

- hCG
- hPL
- Relaxin
- Progesterone
- Estrogen

Table 11.3 summarizes the role of these hormones.

Immune System

The immune system is made up of organs and specialized cells whose primary purpose is to defend the body from foreign substances (antigens) that may cause tissue injury or disease. The mechanisms of innate and adaptive immunity work cooperatively to prevent, control, and eradicate foreign antigens in the body.

A general enhancement of innate immunity (inflammatory response and phagocytosis) and suppression of adaptive immunity (protective response to a specific foreign antigen) take place during pregnancy. These immunologic alterations help prevent the mother's immune system from rejecting the fetus (foreign body), increase her risk of developing certain infections such as urinary tract infections, and influence the course of chronic disorders such as autoimmune diseases. Some chronic conditions worsen (diabetes) while others seem to stabilize (asthma) during pregnancy, but this is individualized and not predictable. In general, immune function in pregnant women is similar to immune function in nonpregnant women. Table 11.4 summarizes the general body systems' adaptations to pregnancy.

***Marva* returns for her first prenatal appointment and tells the nurse that her whole body is "out of sorts." She is overwhelmed and feels poorly. Outline the bodily changes Marva can expect each trimester to help her understand the adaptations taking place. What guidance can the nurse give Marva to help her understand the changes of pregnancy?**

TABLE 11.3 PLACENTAL HORMONES

Hormone	Description
Human chorionic gonadotropin (hCG)	• Responsible for maintaining the maternal corpus luteum, which secretes progesterone and estrogens, with synthesis occurring before implantation • Production by fetal trophoblast cells until the placenta is developed sufficiently to take over that function • Basis for early pregnancy tests because it appears in the maternal bloodstream soon after implantation • Production peaks at 8 weeks and then gradually declines
hPL (also known as human chorionic somatomammotropin [hCS])	• Preparation of mammary glands for lactation and involved in the process of making glucose available for fetal growth by altering maternal carbohydrate, fat, and protein metabolism • Antagonist of insulin because it decreases tissue sensitivity or alters the ability to use insulin • Increase in the amount of circulating free fatty acids for maternal metabolic needs and decrease in maternal metabolism of glucose to facilitate fetal growth
Relaxin	• Secretion by the placenta as well as the corpus luteum during pregnancy • Thought to act synergistically with progesterone to maintain pregnancy • Increase in flexibility of the pubic symphysis, permitting the pelvis to expand during delivery • Dilation of the cervix, making it easier for the fetus to enter the vaginal canal; thought to suppress the release of oxytocin by the hypothalamus, thus delaying the onset of labor contractions
Progesterone	• Often called the "hormone of pregnancy" because of the critical role it plays in supporting the endometrium of the uterus • Supports the endometrium to provide an environment conducive to fetal survival • Produced by the corpus luteum during the first few weeks of pregnancy and then by the placenta until term • Initially, causes thickening of the uterine lining in anticipation of implantation of the fertilized ovum. From then on, it maintains the endometrium, inhibits uterine contractility, and assists in the development of the breasts for lactation
Estrogen	• Promotes enlargement of the genitals, uterus, and breasts, and increases vascularity, causing vasodilatation • Relaxation of pelvic ligaments and joints • Associated with hyperpigmentation, vascular changes in the skin, increased activity of the salivary glands, and hyperemia of the gums and nasal mucous membranes • Aids in developing the ductal system of the breasts in preparation for lactation

CHANGING NUTRITIONAL NEEDS OF PREGNANCY

Maternal body weight and diet quality, even prepregnancy, can affect the uterine environment, birth weight, and the infant's subsequent health into adulthood. Healthy eating during pregnancy enables optimal gestational weight gain and reduces complications, both of which are associated with positive birth outcomes. During pregnancy, maternal nutritional needs change to meet the demands of the pregnancy. Healthy eating can help ensure that adequate nutrients are available for both mother and fetus.

Nutritional intake during pregnancy has a direct effect on fetal well-being and birth outcome. Inadequate nutritional intake, for example, is associated with preterm birth, low birth weight, and congenital anomalies. Excessive nutritional intake is connected with fetal macrosomia (>4,000 g), leading to a difficult birth, neonatal hypoglycemia, and continued obesity in the mother and the potential for childhood obesity and the components of metabolic syndrome (Ojha et al., 2015).

Since the requirements for so many nutrients increase during pregnancy, pregnant women should take a vitamin and mineral supplement daily. Prenatal vitamins are

prescribed routinely as a safeguard against a less-than-optimal diet. In particular, iron and folic acid need to be supplemented because their increased requirements during pregnancy are usually too great to be met through diet alone. With the exception of folic acid, there is little scientific evidence to support giving vitamin supplements to healthy pregnant women, but it seems to be a standard of care today. Prenatal vitamins are prescribed in the United States almost universally (Jordan et al., 2014). Iron and folic acid are needed to form new blood cells for the expanded maternal blood volume and to prevent anemia. Iron is essential for fetal growth and brain development and in the prevention of maternal anemia. An increase in folic acid is essential before pregnancy and in the early weeks of pregnancy to prevent neural tube defects in the fetus. For most pregnant women, supplements of 27 mg of ferrous iron and 400 to 800 mcg of folic acid per day are recommended by the **dietary reference intakes (DRIs)** (American College of Obstetricians and Gynecologists [ACOG], 2015a; Hankey, 2015; U.S. Preventive Services Task Force [USPSTF], 2015). Women with a previous history of a fetus with a neural tube defect are often prescribed a higher dose of folic acid.

TABLE 11.4 SUMMARY OF GENERAL BODY SYSTEM ADAPTATIONS

System	Adaptation
Gastrointestinal system	*Mouth and pharynx:* Gums become hyperemic, swollen, and friable and tend to bleed easily. Saliva production increases. *Esophagus:* Decreased lower esophageal sphincter pressure and tone, which increases the risk of developing heartburn. *Stomach:* Decreased tone and mobility with delayed gastric emptying time, which increases the risk of gastroesophageal reflux and vomiting; decreased gastric acidity and histamine output, which improves symptoms of peptic ulcer disease. *Intestines:* Decreased intestinal tone motility with increased transit time, which increases risk of constipation and flatulence. *Gallbladder:* Decreased tone and motility, which may increase risk of gallstone formation.
Cardiovascular system	*Blood volume:* Marked increase in plasma (50%) and RBCs (25–33%) compared to nonpregnant values; causes hemodilution, which is reflected in a lower hematocrit and hemoglobin. *Cardiac output and heart rate:* CO increases from 30–50% over the nonpregnant rate by the 32nd week of pregnancy. The increase in CO is associated with an increase in venous return and greater right ventricular output, especially in the left lateral position. Heart rate increases by 10–15 bpm between 14 and 20 weeks of gestation, and this increase will persist to term. *Blood pressure:* Diastolic pressure decreases typically 10–15 mmHg to reach its lowest point by mid-pregnancy; it then gradually returns to nonpregnant baseline values by term. *Blood components:* The number of RBCs increases throughout pregnancy to a level 25–33% higher than nonpregnant values. Both fibrin and plasma fibrinogen levels increase, along with various blood-clotting factors. These factors make pregnancy a hypercoagulable state.
Respiratory system	Enlargement of the uterus shifts the diaphragm up to 4 cm above its usual position. As muscles and cartilage in the thoracic region relax, the chest broadens, with conversion from abdominal breathing to thoracic breathing. This leads to a 50% increase in air volume per minute. Tidal volume, or the volume of air inhaled, increases gradually by 30–40% (from 500 to 700 mL) as the pregnancy progresses.

Renal/urinary system	The renal pelvis becomes dilated. The ureters (especially the right ureter) elongate, widen, and become more curved above the pelvic rim. Bladder tone decreases and bladder capacity doubles by term. GFR increases 40–60% during pregnancy. Blood flow to the kidneys increases by 50–80% as a result of the increase in cardiac output.
Musculoskeletal system	Distention of the abdomen with growth of the fetus tilts the pelvis forward, shifting the center of gravity. The woman compensates by developing an increased curvature (lordosis) of the spine. Relaxation and increased mobility of joints occur because of the hormones progesterone and relaxin, which lead to the characteristic "waddle gait" that pregnant women demonstrate toward term.
Integumentary system	Hyperpigmentation of the skin is the most common alteration during pregnancy. The most common areas include the areola, genital skin, axilla, inner aspects of the thighs, and linea nigra. Striae gravidarum, or stretch marks, are irregular reddish streaks that may appear on the abdomen, breasts, and buttocks in about half of pregnant women. The skin in the middle of the abdomen may develop a pigmented line called linea nigra, which extends from the umbilicus to the pubic area. Melasma ("mask of pregnancy") occurs in up to 70% of pregnant women. It is characterized by irregular, blotchy areas of pigmentation on the face, most commonly on the cheeks, chin, and nose.
Endocrine system	Controls the integrity and duration of gestation by maintaining the corpus luteum via hCG secretion; production of estrogen, progesterone, hPL, and other hormones and growth factors via the placenta; release of oxytocin (by the posterior pituitary gland), prolactin (by the anterior pituitary), and relaxin (by the ovary, uterus, and placenta).
Immune system	A general enhancement of innate immunity (inflammatory response and phagocytosis) and suppression of adaptive immunity (protective response to a specific foreign antigen) take place during pregnancy. These immunologic alterations help prevent the mother's immune system from rejecting the fetus (foreign body), increase her risk of developing certain infections, and influence the course of chronic disorders such as autoimmune diseases.

There is an abundance of conflicting advice about nutrition during pregnancy and what is good or bad to eat. Overall, the following guidelines are helpful:

- Increase consumption of fruits and vegetables.
- Replace saturated fats with unsaturated ones.
- Make half the plate fruits and vegetables.
- Choose whole grains in place of refined grains.
- Choose foods with a lot of fiber to prevent constipation.
- Avoid hydrogenated or partially hydrogenated fats.
- Do not consume any alcoholic beverages.
- Use reduced-fat spreads and dairy products instead of full-fat ones.
- Eat at least two servings of fish weekly, with one of them being an oily fish.
- Consume at least 2 quarts of water daily (U.S. Department of Agriculture [USDA], 2015).

In the months before conception, food choices are key. The foods and vitamins consumed can ensure that the woman and her fetus will have the nutrients that are essential for the very start of pregnancy.

While most women recognize the importance of healthy eating during pregnancy, some find it challenging to achieve. Many women say they have little time and energy to devote to meal planning and preparation. Another barrier to healthy eating is conflicting messages from various sources, resulting in a lack of clear, reliable, and relevant information. Moreover, many women are eating less in an effort to control their weight, putting them at greater risk of inadequate nutrient intake.

Nutritional Requirements During Pregnancy

Pregnancy is one of the most nutritionally demanding periods of a woman's life. Gestation involves rapid cell division and organ development, and an adequate supply of nutrients is essential to support this tremendous fetal growth. Optimal maternal health via good nutritional practices during pregnancy reduces the risk of suboptimal fetal development.

Most women are usually motivated to eat properly during pregnancy for the sake of the fetus. The Food and Nutrition Board of the National Research Council has made recommendations for nutrient intakes for people living in the United States. The DRIs are more comprehensive than previous nutrient guidelines issued by the Board. They have replaced previous recommendations because they are not limited to preventing deficiency diseases. Rather, the DRIs incorporate current concepts about the role of nutrients and food components in reducing the risk of chronic disease, developmental disorders, and other related problems. The DRIs can be used to plan and assess diets for healthy people (Kruger & Butte, 2015).

These dietary recommendations also include information for women who are pregnant or lactating, because growing fetal and maternal tissues require increased quantities of essential dietary components. For example, the current DRIs suggest an increase in the pregnant woman's intake of protein from 60 to 80 g/day, iron from 18 to 27 g/day, and folic acid from 400 to 800 mcg/day, along with an increase of 300 calories/day over the recommended intake of 1,800 to 2,200 calories/day for nonpregnant women (Walsh & McAuliffe, 2015; Storck, 2015) (Table 11.5).

Gluten Free Diet During Pregnancy

In recent years, gluten free foods have become popular, fueling a growing market for the Food Industry. Pregnant women may be missing out on important nutrients if they adopt gluten-free diets as many are also joining the ever-expanding "G-free" bandwagon. Many people feel that these products are healthier than their conventional counterparts. But is it really a health-promotion diet or just another trend during pregnancy? Gluten may have gotten its bad rap because it is frequently found in many processed, unhealthy foods. Several gluten free foods contain more fat, including saturated, and sodium, but fewer minerals and vitamins than their equivalents with gluten (Pellegrini & Agostoni, 2015). Skipping processed foods altogether and focusing on fruits, vegetables, lean protein, and whole grains would provide a well-balanced healthy diet.

TABLE 11.5 DIETARY RECOMMENDATIONS FOR THE PREGNANT AND LACTATING WOMAN

Nutrient	Nonpregnant Women	Pregnant Woman	Lactating Woman
Calories	2,200	2,500	2,700
Protein	60 g	80 g	80 g
Water/fluids	6–8 glasses daily	8 glasses daily	8 glasses daily
Vitamin A	700 mcg	770 mcg	1,300 mcg
Vitamin C	75 mg	85 mg	120 mg
Vitamin D	5 mcg	5 mcg	5 mcg
Folate	400 mcg	600 mcg	500 mcg
Calcium	1,000 mg	1,000 mg	1,000 mg
Iodine			
Iron	18 mg	27 mg	9 mg

Adapted from American Pregnancy Association. (2015). *Pregnancy nutrition.* Retrieved from http://americanpregnancy.org/pregnancyhealth/pregnancynutrition.html; Ural, S. H. (2015). Prenatal nutrition. *eMedicine.* Retrieved from http://emedicine.medscape.com/article/259059-overview; Lutz, C.A., Mazur, E., & Litch, N. (2014). *Nutrition and diet therapy* (6th ed.). Philadelphia, PA: F. A. Davis.

Eating a gluten free diet can make it hard to get the recommended amount of folate, vitamin B, iron, calcium, fiber, and grain-servings that all pregnant women need. That is why, unless there is medical reason in which gluten must be eliminated from the diet due to celiac disease or a gluten allergy, there isn't a scientific reason to cut out wholesome, nutrient-dense grains from the diet (Neifeld, 2015).

USDA and MyPlate

For a pregnant woman to meet recommended DRIs, she should eat according to the U.S. Department of Agriculture (USDA) Food Guide *MyPlate* (Fig. 11.5). The USDA Food Guide *MyPlate* replaced the Food Guide Pyramid in 2011 as the government's primary food group symbol. *MyPlate* is an easy-to-understand visual cue to help consumers adopt healthy eating habits by encouraging them to build a healthy plate, consistent with the *Dietary Guidelines for Americans, 2015* (USDA & U.S. Department of Health and Human Services [USDHHS], 2015), which are the basis for federal nutrition policy (USDA & USDHHS, 2015). This new tool will serve as a basis for dietary instruction and it can be tailored to meet each woman's individual needs.

MyPlate provides guidance to help implement the dietary guidelines. The USDA has designed an interactive online diet-planning program called the Daily Food Plan for Moms that helps pregnant women personalize their dietary intake throughout their pregnancy. (Refer to thePoint for additional information about this food plan.) A summary of the new guidelines is as follows:

- Eat a variety of food from all food groups using portion control.
- Increase intake of vitamins, minerals, and dietary fiber.
- Lower intake of saturated fats, trans fats, and cholesterol.
- Consume adequate synthetic folic acid from supplements or from fortified foods.
- Increase intake of fruits, vegetables, and whole grains.
- Balance calorie intake with exercise to maintain ideal healthy weight (USDA, 2015).

An eating plan that follows *MyPlate* should provide sufficient nutrients for a healthy pregnancy. Except for iron, folic acid, and calcium, most of the nutrients a woman needs during pregnancy can be obtained by making healthy food choices. However, a vitamin and mineral supplement is generally prescribed.

Take Note!

Good food sources of folic acid include dark green vegetables, such as broccoli, romaine lettuce, and spinach; baked beans; black-eyed peas; citrus fruits; peanuts; and liver.

Food Concerns During Pregnancy

ARTIFICIAL SWEETENERS

Artificial sweeteners or intense sweeteners are sugar substitutes that are used as an alternative to table sugar. They are many times sweeter than natural sugar and contain no calories. Extensive scientific research has demonstrated the safety of the six low-calorie sweeteners currently approved for use in foods in the United States and Europe (stevia, acesulfame-K, aspartame, neotame, saccharin, and sucralose), if taken in acceptable quantities daily. But there is an ongoing debate over whether artificial sweeteners pose a health threat (Qurrat-ul-Ain & Khan, 2015).

FIGURE 11.5 Food Guide *MyPlate* for pregnancy.

The safety of artificial sweeteners consumed during pregnancy remains controversial also. Some health care providers advise their pregnant clients to avoid all nonnutritive sweeteners during pregnancy, while others suggest they can be used in moderation (Hankley, 2015). The debate continues on this matter until additional research can be completed.

FISH, SHELLFISH, AND LEVELS OF MERCURY

Fish and shellfish are an important part of a healthy diet because they contain high-quality protein, are low in saturated fat, and contain omega-3 fatty acids. However, nearly all fish and shellfish contain traces of mercury and some contain higher levels of mercury that may harm a developing fetus if ingested by pregnant women in

large amounts. Human exposure to mercury occurs primarily through the consumption of fish contaminated through atmospheric mercury releases. The U.S. Environmental Protection Agency (EPA) and the United Nations Environment Program have identified coal-fired power plants as the source of 50% to 75% of the atmospheric mercury pollution in the United States and worldwide. Once airborne, rainfall transfers mercury particles into waterways where it is converted to the neurotoxic methylmercury form through a microbial process. Plankton absorbs the methylmercury and as the smaller fish eat the plankton and the larger predatory fish consume the smaller fish, the methylmercury bioaccumulates up the food chain to humans. Mercury exposure in pregnancy has been associated with both pregnancy complications and developmental problems in infants. Apart from the environmental exposure, mercury is likely to arise from predatory fish consumption. It would be prudent to advise all pregnant women to avoid these potential problems and minimize any risk.

All fish contain methylmercury regardless of the size or the geographic location of the waters from which the fish is caught, although size and type of fish as well as the geographic location of waters can influence lower or higher amounts of methylmercury. In addition, because methylmercury resides in the tissue of the fish, no method of cleaning or cooking will reduce the amount of mercury in a meal of contaminated fish (Nelson, 2015).

With this in mind, the FDA and the EPA are advising women who may become pregnant, pregnant women, and nursing mothers to do the following:

- Avoid consumption of fish with moderate-to-high mercury levels (e.g., for 6 to 12 months prior to conception and throughout pregnancy).
- Avoid eating shark, swordfish, king mackerel, orange roughy, ahi tuna, and tilefish because they are high in mercury levels.
- Eat up to 12 ounces (two average meals) weekly of low-mercury-level fish such as shrimp, canned light tuna, salmon, pollock, and catfish.
- Check local advisories about the safety of fish caught by family and friends in local lakes, rivers, and coastal areas (FDA, 2015).

LISTERIOSIS AND PREGNANCY

Another food issue concern for pregnant women is consumption of food contaminated with the gram-positive bacillus *Listeria. Listeria* is a type of bacteria found in soil, water, and sometimes on plants. *Listeria* is commonly found in processed and prepared foods and in raw or unpasteurized milk. Listeriosis is associated with high morbidity and mortality. Though *Listeria* is all around our environment, most *Listeria* infections in people result from eating contaminated foods. Listeriosis during pregnancy usually presents as an unremarkable febrile illness in the mother, but can be fatal for the fetus and newborn. Reliable laboratory testing for early diagnosis is lacking. Listeriosis can be passed to an unborn baby through the placenta even if the mother is not showing signs of illness. This can lead to preterm births, miscarriages, stillbirths, and high neonatal mortality rates (Allerberger & Huhulescu, 2015). The Food Safety and Inspection Service and the FDA (2015) the following advice for pregnant women:

- Do not eat hot dogs, luncheon meats, or deli meats unless they are reheated until steaming hot.
- Avoid getting fluid from hot dog packages on other foods, utensils, and food

preparation surfaces, and wash hands after handling hot dogs, luncheon meats, and deli meats.
- Do not eat soft cheeses such as feta, Brie, Camembert, and blue-veined cheeses.
- It is safe to eat hard cheeses, semi-soft cheeses such as mozzarella, pasteurized processed cheese slices and spreads, cream cheese, and cottage cheese.
- Do not eat refrigerated pâté or meat spreads.
- It is safe to eat canned or shelf-stable pâté and meat spreads.
- Do not eat refrigerated smoked seafood unless it is an ingredient in a cooked dish such as a casserole. Examples of refrigerated smoked seafood include salmon, trout, whitefish, cod, tuna, and mackerel and are most often labeled as "nova-style," "lox," "kippered," "smoked," or "jerky." This fish is found in the refrigerated section or sold at deli counters of grocery stores and delicatessens.
- It is safe to eat canned fish such as salmon and tuna or shelf-stable smoked seafood.
- Do not drink raw (unpasteurized) milk or eat foods that contain unpasteurized milk.
- Use all refrigerated perishable items that are precooked or ready-to-eat as soon as possible.
- Use a refrigerator thermometer to make sure that the refrigerator always stays at 40°F (about 5 °C) or below.
- Do not eat salads made in the store such as ham salad, chicken salad, egg salad, tuna salad, or seafood salad.
- Clean your refrigerator regularly.

Maternal Weight Gain

The amount of weight that a woman gains during pregnancy is not as important as what she eats. A woman can lose extra weight after a pregnancy, but she can never make up for a poor nutritional status during the pregnancy. Earlier guidelines recommended weight gain that would be optimal for the infant, but new guidelines take into account the well-being of the mother too (Table 11.6).

TABLE 11.6 NORMAL DISTRIBUTION OF WEIGHT GAIN DURING PREGNANCY

Component	Weight (lb)
Infant birth weight	7.5
Blood volume increase	4
Uterus	2
Increase in breast tissue	2
Placenta	1.5
Maternal fluid volume	4
Maternal fat tissue	7
Amniotic fluid	2
Approximate total weight gain	30

Adapted from American College of Obstetricians and Gynecologists [ACOG]. (2015b). *Weight gain guidelines by ACOG for pregnancy.* Retrieved from http://www.womenshealthcaretopics.com/weight_gain_during_pregnancy.htm; Lutz, C.A., Mazur, E., & Litch, N. (2014). *Nutrition and diet therapy* (6th ed.). Philadelphia, PA: F. A. Davis.

In 2009 Health and Medicine Division revised the recommendations regarding maternal gestational weight gain. The revisions took into account that presently American women (1) have more multiple pregnancies; (2) are becoming pregnant at an older age; (3) are exceeding the ideal weight gain during pregnancy; and (4) tend to be more overweight and obese when becoming pregnant. The new recommendations are based on the woman's pregnancy body mass index (BMI) as follows (Box 11.3):

- Underweight (BMI < 18.5) total weight gain range = 28 to 40 lb
- Normal weight (BMI = 18.5–24.9) total weight gain range = 25 to 35 lb
- Overweight (BMI = 25–29.9) total weight gain range = 15 to 25 lb
- Obese (BMI = 30 or higher) total weight gain range = 11 to 20 lb

A woman who is underweight before pregnancy or who has a low maternal weight gain pattern should be monitored carefully because she is at risk of giving birth to a low-birth-weight infant (<2,500 g or 5.5 lb). Frequently these women simply need advice on what to eat to add weight. Encourage the woman to eat snacks that are high in calories such as nuts, peanut butter, milkshakes, cheese, fruit, yogurt, and ice cream. Any woman who has a prepregnancy BMI of less than 18.5 is considered to be high risk and should be referred to a nutritionist (Sharma et al., 2015).

BOX 11.3

BODY MASS INDEX

Body mass index (BMI) provides an accurate estimate of total body fat and is considered a good method to assess overweight and obesity in people. BMI is a

weight-to-height ratio calculation that can be determined by dividing a woman's weight in kilograms by her height in meters squared. BMI can also be calculated by weight in pounds divided by the height in inches squared, multiplied by 704.5.

The Centers for Disease Control and Prevention (2015) categorizes BMI as follows:

- Underweight: <18.5
- Healthy weight: 18.5–24.9
- Overweight: 25–29.9
- Obese: 30 or higher

Use this example to calculate BMI:

Mary is 5 feet 5 inches tall and weighs 150 lb.

1. Convert weight into kilograms: 150 divided by 2.2 lb/kg = 68.18 kg.
2. Convert height into meters:
   a. 5 feet 5 inches = 65 inches ÷ 2.54 cm/in. = 165.1 cm
   b. 165.1 cm/100 cm = 1.65 m
3. Then square the height in meters: $1.65 \times 1.65 = 2.72$
4. Calculate BMI: 68.18 kg divided by 2.72 = 25.

Adapted from Centers for Disease Control and Prevention [CDC]. (2015). ***BMI for adults: Body mass index calculator.*** **Retrieved from http://www.cdc.gov/nc cdphp/dnpa/bmi/calc-bmi.htm**

Conversely, women who start a pregnancy while overweight (BMI >25–29) run the risk of having a high-birth-weight infant, with resulting cephalopelvic disproportion and, potentially, a surgical birth. Two thirds of reproductive-age women in the United States are overweight or obese and at risk for numerous adverse pregnancy outcomes, in additional to a surgical birth. Some researchers have suggested that the uterine environment may influence the potential development of offspring obesity later in life. In a recent study, just a 10% weight loss before conception was associated with at least a 10% lower risk of preeclampsia, gestational diabetes, preterm birth, macrosomia, and stillbirth (Schummers et al., 2015). Dieting during pregnancy is never recommended, even for women who are obese. Severe restriction of caloric intake is associated with a decrease in birth weight. Because of the expansion of maternal blood volume and the development of fetal and placental tissues, some weight gain is essential for a healthy pregnancy. Women who gain more than the recommended weight during pregnancy and who fail to lose this weight 6 months after giving birth are at much higher risk of being obese nearly a decade later (ACOG, 2015a). Women who are overweight when beginning a pregnancy should gain no more than 15 to 25 lb during the pregnancy, depending on their nutritional status and degree of obesity (ACOG, 2015a).

The best way to assess whether a pregnant woman is consuming enough calories is to follow her pattern of weight gain. All pregnant women should aim for a steady rate of weight gain throughout pregnancy. If she is gaining in a steady, gradual manner, then she is taking in enough calories. However, consuming an adequate amount of calories does not guarantee that her nutrients are sufficient. It is critical to evaluate both the quantity and the quality of the foods eaten.

During the first trimester, for women whose prepregnancy weight is within the normal weight range, weight gain should be about 3.5 to 5 lb. For underweight women, weight gain should be at least 5 lb. For overweight women, weight gain should be about 2 lb. Much of the weight gained during the first trimester is caused by growth of the uterus and expansion of the blood volume.

During the second and third trimesters, the following pattern is recommended: for women whose prepregnancy weight is within the normal weight range, weight gain should be about 1 pound per week. For underweight women, weight gain should be slightly more than 1 pound per week. For overweight women, weight gain should be about two thirds of a pound per week (Hankley, 2015).

Nutrition Promotion

Through education, nurses can play an important role in ensuring adequate nutrition for pregnant women. During the initial prenatal visit, health care providers conduct a thorough assessment of a woman's typical dietary practices and address any conditions that may cause inadequate nutrition, such as nausea and vomiting or lack of access to adequate food. Assess and reinforce dietary information at every prenatal visit to promote good nutrition. A normal pregnancy and a well-balanced diet generally provide most of the recommended nutrients except iron and folate, both of which must be supplemented in the form of prenatal vitamins. See Teaching Guidelines 11.1.

Teaching Guidelines 11.1
TEACHING TO PROMOTE OPTIMAL NUTRITION DURING PREGNANCY

- Follow the USDA Food Guide *MyPlate* and select a variety of foods from each group.
- Gain between 15 and 40 lb in a gradual and steady manner depending on prepregnancy weight as follows:
  - Underweight (BMI >18.5) total weight gain range = 28–40 lb
  - Normal weight (BMI = 18.5–24.0) total weight gain range = 25–35 lb
  - Overweight (BMI = 25–29) total weight gain range = 15–25 lb
  - Obese (BMI = 30 or higher) total weight gain range = 11–20 lb (Health and Medicine Division [HMD], 2009)
- Take your prenatal vitamin/mineral supplementation daily.
- Avoid weight-reduction diets during pregnancy.
- Do not skip meals; eat three meals with one or two snacks daily.
- Limit the intake of sodas and caffeine-rich drinks.
- Avoid the use of diuretics during pregnancy.
- Do not restrict the use of salt unless instructed to do so by your health care provider.
- Engage in reasonable physical activity daily.

Special Nutritional Considerations

Many factors play an important role in shaping a person's food habits, and these factors must be taken into account if nutritional counseling is to be realistic and appropriate. Nurses need to be aware of these factors to ensure individualized teaching and care.

Cultural Variations and Restrictions

Food is important to every cultural group. It is often part of celebrations and rituals. When working with women from various cultures, the nurse needs to adapt American nutritional guidelines to meet their nutritional needs within their cultural framework. Food choices and variations for different cultures might include the following:

- Bread, cereal, rice, and pasta group:
  - Bolillo
  - Couscous
  - Flaxseed
  - Hau juan
- Vegetable group:
  - Agave
  - Bok choy
  - Jicama
  - Okra
  - Water chestnuts
- Protein group:
  - Bean paste
  - Blood sausage
  - Legumes
  - Shellfish
- Fruit group:
  - Catalpa
  - Kumquats
  - Plantain
  - Yucca fruit
  - Zapote
- Milk and dairy:
  - Buffalo milk
  - Buttermilk
  - Soybean milk (Academy of Nutrition and Dietetics [AND], 2015a)

Lactose Intolerance

The best source of calcium is milk and dairy products, but for women with lactose intolerance, adaptations are necessary. Women with lactose intolerance lack an enzyme (lactase) needed for the breakdown of lactose into its component simple sugars, glucose and galactose. Without adequate lactase, lactose passes through the small intestine undigested and causes abdominal discomfort, gas, and diarrhea. Lactose intolerance is especially common among women of African, Asian, and Middle Eastern descent (Szilagyi, 2015).

Additional or substitute sources of calcium may be necessary. These may include peanuts, almonds, sunflower seeds, broccoli, salmon, kale, and molasses (McIndoo, 2015). In addition, encourage the woman to drink lactose-free dairy products or calcium-enriched orange juice or soy milk (Evidence-Based Practice 11.1).

Vegetarians

Vegetarian diets are becoming increasing prevalent in the United States. People choose a vegetarian diet for various reasons including environmental, animal rights, philosophical, religious, and health beliefs (Dunlevy, 2015). Vegetarians choose not to eat meat, poultry, and fish. Their diets consist mostly of plant-based foods, such as legumes, vegetables, whole grains, nuts, and seeds. Vegetarians fall into groups defined by the types of foods they eat. Lacto-ovo-vegetarians omit red meat, fish, and poultry, but eat eggs, milk, and dairy products in addition to plant-based foods. Lacto-vegetarians consume milk and dairy products along with plant-based foods; they omit eggs, meat, fish, and poultry. Vegans eliminate all foods from animals, including milk, eggs, and cheese, and eat only plant-based foods (Foster & Samman, 2015).

EVIDENCE-BASED PRACTICE 11.1

INTERVENTIONS FOR NAUSEA AND VOMITING IN EARLY PREGNANCY

Nausea, retching or dry heaving, and vomiting in early pregnancy are very common and can be very distressing for women. Many treatments are available to women with 'morning sickness,' including drugs and complementary and alternative therapies. Because of concerns that taking medications may adversely affect the development of the fetus, this review aimed to examine if these treatments have been found to be effective and safe.

STUDY

The purpose of this study was to assess the effectiveness and safety of all interventions for nausea and vomiting in early pregnancy, up to 20 weeks' gestation. Thirty-seven trials involving 5,049 women met the inclusion criteria. These trials covered many interventions, including acupressure, acustimulation, acupuncture, ginger, chamomile, lemon oil, mint oil, vitamin B6, and several antiemetic drugs.

Evidence regarding the effectiveness of P6 acupressure, auricular (ear) acupressure, and acustimulation of the P6 point was limited. Acupuncture (P6 or traditional) showed no significant benefit to women in pregnancy. The use of ginger products may be helpful to women, but the evidence of effectiveness was limited and not consistent, though two recent studies support ginger over placebo. There was only limited evidence from trials to support the use of pharmacological agents including vitamin B6, and anti-emetic drugs to relieve mild or moderate nausea and vomiting. There was little information on maternal and fetal adverse outcomes and on psychological, social, or economic outcomes. The methodological quality of the included studies was mixed.

Findings

This review found a lack of high-quality evidence to back up any advice on which interventions to use. Some of the studies showed a benefit in improving nausea and vomiting symptoms for women, but generally effects were inconsistent and limited.

Studies were carried out in a way that meant they were at high risk of bias and, therefore, it was difficult to draw firm conclusions. Most studies had different ways of measuring the symptoms of nausea and vomiting and therefore, could not be looked at these findings together. Few studies reported maternal and fetal adverse outcomes and there was very little information on the effectiveness of treatments for improving women's quality of life.

Nursing Implications

Given the high prevalence of nausea and vomiting in early pregnancy, women and nurses caring for them need clear guidance about effective and safe interventions based on systematically reviewed evidence. Diclegis is the only FDA approved medicine for treatment of morning sickness presently, but causes drowsiness, so women should avoid engaging in activities requiring complete mental alertness, such as driving. There is a lack of high-quality evidence to support any particular intervention at this time. This is not the same as saying that the interventions studied are ineffective, but that there is insufficient strong evidence for any one intervention. Advice provided by nurses to pregnant clients experiencing morning sickness should remain general and individualized, based on the findings of this study.

Adapted from Matthews, A., Haas, D. M., O'Mathúna, D. P., Dowswell, T., & Doyle, M. (2014). Interventions for nausea and vomiting in early pregnancy. *Cochrane Database of Systematic Reviews* 2014, *3*, CD007575.

The concern with any form of vegetarianism, especially during pregnancy, is that the diet may be inadequate in nutrients. Other risks of vegetarian eating patterns during pregnancy may include low gestational weight gain, iron-deficiency anemia, compromised protein utilization, and decreased mineral absorption (Piccoli et al., 2015). A diet can become so restrictive that a woman is not gaining weight or is consistently not eating enough from one or more of the food groups. Generally, the more restrictive the diet is, the greater the chance of nutrient deficiencies.

Well-balanced vegetarian diets that include dairy products provide adequate caloric and nutrient intake and do not require special supplementation; however, vegan diets do not include any meat, eggs, or dairy products. Pregnant vegetarians must pay special attention to their intake of protein, iron, calcium, and vitamin B_{12}. Suggestions include:

- *For protein:* substitute soy foods, beans, lentils, nuts, grains, and seeds.
- *For iron:* eat a variety of meat alternatives, along with vitamin C–rich foods.
- *For calcium:* substitute soy, calcium-fortified orange juice, and tofu.
- *For vitamin B_{12}:* eat fortified soy foods and a B_{12} supplement.

The AND (2015b) used an evidence-based review to show that well-planned vegetarian diets are appropriate for individuals during all stages of the life cycle, including pregnancy, lactation, infancy, childhood, and adolescence, and for athletes.

Pica

Pica is a term used to describe the intense craving for and eating of non-food items. Many women experience unusual food cravings during their pregnancy. Having cravings during pregnancy is perfectly normal. Sometimes, however, women crave

substances that have no nutritional value and can even be dangerous to themselves and their fetus. Pica is the compulsive ingestion of nonfood substances. Pica is derived from the Latin term for magpie, a bird that is known to consume a variety of nonfood substances. Unlike the bird, however, pregnant women who develop a pica habit typically have one or two specific cravings.

The exact cause of pica is not known. Many theories have been advanced to explain it, but none has been proven scientifically. The incidence of pica is difficult to determine, since it is underreported. It is more common in the United States among African American women compared with other ethnicities, but the practice of pica is not limited to any one geographic area, race, creed, or culture. In the United States, pica is also common in women from rural areas and women with a family history of it. Common substances ingested include dirt, clay, and laundry starch. Other pica cravings are burnt matches, stones, charcoal, mothballs, ice, cornstarch, toothpaste, soap, sand, plaster, coffee grounds, paint chips, coffee grounds, baking soda, and cigarette ashes (Jyothi, 2015).

The three main substances consumed by women with pica are soil or clay (geophagia), ice (pagophagia), and laundry starch (amylophagia). Nutritional implications include:

- *Soil:* replaces nutritive sources and causes iron-deficiency anemia
- *Clay:* produces constipation; can contain toxic substances and cause parasitic infection
- *Ice:* can cause iron-deficiency anemia, tooth fractures, freezer burn injuries
- *Laundry starch:* replaces iron-rich foods, leads to iron deficiencies, and replaces protein metabolism, thus depriving the fetus of amino acids needed for proper development (American Pregnancy Association, 2015)

Clinical manifestations of anemia often precede the identification of pica because the health care provider rarely addresses the behavior and the woman does not usually volunteer such information (King et al., 2015). Secrecy surrounding this habit makes research and diagnosis difficult because some women fail to view their behavior as anything unusual, harmful, or worth reporting. Because of the clinical implications, pica should be discussed with all pregnant women as a preventive measure. The topic can be part of a general discussion of cravings, and the nurse should stress the harmful effects outlined above.

Suspect pica when the woman exhibits anemia although her dietary intake is appropriate. Ask about her usual dietary intake, and include questions about the ingestion of nonfood substances. Consider the potential negative outcomes for the pregnant woman and her fetus, and take appropriate action.

PSYCHOSOCIAL ADAPTATIONS DURING PREGNANCY

Pregnancy is a unique time in a woman's life. It is a time of dramatic alterations in her body and her appearance, as well as a time of change in her social status. All of these changes occur simultaneously. Concurrent with the physiologic changes within her body systems are psychosocial changes within the mother and family members as they face significant role and lifestyle changes.

Maternal Emotional Responses

Motherhood, perhaps more than any role in society, has acquired a special

significance for women. Women are taught they should find fulfillment and satisfaction in the role of the "ever-bountiful, ever-giving, self-sacrificing mother." Pregnancy and transitioning to motherhood are critical experiences in a woman's life, stirring a whole range of powerful emotions (Einstein, 2015). With such high expectations, many pregnant women experience various emotions throughout their pregnancy. The woman's approach to these emotions is influenced by her emotional makeup, her sociologic and cultural background, her acceptance or rejection of the pregnancy, whether the pregnancy was planned, if the father is known, and her support network (Alexander et al., 2014).

Despite the wide-ranging emotions associated with the pregnancy, many women experience similar responses. These responses commonly include ambivalence, introversion, acceptance, mood swings, and changes in body image.

Ambivalence

The realization of a pregnancy can lead to fluctuating responses, possibly at the opposite ends of the spectrum. For example, regardless of whether the pregnancy was planned, the woman may feel proud and excited by the news, while at the same time fearful and anxious of the implications. The reactions are influenced by several factors, including the way the woman was raised, her current family situation, the quality of the relationship with the expectant father, and her hopes for the future. Some women express concern over the timing of the pregnancy, wishing that goals and life objectives had been met before becoming pregnant. Other women may question how a newborn or infant will affect their career or their relationships with friends and family. These feelings can cause conflict and confusion about the pregnancy.

Ambivalence, or having conflicting feelings at the same time, is a universal feeling and is considered normal when preparing for a lifestyle change and new role. Pregnant women commonly experience ambivalence during the first trimester. Usually ambivalence evolves into acceptance by the second trimester, when fetal movement is felt. The woman's personality, her ability to adapt to changing circumstances and the reactions of her partner will affect her adjustment to being pregnant and her acceptance of impending motherhood.

Introversion

Introversion, or focusing on oneself, is common during the early part of pregnancy. The woman may withdraw and become increasingly preoccupied with herself and her fetus. As a result, she may participate less with the outside world, and she may appear passive to her family and friends.

This introspective behavior is a normal psychological adaptation to motherhood for most women. Introversion seems to heighten during the first and third trimesters, when the woman's focus is on behaviors that will ensure a safe and health pregnancy outcome. Couples need to be aware of this behavior and should be informed about measures to maintain and support the focus on the family.

Acceptance

During the second trimester, the physical changes of the growing fetus, including an enlarging abdomen and fetal movement, bring reality and validity to the pregnancy.

There are many tangible signs that someone separate from herself is present. The pregnant woman feels fetal movement and may hear the heartbeat. She may see the fetal image on an ultrasound screen and feel distinct parts, recognizing independent sleep and wake patterns. She becomes able to identify the fetus as a separate individual and accepts this.

Many women will verbalize positive feelings about the pregnancy and will conceptualize the fetus. The woman may accept her new body image and talk about the new life within. Generating a discussion about the woman's feelings and offering support and validation at prenatal visits are important.

Mood Swings

Emotional lability is characteristic throughout most pregnancies. One moment a woman can feel great joy, and within a short time she can feel shock and disbelief. Frequently, pregnant women will start to cry without any apparent cause. Some women feel as though they are riding an emotional "roller-coaster." These extremes in emotion can make it difficult for partners and family members to communicate with the pregnant woman without placing blame on themselves for their mood changes. Clear explanations about how common mood swings are during pregnancy are essential.

Change in Body Image

The way in which pregnancy affects a woman's body image varies greatly from person to person. Some women feel as if they have never been more beautiful, whereas others spend their pregnancy feeling overweight and uncomfortable. For some women pregnancy is a relief from worrying about weight, whereas for others it only exacerbates their fears of weight gain. Changes in body image are normal but can be very stressful for the pregnant woman. Offering a thorough explanation and initiating discussion of the expected bodily changes may help the family to cope with them.

Becoming a Mother

Reva Rubin (1984) identified maternal tasks that a woman must accomplish to incorporate the maternal role into her personality. Accomplishing these tasks helps the expectant mother to develop her self-concept as a mother and to form a mutually gratifying relationship with her infant. These tasks are listed in Box 11.4.

Pregnancy and Sexuality

Sexuality is an important part of health and well-being. Sexual behavior modifies as pregnancy progresses, influenced by biologic, psychological, and social factors. The way a pregnant woman feels and experiences her body during pregnancy can affect her sexuality. The woman's changing shape, emotional status, fetal activity, changes in breast size, pressure on the bladder, and other discomforts of pregnancy result in increased physical and emotional demands. These can produce stress on the sexual relationship between the pregnant woman and her partner. As the changes of pregnancy ensue, many partners become confused, anxious, and fearful of how the relationship may be affected.

BOX 11.4

BECOMING A MOTHER

- **Ensuring safe passage throughout pregnancy and birth**
  - Primary focus of the woman's attention
  - First trimester: woman focuses on herself, not on the fetus
  - Second trimester: woman develops attachment of great value to her fetus
  - Third trimester: woman has concern for herself and her fetus as a unit
  - Participation in positive self-care activities related to diet, exercise, and overall well-being
- **Seeking acceptance of infant by others**
  - First trimester: acceptance of pregnancy by herself and others
  - Second trimester: family needs to relate to the fetus as member
  - Third trimester: unconditional acceptance without rejection
- **Seeking acceptance of self in maternal role to infant ("binding in")**
  - First trimester: mother accepts idea of pregnancy, but not of infant
  - Second trimester: with sensation of fetal movement (**quickening**), mother acknowledges fetus as a separate entity within her.
  - Third trimester: mother longs to hold infant and becomes tired of being pregnant.
- **Learning to give of oneself**
  - First trimester: identifies what must be given up to assume new role
  - Second trimester: identifies with infant, learns how to delay own desires
  - Third trimester: questions her ability to become a good mother to infant

Adapted from Rubin, R. (1984). *Maternal identity and the maternal experience*. New York, NY: Springer.

The sexual desire of pregnant women may change throughout the pregnancy. During the first trimester, the woman may be less interested in sex because of fatigue, nausea, and fear of disturbing the early embryonic development. During the second trimester, her interest may increase because of the stability of the pregnancy. During the third trimester, her enlarging size may produce discomfort during sexual activity (Bope & Kellerman, 2015).

Potential complications of sex during pregnancy include preterm labor, pelvic inflammatory disease, antepartum hemorrhage in placenta previa, and venous air embolism. Generally, sexual relations are generally considered safe in pregnancy. Abstinence is usually only recommended for women who are at risk for preterm labor or for antepartum hemorrhage because of placenta previa (Boynton, 2015).

A woman's sexual health is intimately linked to her own self-image. Sexual positions to increase comfort as the pregnancy progresses as well as alternative noncoital modes of sexual expression, such as cuddling, caressing, and holding, should be discussed. Giving permission to talk about and then normalizing sexuality can help enhance the sexual experience during pregnancy and, ultimately, the couple's relationship. If avenues of communication are open regarding sexuality during pregnancy, any fears and myths the couple may have can be dispelled.

Pregnancy and the Partner

Nursing care related to childbirth has expanded from a narrow emphasis on the physical health needs of the mother and infant to a broader focus on family-related social and emotional needs. One prominent feature of this family-centered approach is the recent movement toward promoting the mother–infant bond. To achieve a truly family-centered practice, nursing must make a comparable commitment to understanding and meeting the needs of the partner in the emerging family. Recent studies suggest that the partner's potential contribution to the infant's overall development has been misperceived or devalued and that the partner's ability and willingness to assume a more active role in the infant's care may have been underestimated.

Reactions to pregnancy and to the psychological and physical changes by the woman's partner vary greatly. Some enjoy the role of being the nurturer, whereas others experience alienation and may seek comfort or companionship elsewhere. Some expectant fathers may view pregnancy as proof of their masculinity and assume the dominant role, whereas others see their role as minimal, leaving the pregnancy up to the woman entirely. Each expectant partner reacts uniquely.

Emotionally and psychologically, expectant partners may undergo fewer visible changes than women, but most of these changes remain unexpressed and unappreciated (Davies, 2015). Expectant partners also experience a multitude of adjustments and concerns. Physically, they may gain weight around the middle and experience nausea and other GI disturbances—a reaction termed *couvade syndrome* that is a sympathetic response to their partner's pregnancy. They also experience ambivalence during early pregnancy, with extremes of emotions (e.g., pride and joy versus an overwhelming sense of impending responsibility).

During the second trimester of pregnancy, partners go through acceptance of their role of breadwinner, caretaker, and support person. They come to accept the reality of the fetus when movement is felt, and they experience confusion when dealing with the woman's mood swings and introspection. During the third trimester, the expectant partner prepares for the reality of this new role and negotiates what the role will be during the labor and birthing process. Many express concern about being the primary support person during labor and birth and worry how they will react when faced with their loved one in pain. Expectant partners share many of the same anxieties as their pregnant partners. However, it is uncommon for them to reveal these anxieties to the pregnant partner or health care providers. Often, how the expectant partner responds during the third trimester depends on the state of the marriage or partnership. When the marriage or partnership is struggling, the impending increase in responsibility toward the end of pregnancy acts to drive the expectant partner further away. Often it manifests as working late, staying out late with friends, or beginning new or superficial relationships. In the stable marriage or partnership, the expectant partner who may have been struggling to find his or her place in the pregnancy now finds concrete tasks to do—for example, painting the nursery, assembling the car seat, or attending Lamaze classes.

Pregnancy and Siblings

A sibling's reaction to pregnancy is age dependent. Some children might express excitement and anticipation, whereas others might have negative reactions. A young toddler might regress in toilet training or ask to drink from a bottle again. An older

school-aged child may ignore the new addition to the family and engage in outside activities to avoid the new member. The introduction of an infant into the family is often the beginning of sibling rivalry, which results from the child's fear of change in the security of the relationship with his or her parents (Jordan et al., 2014). Preparation of the siblings for the anticipated birth is imperative and must be designed according to the age and life experiences of the sibling at home. Constant reinforcement of love and caring will help to reduce the older child's fear of change and worry about being replaced by the new family member.

FIGURE 11.6 **Parents preparing sibling for the birth of a new baby.**

If possible, parents should include siblings in preparation for the birth of the new baby to help them feel as if they have an important role to play (Fig. 11.6). Parents must also continue to focus on the older sibling after the birth to reduce regressive or aggressive behavior toward the newborn.

Pregnancy is an extremely busy time, not only in terms of the bodily changes taking place, but tasks that must be done such as choosing a provider to care for them, preparing for the new family member in a matter of months, and making lifestyle modifications to promote the best possible pregnancy outcome. We will explore this more in Chapter 12.

KEY CONCEPTS

- Pregnancy is a normal life event that involves considerable physical, psychosocial, emotional, and relationship adjustments.
- The signs and symptoms of pregnancy have been grouped into those that are subjective (presumptive) and experienced by the woman herself, those that are objective (probable) and observed by the health care provider, and those that are the positive, certain signs.
- Physiologically, almost every system of a woman's body changes during pregnancy with startling rapidity to accommodate the needs of the growing fetus. A majority of the changes are influenced by hormonal changes.

- The placenta is a unique kind of endocrine gland; it has a feature possessed by no other endocrine organ—the ability to form protein and steroid hormones.
- Occurring in conjunction with the physiologic changes in the woman's body systems are psychosocial changes occurring within the mother and family members as they face significant role and lifestyle changes.
- Commonly experienced emotional responses to pregnancy in the woman include ambivalence, introversion, acceptance, mood swings, and changes in body image.
- Reactions of expectant partners to pregnancy and to the physical and psychological changes in the woman vary greatly.
- A sibling's reaction to pregnancy is age dependent. The introduction of a new infant to the family is often the beginning of sibling rivalry, which results from the established child's fear of change in security of their relationships with their parents. Therefore, preparation of the siblings for the anticipated birth is imperative.

CHAPTER WORKSHEET

MULTIPLE-CHOICE QUESTIONS

1. What factors would change during a pregnancy if the hormone progesterone were reduced or withdrawn?
   a. The woman's gums would become red and swollen and would bleed easily.
   b. The uterus would contract more and peristalsis would increase.
   c. Morning sickness would increase and would be prolonged.
   d. The secretion of prolactin by the pituitary gland would be inhibited.
2. Which of the following is a presumptive sign or symptom of pregnancy?
   a. Restlessness
   b. Elevated mood
   c. Urinary frequency
   d. Low backache
3. When obtaining a blood test for pregnancy, which hormone would the nurse expect the test to measure?
   a. Human chorionic gonadotropin (hCG)
   b. Human placental lactogen (hPL)
   c. Follicle-stimulating hormone (FSH)
   d. Luteinizing hormone (LH)
4. During pregnancy, which of the following should the expectant mother reduce or avoid?
   a. Raw meat or uncooked shellfish
   b. Fresh, washed fruits and vegetables
   c. Whole grains and cereals
   d. Protein and iron from meat sources
5. A feeling expressed by most women upon learning they are pregnant is:
   a. Acceptance
   b. Depression
   c. Jealousy
   d. Ambivalence
6. Reva Rubin identified four major tasks that the pregnant woman undertakes to form a mutually gratifying relationship with her infant. What is "binding in"?
   a. Ensuring safe passage through pregnancy, labor, and birth
   b. Seeking acceptance of this infant by others
   c. Seeking acceptance of self as mother to the infant
   d. Learning to give of oneself on behalf of the infant
7. A pregnant client close to term comes into the clinic for an exam. The woman complains about experiencing shortness of breath. The nurse knows that this

complaint can be explained as the:
   a. Fetus is needing more oxygen now that his/her size is larger.
   b. Fundus of the uterus is high and pushing the diaphragm upwards.
   c. Woman is experiencing an allergic reaction because of high histamine levels.
   d. Oxygen partial pressure concentration is lower in the third trimester.

8. Which of the following fish should be limited in a pregnant woman's diet because of the high mercury content?
   a. Salmon
   b. Cod
   c. Shrimp
   d. Sword fish

CRITICAL THINKING EXERCISES

1. When interviewing a woman at her first prenatal visit, the nurse asks about her feelings. The woman replies, "I'm frightened and confused. I don't know whether I want to be pregnant or not. Being pregnant means changing our whole life, and now having somebody to care for all the time. I'm not sure I would be a good mother. Plus I'm a bit afraid of all the changes that would happen to my body. Is this normal? Am I okay?"
   a. How should the nurse answer this question?
   b. What specific information is needed to support the client during this pregnancy?
2. Sally, age 23, is 9 weeks pregnant. At her clinic visit she says, "I'm so tired I can barely make it home from work. Then once I'm home, I don't have the energy to make dinner." She says she is so sick in the morning that she is frequently late to work and spends much of the day in the bathroom. Sally's current lab work is within normal limits.
   a. What explanation can the nurse offer Sally about her discomforts?
   b. What interventions can the nurse offer to Sally?
3. Bringing a new infant into the family affects the siblings. What strategies can a nurse discuss when a mother asks how to deal with this?

STUDY ACTIVITIES

1. Go to your local health department's maternity clinic and interview several women regarding their feelings and the bodily changes that have taken place since they became pregnant. Based on your findings, place them into appropriate trimesters of their pregnancy.
2. Search the Internet for information about the psychological changes that occur during pregnancy. Share information from the websites you found with your clinical group.
3. During pregnancy, the plasma volume increases by 50% but the RBC volume increases by only 25% to 33%. This disproportion is manifested as _____.
4. When a pregnant woman in her third trimester lies on her back and experiences dizziness and light-headedness, the underlying cause of this is _____.

BRINGING IT ALL TOGETHER: A CASE STUDY

A 22-year-old pregnant client presents to the maternity clinic with a 4-day history of loss of appetite, constipation, and abdominal pain. She is in the first trimester of her first pregnancy and came to this country recently from India. Her mother accompanies her and answers most of the questions for her daughter. After much questioning, the mother reveals that her daughter frequently eats dirt, which was common practice in her country.

Go to thePoint to find questions to consider about this case.

Nursing Management During Pregnancy

WOW

Words of Wisdom

The secret of human touch is simple: showing a sincere liking and interest in people. Nurses need to use touch often.

KEY TERMS

alpha-fetoprotein
amniocentesis
biophysical profile (BPP)
chorionic villus sampling (CVS)
gravida
high-risk pregnancy
linea nigra
natural childbirth
para
perinatal education
preconception care

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Relate the information typically collected at the initial prenatal visit.
2. Determine an appropriate reproductive life plan based on a couple's risk profile.
3. Select the assessments completed at follow-up prenatal visits.
4. Evaluate the tests used to assess maternal and fetal well-being, including nursing management for each.
5. Outline appropriate nursing management to promote maternal self-care and to minimize the common discomforts of pregnancy.
6. Examine the key components of perinatal education.

***Linda and her husband, Rob*, are eager to start a family within the next year. They are stable in their careers and financially secure. They decide to investigate a new nurse-midwife practice associated with the local hospital, and they go for a preconception appointment. They leave their appointment overwhelmed with all the information they were given about having a healthy pregnancy.**

INTRODUCTION

Pregnancy is a time of many physiologic and psychological changes that can positively or negatively affect the woman, her fetus, and her family. Misconceptions, inadequate information, and unanswered questions about pregnancy, birth, and parenthood are common. The ultimate goal of any pregnancy is the birth of a healthy newborn, and nurses play a major role in helping the pregnant woman and her partner achieve this goal. Ongoing assessment and education are essential.

This chapter describes the nursing management required during pregnancy. It begins with a brief discussion of **preconception care** and then describes the assessment of the woman at the first prenatal visit and on follow-up visits. The chapter discusses tests commonly used to assess maternal and fetal well-being, including specific nursing management related to each test. The chapter also identifies important strategies to minimize the common discomforts of pregnancy and promote self-care. Finally, the chapter discusses **perinatal education**, including childbirth education, birthing options, health care provider options, preparation for breast-feeding or bottle-feeding, and final preparation for labor and birth.

PRECONCEPTION CARE

Ideally, couples thinking about having a child should schedule a visit with their health care provider for preconception counseling to ensure that they are in the best possible state of health before pregnancy. Preconception care is the promotion of the health and well-being of a woman and her partner before pregnancy. The goal of preconception care is to identify and modify biomedical, behavioral, and social risks to a woman's health or pregnancy outcome through prevention and management interventions (Centers for Disease Control and Prevention [CDC], 2015a).

Preconception care is advocated throughout the world as a tool for improving

perinatal outcomes. Preconception care should occur any time a health care provider sees a woman of reproductive age. Primary care for all women of childbearing age by nurses should include a routine assessment of a woman's reproductive goals and planning. Women who could potentially become pregnant should be assessed for preconception risks and educated about the importance of maternal health in ensuring healthy pregnancies. Women may be motivated to address modified health risks by learning about the way their present health will affect a future pregnancy. For women not intending a pregnancy soon, preconception care should focus on contraception counseling (Callegari, Ma, & Schwartz, 2015). Personal and family history, physical examination, laboratory screening, reproductive plan, nutrition, supplements, weight, exercise, vaccinations, and injury prevention should be reviewed in all women. Encourage folic acid 400 to 800 mcg per day depending on risk profile, as well as proper diet and exercise. Women should receive the influenza vaccine if planning pregnancy during flu season; the rubella and varicella vaccines if there is no evidence of immunity to these viruses; and tetanus/diphtheria/pertussis if lacking adult vaccination. Offer specific interventions to reduce morbidity and mortality for both the woman who has been identified with chronic diseases or exposed to teratogens or illicit substances and her baby. Several interventions have been proven to effectively improve pregnancy outcome when provided as preconception care. Recent research suggests that events that occur in the uterine decidua, even before a woman knows she is pregnant, may have a significant impact on fetal growth and the outcome of pregnancy. In addition, an intact immune system optimizes placental development and function and is essential for fetal survival (Regal, Gilbert, & Burwick, 2015). New insights reveal that the early embryo is extremely sensitive to signals from gametes, trophoblastic tissue, and periconception maternal lifestyles. Also, environmental factors prior to and after conception have an enormous impact on the developing embryo and cause long-term health problems. There is a growing body of evidence that environmental factors during embryonic development can cause irreversible alteration in epigenetic markers and induce various adult diseases, such as cardiovascular, neurologic, and metabolic disorders later in life (Keytash, Jones, & Frances, 2015). With this in mind, shifting the focus on the periconception period and the very early stages of pregnancy should offer significant benefits to the health of both the mother and her infant. The overall aim should be to effectively use every pregnancy as the health care opportunity of two lifetimes (Steeggers-Theunissen & Steegers, 2015).

The CDC (2015b) formulated 10 guidelines for preconception care (Box 12.1).

Risk Factors for Adverse Pregnancy Outcomes

Preconception care is just as important as prenatal care to reduce adverse pregnancy outcomes such as maternal and infant mortality, preterm births, and low-birth-weight infants. Adverse pregnancy outcomes constitute a major public health challenge: 13% of infants are born premature; 8.3% are born with low birth weight; 1 in 33 live births have major birth defects; and 32% of women suffer pregnancy complications (CDC, 2015c). Risk factors for these adverse pregnancy outcomes are prevalent among women of reproductive age, as demonstrated by the following statistics:

- 10% of women smoke during pregnancy, contributing to fetal addiction to nicotine.
- 7.6% consume alcohol during pregnancy, leading to fetal alcohol spectrum disorder.
- 70% of women do not take folic acid supplements, increasing the risk of neural tube defects in the newborn. Taking folic acid reduces the incidence of neural tube defects by two thirds.
- 35% of women starting a pregnancy are obese, which may increase their risk of developing hypertension, diabetes, and thromboembolic disease and may increase the need for cesarean birth.
- 3% take prescription or over-the-counter drugs that are known teratogens (substances harmful to the developing fetus).
- 5% of women have pre-existing medical conditions that can negatively affect pregnancy if unmanaged (CDC, 2015d).

BOX 12.1

TEN GUIDELINES FOR PRECONCEPTION CARE

- **Recommendation 1.** Individual responsibility across the life span: Each woman, man, and couple should be encouraged to have a reproductive life plan.
- **Recommendation 2.** Consumer awareness: Increase public awareness of the importance of preconception health behaviors and preconception care services by using information and tools appropriate across various ages; literacy, including health literacy; and cultural/linguistic contexts.
- **Recommendation 3.** Preventive visits: As a part of primary care visits, provide risk assessment and educational and health promotion counseling to all women of childbearing age to reduce reproductive risks and improve pregnancy outcomes.
- **Recommendation 4.** Interventions for identified risks: Increase the proportion of women who receive interventions as follow-up to preconception risk screening, focusing on high-priority interventions (i.e., those with evidence of effectiveness and greatest potential impact).
- **Recommendation 5.** Interconception care: Use the interconception period to provide additional intensive interventions to women who have had a previous pregnancy that ended in an adverse outcome (i.e., infant death, fetal loss, birth defects, low birth weight, or preterm birth).
- **Recommendation 6.** Prepregnancy checkup: Offer, as a component of maternity care, one prepregnancy visit for couples and persons planning pregnancy.
- **Recommendation 7.** Health insurance coverage for women with low incomes: Increase public and private health insurance coverage for women with low incomes to improve access to preventive women's health and preconception and interconception care.
- **Recommendation 8.** Public health programs and strategies: Integrate components of preconception health into existing local public health and related programs, including emphasis on interconception interventions for

women with previous adverse outcomes.
- **Recommendation 9.** Research: Increase the evidence base and promote the use of the evidence to improve preconception health.
- **Recommendation 10.** Monitoring improvements: Maximize public health surveillance and related research mechanisms to monitor preconception health.

Adapted from Centers for Disease Control and Prevention. (2015b). *Preconception care recommendations.* Retrieved from http://www.cdc.gov/preconception/hcp/recommendations.html

All of the preceding factors pose risks to pregnancy and could be addressed with early interventions if the woman seeks preconception health care. Specific recognized risk factors for adverse pregnancy outcomes that fall into one or more of these categories are listed in Box 12.2.

The period of greatest environmental sensitivity and consequent risk for the developing embryo is between days 17 and 56 after conception. The first prenatal visit, which is usually a month or later after a missed menstrual period, may occur too late to affect reproductive outcomes associated with abnormal organogenesis secondary to poor lifestyle choices. In some cases, such as with unplanned pregnancies, women may delay seeking health care because they deny that they are pregnant. Thus, commonly used prevention practices may begin too late to avert the morbidity and mortality associated with congenital anomalies and low birth weight. A more global preventative strategy is needed to reduce the high rates of pregnancy complications in all populations. Securing international level political priority for maternal and newborn care remains critical to accomplish the goal of better health for all families. All couples should take on the responsibility of developing their reproductive life plan and share it with their health care providers at office visits (Darmstadt, Shiffman, & Lawn, 2015).

What is the purpose of couples like Linda and Rob going for preconception counseling? What are the goals of preconception care for this couple? What psychologic support can be offered by the nurse to this couple at this stage?

Nursing Management

In the United States, rates of maternal mortality, unintended pregnancies, low birth weight and preterm infants continue to rise, making the need for preconception care a priority for all nurses. Traditionally, women have thought that preconception care is a single visit made before getting pregnant; however, the maximum benefits are obtained when the woman and her partner receive care throughout her reproductive years. The nurse's role is vital in identifying risk factors and encouraging healthier behaviors that potentially improve maternal and perinatal outcomes. Preconception care involves obtaining a complete health history and physical examination of the woman and her partner. Key areas include:

- Immunization status of the woman
- Underlying medical conditions, such as cardiovascular and respiratory problems or genetic disorders
- Reproductive health data, such as pelvic examinations, use of contraceptives, and

sexually transmitted infections (STIs)
- Sexuality and sexual practices, such as safer-sex practices and body image issues
- Nutrition history and present status
- Lifestyle practices, including occupation and recreational activities
- Psychosocial issues such as levels of stress and exposure to abuse and violence
- Medication and drug use, including use of tobacco, alcohol, over-the-counter and prescription medications, and illicit drugs
- Support system, including family, friends, and community

BOX 12.2

RISK FACTORS FOR ADVERSE PREGNANCY OUTCOMES

- **Isotretinoins**. Use of isotretinoins (e.g., Accutane®) in pregnancy to treat acne can result in high risk of congenital malformations which may include craniofacial, cardiac, and central nervous systems injuries. It is contraindicated in pregnancy
- **Alcohol misuse.** No time during pregnancy is safe to drink alcohol, and harm can occur early, before a woman has realized that she is or might be pregnant. Fetal alcohol syndrome and other alcohol-related birth defects can be prevented if women cease intake of alcohol before conception.
- **Antiepileptic drugs.** Certain antiepileptic drugs are known teratogens (e.g., valproic acid). Recommendations suggest that before conception, women who are on a regimen of these drugs and who are contemplating pregnancy should be prescribed a lower dosage of these drugs.
- **Diabetes (preconception).** The threefold increase in the prevalence of birth defects among infants of women with type 1 and type 2 diabetes is substantially reduced through proper management of diabetes.
- **Folic acid deficiency.** Daily use of vitamin supplements containing folic acid (400 mcg) has been demonstrated to reduce the occurrence of neural tube defects by two thirds.
- **Hepatitis B.** Vaccination is recommended for men and women who are at risk for acquiring hepatitis B virus (HBV) infection. Preventing HBV infection in women of childbearing age prevents transmission of infection to infants and eliminates risk to the woman of HBV infection and sequelae, including hepatic failure, liver carcinoma, cirrhosis, and death.
- **HIV/AIDS.** If HIV infection is identified before conception, timely antiretroviral treatment can be administered, and women (or couples) can be given additional information that can help prevent mother-to-child transmission.
- **Rubella seronegativity.** Rubella vaccination provides protective seropositivity and prevents congenital rubella syndrome.
- **Obesity.** Adverse perinatal outcomes associated with maternal obesity include neural tube defects, preterm delivery, diabetes, cesarean section, and hypertensive and thromboembolic disease. Appropriate weight loss and nutritional intake before pregnancy reduce these risks.
- **STIs.** *Chlamydia trachomatis* and *Neisseria gonorrhoeae* have been strongly associated with ectopic pregnancy, infertility, and chronic pelvic pain. STIs during pregnancy might result in fetal death or substantial physical and

developmental disabilities, including intellectual disability and blindness. Early screening and treatment prevents these adverse outcomes.

- **Smoking.** Preterm birth, low birth weight, and other adverse perinatal outcomes associated with maternal smoking in pregnancy can be prevented if women stop smoking before or during early pregnancy. Because only 20% of women successfully control tobacco dependency during pregnancy, cessation of smoking is recommended before pregnancy.

T. (2014). *Epidemiology of women's health*. Burlington, MA: Jones & Bartlett Learning.

Figure 12.1 gives a sample preconception screening tool.

This information provides a foundation for planning health promotion activities and education. For example, to have a positive impact on the pregnancy:

- Ensure that the woman's immunizations are up to date.
- Create a reproductive life plan to address and outline their reproductive needs.
- Take a thorough history of both partners to identify any medical or genetic conditions that need treatment or a referral to specialists.
- Identify history of STIs and high-risk sexual practices so they can be modified.
- Complete a dietary history combined with nutritional counseling.
- Gather information regarding exercise and lifestyle practices to encourage daily exercise for well-being and weight maintenance.
- Stress the importance of taking folic acid to prevent neural tube defects.
- Urge the woman to achieve optimal weight before a pregnancy.
- Identify work environment and any needed changes to promote health.
- Address substance use issues, including smoking and drugs.
- Identify victims of violence and assist them to get help.
- Manage chronic conditions such as diabetes and asthma.
- Educate the couple about environmental hazards, including metals and herbs.
- Offer genetic counseling to identify carriers.
- Suggest the availability of support systems, if needed (Hurst & Linton, 2015; Templeton, 2015).

PRECONCEPTION SCREENING AND COUNSELING CHECKLIST

NAME	BIRTHPLACE	AGE

DATE: / / ARE YOU PLANNING TO GET PREGNANT IN THE NEXT SIX MONTHS? ___ Y ___N

IF YOUR ANSWER TO A QUESTION IS YES, PUT A CHECK MARK ON THE LINE IN FRONT OF THE QUESTION. FILL IN OTHER INFORMATION THAT APPLIES TO YOU.

DIET AND EXERCISE

What do you consider a healthy weight for you?_____
___Do you eat three meals a day?
___Do you follow a special diet (vegetarian, diabetic, other)?
___Which do you drink (__ coffee __ tea __ cola __ milk __ water __ soda/pop other_____)?
___Do you eat raw or undercooked food (meat, other)?
___Do you take folic acid?
___Do you take other vitamins daily (__ multivitamin __ vitamin A __ other)?
___Do you take dietary supplements (__ black cohosh __ pennyroyal __ other)?
___Do you have current/past problems withh eating disorders?
___Do you exercise? Type/frequency:_____
Notes:

LIFESTYLE

___Do you smoke cigarettes or use other tobacco products?
How many cigarettes/packs a day?_____
___Are you exposed to second-hand smoke?
___Do you drink alcohol?
What kind?_____How often?_____How much?_____
___Do you use recreational drugs (cocaine, heroin, ecstasy, meth/ice, other?
List:_____
___Do you see a dentist regularly?
What kind of work do you do?_____
___Do you work or live near possible hazards (chemicals, x-ray or other radiation, lead)? List:_____
___Do you use saunas or hot tubs?
Notes:

MEDICATION /DRUGS

___Are you taking prescribed drugs (Accutane, valproic acid, blood thinners)? List them_____
___Are you taking non-prescribed drugs?
List them:_____
___Are you using birth control pills?
___Do you get injectable contraceptives or shots for birth control?
___Do you use any herbal remedies or alternative medicine?
List:_____
NOTES:

MEDICAL/FAMILY HISTORY

Do you have or have you ever had:
___Epilepsy?
___Diabetes?
___Asthma?
___High blood pressure?
___Heart disease?
___Anemia?
___Kidney or bladder disorders?
___Thyroid disease?
___Chickenpox?
___Hepatitis C?
___Digestive problems?
___Depression or other mental health problem?
___Surgeries?
___Lupus?
___Scleroderma?
___Other conditions?
Have you ever been vaccinated for:
___Measles, mumps, rubella?
___Hepatitis B?
___Chickenpox?
NOTES:

WOMEN'S HEALTH

___Do you have any problems with your menstrual cycle?
___How many times have you been pregnant?
What was/ were the outcomes(s)?_____
___Did you have difficulty getting pregnant last time?
___Have you been treated for infertility?
Have you had surgery on your uterus, cervix, ovaries, or tubes?
___Did you mother take the hormone DES during pregnancy?
Have you ever had HPV, genital warts or chlamydia?
___Have you ever been treated for a sexually transmitted infection (genital herpes, gonorrhea, syphilis, HIV/AIDS, other)? List:_____
NOTES:

Nurses can act as advocates and educators, creating healthy, supportive communities for women and their partners in the childbearing phases of their lives. It is important to enter into a collaborative partnership with the woman and her partner, enabling them to examine their own health and its influence on the health of their future baby. Provide information to allow the woman and her partner to make an informed decision about having a baby, but keep in mind that this decision

rests solely with the couple.

Take Note!

Because all women of reproductive age, from menarche to menopause, benefit from preventive care, preconception care should be an integral part of that continuum (Boggess & Berggren, 2015).

***Linda and Rob* decide to change several aspects of their lifestyle and nutritional habits before conceiving a baby, based on advice from the nurse-midwife. They both want to lose weight, stop smoking, and increase their intake of fruits and vegetables. How will these lifestyle and dietary changes benefit Linda's future pregnancy? What other areas might need to be brought up to date to prepare for a future pregnancy?**

THE FIRST PRENATAL VISIT

Once a pregnancy is suspected and, in some cases, tentatively confirmed by a home pregnancy test, the woman should seek prenatal care to promote a healthy outcome. Although the most opportune window (preconception) for improving pregnancy outcomes may be missed, appropriate nursing management starting at conception and continuing throughout the pregnancy can have a positive impact on the health of pregnant women and their unborn children.

The assessment process begins at this initial prenatal visit and continues throughout the pregnancy. The initial visit is an ideal time to screen for factors that might place the woman and her fetus at risk for problems such as preterm delivery. The initial visit also is an optimal time to begin educating the client about changes that will affect her life.

Prenatal care can be delivered in one of two methods: individually or in a group format termed *centering*. The first method is the traditional model whereby a pregnant woman sees her health care provider at specified interims throughout her pregnancy and all visits occur on a one-to-one basis. The centering pregnancy model of group prenatal care involves groups of up to a dozen women in similar gestational ages meeting with their health care provider for 10 sessions of approximately 1.5 to 2 hours each. The centering group method has been theorized to produce better birth outcomes than traditional individually delivered prenatal care due to increased client–provider interaction, increased social support, and greater perceived empowerment (Tracy, 2014). See Evidence-Based Practice 12.1.

The International Association of Diabetes and Pregnancy Study Groups (IADPSG) recently issued recommendations on the diagnosis and classification of hyperglycemia in pregnancy. Specific recommendations for diagnosing hyperglycemic disorders in pregnancy include the following:

- At the *first prenatal visit,* measure fasting plasma glucose, HbA1c, or random plasma glucose of all women or all high-risk women based on her risk factors, weight status, and family history. Thresholds for diagnosis of overt diabetes during pregnancy are shown in Box 12.3.
- If glucose testing is not diagnostic of overt diabetes, the woman should be tested for gestational diabetes from 24 to 28 weeks of gestation with a 2-hour 75-g oral glucose tolerance test (American Diabetes Association [ADA], 2015).

Given our society's poor food choices, sedentary tendencies, obesity, increasing life stresses, and the increasing immigration of high-risk populations (Hispanic, African American, Southeast Asian, Arab, Afro-Caribbean, Mediterranean, and Native American), the incidence of gestational diabetes is growing. The American College of Obstetricians and Gynecologists (ACOG), the American Diabetes Association (ADA), and the World Health Organization have all recommended screening at the first prenatal visit for women who are over 25 years old, overweight, have polycystic ovary syndrome, history of gestational diabetes, and a positive family history of diabetes (Satyan et al., 2015). Global guidelines for screening, diagnosis, and classification have been established, and offer the potential to stop the cycle of diabetes and obesity caused by hyperglycemia in pregnancy. Normoglycemia is the goal in all aspects of pregnancy and offers the benefits of decreased short-term and long-term complications of diabetes.

BOX 12.3

THRESHOLDS FOR DIAGNOSIS OF OVERT DIABETES DURING PREGNANCY

The thresholds for the diagnosis of overt diabetes during pregnancy are:
- Fasting plasma glucose: 126 mg/dL
- Hemoglobin A1c level: at least 6.5%
- Random plasma glucose: 200 mg/dL

EVIDENCE-BASED PRACTICE 12.1

THE EFFECTS OF CENTERING PREGNANCY GROUP PRENATAL CARE ON GESTATIONAL AGE, BIRTH WEIGHT, AND FETAL DEMISE

STUDY

Although rates of infant mortality in the United States have declined over the last several decades, rates of preterm births (<27 weeks' gestation) and low birth weight (<2,500 g) have increased. Access to quality prenatal care has demonstrated improvement of maternal and child outcomes, and may help reduce infant mortality, preterm birth, and low weight infants. The centering group prenatal care model has been theorized to produce better birth outcomes than traditional individually delivered prenatal care due to increased patient–provider interaction, increased social support, greater perceived empowerment, and increased exposure to useful skills and information about pregnancy, birthing, and childcare.

This study compared birth outcomes for women who received two different forms of prenatal care. The objective of this study was to examine the effects of centering prenatal care versus individually delivered prenatal care on gestational age, birth weight, and fetal demise. Samples of 6,155 women were divided into two groups-–individual prenatal care and group prenatal care at five sites. The sample included women who received prenatal care at one of five sites that offered both individual and group prenatal care.

Findings

Results indicated that women in the centering pregnancy group prenatal care, compared with women in traditional individually delivered prenatal care, had significantly longer gestational ages (b = 0.35, 95% CI [0.29, 0.41]) and higher overall birth weights (b = 28.6, 95% CI [4.8, 52.3]). Results also indicated that group delivered prenatal care was associated with significantly and substantially lower odds of very low birth weight and fetal demise.

Nursing Implications

At present there is support to provide centering group prenatal care where possible according to guidelines. The results indicated largely beneficial effects of group prenatal care on women's birth outcomes. Health policy reforms aimed at reducing adverse birth outcomes may consider group prenatal care a promising alternative format for delivering prenatal care. Nurses should continue to encourage all women to obtain prenatal care (group or traditional) as part of their reproductive plan to enhance the outcomes of their pregnancy and all of their future children. Given the evidence of beneficial effects of centering group prenatal care and the cost implications of widespread implementation will be critical for informing state and local health policies aimed at improving maternal and perinatal health outcomes.

Adapted from Tanner-Smith, E., Steinka-Fry, K., & Lipsey, M. (2014). The effects of centering pregnancy group prenatal care on gestational age, birth weight, and fetal demise. *Maternal & Child Health Journal*, *18*(4), 801–809.

Counseling and education of the pregnant woman and her partner are critical to ensure healthy outcomes for mother and her infant. Pregnant women and their partners frequently have questions, misinformation, or misconceptions about what to eat, weight gain, physical discomforts, drug and alcohol use, sexuality, and the birthing process. The nurse needs to allow time to answer questions and provide anticipatory guidance during the pregnancy and to make appropriate community referrals to meet the needs of these clients. To address these issues and foster the overall well-being of pregnant women and their fetuses, specific national health goals have been established (see Healthy People 2020).

Comprehensive Health History

During the initial visit, a comprehensive health history is obtained, including age, menstrual history, prior obstetric history, past medical and surgical history, psychological screening, family history, genetic screening, dietary habits, lifestyle and health practices, medication or drug use, and history of exposure to STIs (Moses, 2015a). Often, use of a prenatal history form (Fig. 12.2) is the best way to document the data collected (Evidence-Based Practice 12.2.)

The initial health history typically includes questions about three major areas: the reason for seeking care; the client's past medical, surgical, and personal history, including that of the family and her partner; and the client's reproductive history. During the history-taking process, the nurse and client establish the foundation of a trusting relationship and jointly develop a plan of care for the pregnancy. They tailor this plan to the client's lifestyle as much as possible and focus primarily on education for overall wellness during the pregnancy. The ultimate goal for the first

prenatal visit is to collect baseline data about the woman and her partner and to detect any risk factors that need to be addressed to facilitate a healthy pregnancy (King et al., 2015). See *Healthy People 2020*.

HEALTHY PEOPLE 2020

Objective	Nursing Significance
MICH-10 Increase the proportion of pregnant women who receive early and adequate prenatal care by 10% over *HP 2010* goal.	Will contribute to reduced rates of perinatal illness, disability, and death by helping to identify possible risk factors and implementing measures to lessen these factors that contribute to poor outcomes
MICH-12 (Developmental) Increase the proportion of pregnant women who attend a series of prepared childbirth classes.	Will contribute to a positive birthing experience because women will be prepared for what they will face; will also help in reducing pain and anxiety
MICH-13 (Developmental) Increase the proportion of mothers who achieve a recommended weight gain during their pregnancies.	Will reduce the risks associated with weight for better perinatal outcomes for mother and infant
MICH-16 Increase the proportion of women delivering a live birth who received preconception care services and practiced key recommended preconception health behaviors: • Took multivitamins/folic acid prior to pregnancy • Did not smoke prior to pregnancy • Did not drink alcohol prior to pregnancy • (Developmental) Used contraception to plan pregnancy	The risk of maternal and infant mortality and pregnancy-related complications can be reduced by increasing access to quality preconception care. This will enhance healthy birth outcomes and early identification and treatment of health.

EVIDENCE-BASED PRACTICE 12.2

ANTENATAL DIETARY EDUCATION AND SUPPLEMENTATION TO INCREASE ENERGY AND PROTEIN INTAKE

STUDY

Gestational weight gain is positively associated with fetal growth, and observational studies of food supplementation in pregnancy have reported increases in gestational weight gain and fetal growth. During pregnancy, the fetus develops based on the nutrition of the mother. Inadequate intake during pregnancy can lead to malnutrition and poor outcomes for the fetus. The objective of this study was to assess the effects of education during pregnancy to increase energy and protein intake, or of actual energy and protein supplementation, on energy and protein intake, and the effect on maternal and infant health outcomes.

Findings

The review included 17 randomized controlled trials, involving 9,030 women. Four main findings included (1) providing nutritional advice resulted in an increase in the mother's protein intake with resulting fewer preterm births and low birth weights; (2) giving mothers balanced energy and protein supplements was associated with fewer infants dying during labor and infants had an increase in birth weights; (3) high protein supplementation showed no benefit for women and potential harm for the infant with more becoming small for gestational age at birth; and (4) isocaloric protein

supplementations showed no benefit for higher birth weight in the infant and weekly gestational gain for the mothers.

Nursing Implications

This review provides encouraging evidence that prenatal nutritional education with the aim of increasing energy and protein intake in the maternal population appears to be effective in reducing the risk of preterm birth, low birth weight, increasing head circumference at birth, increasing birth weight among undernourished women, and increasing protein intake. There remains question about high protein supplementation being beneficial. Nurses can continue to provide good sound evidence-based nutritional education to their pregnant clients to bring about healthy outcomes.

Reason for Seeking Care

The woman commonly comes for prenatal care based on the suspicion that she is pregnant. She may report that she has missed her menstrual period or has had a positive result on a home pregnancy test. Ask the woman for the date of her last normal menstrual period (LMP). Also ask about any presumptive or probable signs of pregnancy that she might be experiencing. Typically a urine or blood test to

check for evidence of human chorionic gonadotropin (hCG) is done to confirm the pregnancy.

Past History

Ask about the woman's past medical and surgical history. This information is important because conditions that the woman experienced in the past (e.g., urinary tract infections) may recur or be exacerbated during pregnancy. Also, chronic illnesses, such as diabetes or heart disease, can increase the risk for complications during pregnancy for the woman and her fetus. Ask about any history of allergies to medications, foods, or environmental substances. Ask about any mental health problems, such as depression or anxiety. Gather similar information about the woman's family and her partner.

The woman's personal history also is important. Ask about her occupation, possible exposure to teratogens, exercise and activity level, recreational patterns (including the use of substances such as alcohol, tobacco, and drugs), use of alternative and complementary therapies, sleep patterns, nutritional habits, and general lifestyle. Each of these may have an impact on the outcome of the pregnancy. For example, if the woman smokes during pregnancy, nicotine in the cigarettes causes vasoconstriction in the mother, leading to reduced placental perfusion. As a result, the newborn may be small for gestational age. The newborn will also go through nicotine withdrawal soon after birth. In addition, no safe level of alcohol ingestion in pregnancy has been determined. Many fetuses exposed to heavy alcohol levels during pregnancy develop fetal alcohol syndrome, a collection of deformities and disabilities.

Reproductive History

The woman's reproductive history includes a menstrual, obstetric, and gynecologic history. Typically, this history begins with a description of the woman's menstrual cycle, including her age at menarche, number of days in her cycle, typical flow characteristics, and any discomfort experienced. The use of contraception also is important, including when the woman last used any contraception.

Establishing an accurate due date is one of the most important assessments for a pregnant woman, one that has both social and medical significance. For women and their families, this estimated due date (EDD) represents the long-awaited birthday of their child and is a time frame around which many economic and social activities are planned. This end point date provides guidance for the timing of specific maternal and fetal testing throughout pregnancy, gauges fetal growth parameters, and provides well-established timelines for specific interventions in the management of prenatal complications. In fact, critical decisions, such as preterm labor management, timing of postdate induction of labor, and identification of fetal growth restriction (FGR), are all based on the presumed gestational age of the fetus, which is calculated backward from the EDD (Bond, 2015).

Ask the woman the date of her LMP to determine the estimated or EDD. Several methods may be used to estimate the date of birth. Nagele rule can be used to establish the EDD (Box 12.4). Using this rule, subtract 3 months from the month of her LMP and then add 7 days to the first day of the LMP. Then correct the year by adding 1 to it where necessary. An alternative way is to add 7 days and then add 9 months = year where needed. This date has a margin of error of plus or minus 2

weeks. For instance, if a woman reports that her LMP was October 14, 2015, you would subtract 3 months (July) and add 7 days (21), then add 1 year (2016). The woman's EDD is July 21, 2016.

Because of the normal variations in women's menstrual cycles, differences in the normal length of gestation among ethnic groups, and errors in dating methods, there is no such thing as an exact due date. In general, a birth 2 weeks before or 2 weeks after the EDD is considered normal. Nagele rule is less accurate if the woman's menstrual cycles are irregular, if the woman conceives while breast-feeding or before her regular menstrual cycle is established after childbirth, if she is ovulating although she is amenorrheic, or after she discontinues oral contraceptives (Schuiling & Likis, 2016).

BOX 12.4

NAGELE RULE FOR CALCULATING THE ESTIMATED DUE DATE (EDD)

1. Use the first day of the last normal menstrual period	10/14/15
2. Subtract 3 from the number of months	7/14/15
3. Add 7 to the number of days	7/21/15
4. Adjust the year by adding one year	7/21/16
5. Estimated due date (+ or – 2 weeks) = July 21st 2016	

A gestational or birth calculator or wheel can also be used to calculate the due date (Fig. 12.3). Some practitioners use ultrasound to more accurately determine the gestational age and date the pregnancy. Ultrasound is typically the most accurate method of dating a pregnancy.

Typically, an obstetric history provides information about the woman's past pregnancies, including any problems encountered during the pregnancy, labor, birth, and postpartum. Such information can provide clues to problems that might develop in the current pregnancy. Some common terms used to describe and document an obstetric history include gravid, **gravida**, gravida I (primigravida), gravida II (secundigravida), multigravida, and para (Table 12.1).

Other systems may be used to document a woman's obstetric history. These systems often break down the category of para more specifically (Box 12.5).

Information about the woman's gynecologic history is important. Ask about any reproductive tract surgeries the woman has undergone. For example, surgery on the uterus may affect its ability to contract effectively during labor. A history of tubal pregnancy increases the woman's risk for another tubal pregnancy. Also ask about safe-sex practices and any history of STIs.

BOX 12.5

OBSTETRIC HISTORY TERMS: GTPAL OR TPAL

G = gravida, T = term births, P = preterm births, A = abortions, L = living

children
- G—the current pregnancy to be included in count
- T—the number of term gestations delivering between 38 and 42 weeks
- P—the number of preterm pregnancies ending >20 weeks or viability but before completion of 37 weeks
- A—the number of pregnancies ending before 20 weeks or viability
- L—the number of children currently living

Consider this example:

Mary Johnson is pregnant for the fourth time. She had one abortion at 8 weeks' gestation.

She has a daughter who was born at 40 weeks' gestation and a son born at 34 weeks.

Mary's obstetric history would be documented as follows:
- Using the gravida/para method: gravida 4, para 2
- Using the TPAL method: 1112 (T = 1 [daughter born at 40 weeks]; P = 1 [son born at 34 weeks]; A = 1 [abortion at 8 weeks]; L = 2 [two living children])

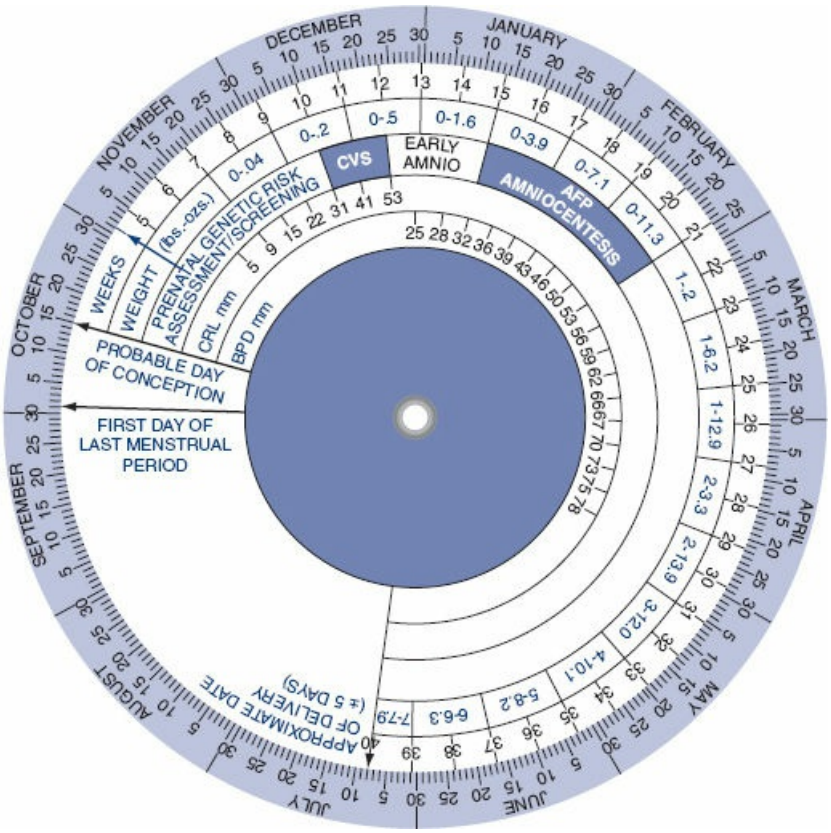

FIGURE 12.3 EDD using a birth wheel. The first day of the woman's last normal menstrual period was October 1. Using the birth wheel, her EDD would be approximately July 8 of the following year. (Used with permission. Copyright March of Dimes, 2015.)

TABLE 12.1 PREGNANCY TERMS

Term	Definition
Gravid	The state of being pregnant
Gravida/ Gravidity	The total number of times a woman has been pregnant, regardless of whether the pregnancy resulted in a termination or if multiple infants were born from a pregnancy.
Nulligravida	A woman who has never experienced pregnancy
Primigravida	A woman pregnant for the first time
Secundigravida	A woman pregnant for the second time
Multigravida	A woman pregnant for at least the third time
Para	The number of times a woman has given birth to a fetus of at least 20 gestational weeks (viable or not), counting multiple births as one birth event.
Parity	Refers to the number of pregnancies, not the number of fetuses, carried to the point of viability, regardless of the outcome
Nullipara (para 0)	A woman who has not produced a viable offspring.
Primipara	A woman who has given birth once after a pregnancy of at least 20 weeks, commonly referred to as a "primip" in clinical practice.
Multipara	A woman who has had two or more pregnancies of at least 20 weeks' gestation resulting in viable offspring. Commonly referred to as a "multip."

Physical Examination

The next step in the assessment process is the physical examination, which detects any physical problems that may affect the pregnancy outcome. The initial physical examination provides the baseline for evaluating changes during future visits.

Preparation

Instruct the client to undress and put on a gown. Also ask her to empty her bladder and, in doing so, to collect a urine specimen. Typically this specimen is a clean-catch urine specimen that is sent to the laboratory for a urinalysis to detect a possible urinary tract infection.

Begin the physical examination by obtaining vital signs, including blood pressure, respiratory rate, temperature, and pulse. Also measure the client's height and weight. Abnormalities such as an elevated blood pressure may suggest pregestational hypertension, requiring further evaluation. Abnormalities in pulse rate and respiration require further investigation for possible cardiac or respiratory disease. If the woman weighs less than 100 lb or more than 200 lb or there has been a sudden weight gain, report these findings to the primary care provider; medical treatment or nutritional counseling may be necessary.

Head-to-Toe Assessment

A complete head-to-toe assessment is usually performed by the health care provider. Every body system is assessed. Some of the major areas are discussed here. Throughout the assessment, be sure to drape the client appropriately to ensure privacy and prevent chilling.

HEAD AND NECK

Assess the head and neck area for any previous injuries and sequelae. Evaluate for any limitations in range of motion. Palpate for any enlarged lymph nodes or swelling. Note any edema of the nasal mucosa or hypertrophy of gingival tissue in the mouth; these are typical responses to increased estrogen levels in pregnancy. Palpate the thyroid gland for enlargement. Slight enlargement is normal, but marked enlargement may indicate hyperthyroidism, requiring further investigation.

CHEST

Auscultate heart sounds, noting any abnormalities. A soft systolic murmur caused by the increase in blood volume may be noted. Anticipate an increase in heart rate by 10 to 15 beats per minute (bpm) (starting between 14 and 20 weeks of pregnancy) secondary to increases in cardiac output and blood volume. The body adapts to the increase in blood volume with peripheral dilation to maintain blood pressure. Progesterone causes peripheral dilation.

Auscultate the chest for breath sounds, which should be clear. Also note symmetry of chest movement and thoracic breathing patterns. Estrogen promotes relaxation of the ligaments and joints of the ribs, with a resulting increase in the anteroposterior chest diameter. Expect a slight increase in respiratory rate to accommodate the increase in tidal volume and oxygen consumption.

Inspect and palpate the breasts and nipples for symmetry and color. Increases in estrogen and progesterone and blood supply make the breasts feel full and more nodular, with increased sensitivity to touch. Blood vessels become more visible and there is an increase in breast size. Striae gravidarum (stretch marks) may be visible in women with large breasts. Darker pigmentation of the nipple and areola is present, along with enlargement of Montgomery glands. Colostrum (yellowish secretion that precedes mature breast milk) is excreted typically in the third trimester.

Take Note!

Use this opportunity to reinforce and teach breast self-examination if the woman has a high-risk history.

ABDOMEN

The appearance of the abdomen depends on the number of weeks of gestation. The abdomen enlarges progressively as the fetus grows. Inspect the abdomen for striae, scars, shape, and size. Inspection may reveal striae gravidarum (stretch marks) and **linea nigra**, a thin brownish black pigmented line running from the umbilicus to the symphysis pubis, depending on the duration of the pregnancy. Palpate the abdomen, which should be rounded and nontender. A decrease in muscle tone may be noted due to the influence of progesterone.

Typically, the height of the fundus is measured when the uterus arises out of the pelvis to evaluate fetal growth. At 12 weeks' gestation the fundus can be palpated at the symphysis pubis. At 16 weeks' gestation the fundus is midway between the symphysis and the umbilicus. At 20 weeks the fundus can be palpated at the umbilicus and measures approximately 20 cm from the symphysis pubis. By 36 weeks the fundus is just below the xiphoid process and measures approximately 36 cm. The uterus maintains a globular/ovoid shape throughout pregnancy (Bope & Kellerman, 2015).

EXTREMITIES

Inspect and palpate both legs for dependent edema, pulses, and varicose veins. If edema is present in early pregnancy, further evaluation may be needed to rule out gestational hypertension. During the third trimester, dependent edema is a normal finding. Ask the woman if she has any pain in her calf that increases when she ambulates. This might indicate a deep vein thrombosis (DVT). High levels of estrogen during pregnancy place women at higher risk for DVT.

Pelvic Examination

The pelvic examination provides information about the internal and external reproductive organs. In addition, it aids in assessing some of the presumptive and probable signs of pregnancy and allows for determination of pelvic adequacy. During the pelvic examination, remain in the examining room to assist the health care provider with any specimen collection, fixation, and labeling. Also provide comfort and emotional support for the woman, who might be anxious. Throughout the examination, explain what is happening and why, and answer any questions as necessary.

EXTERNAL GENITALIA

After the client is placed in the lithotomy position and draped appropriately, the external genitalia are inspected visually. They should be free from lesions, discharge, hematomas, varicosities, and inflammation upon inspection. A culture for STIs may be collected at this time.

INTERNAL GENITALIA

Next, the internal genitalia are examined via a speculum. The cervix should be smooth, long, thick, and closed. Because of increased pelvic congestion, the cervix will be softened (Goodell sign), the uterine isthmus will be softened (Hegar sign), and there will be a bluish coloration of the cervix and vaginal mucosa (Chadwick sign).

The uterus typically is pear shaped and mobile, with a smooth surface. It will undergo cell hypertrophy and hyperplasia so that it enlarges throughout the

pregnancy to accommodate the growing fetus.

During the pelvic examination, a Papanicolaou (Pap) smear may be obtained. Additional cultures, such as for gonorrhea and chlamydia screening, also may be obtained. Ensure that all specimens obtained are labeled correctly and sent to the laboratory for evaluation. A rectal examination is done last to assess for lesions, masses, prolapse, or hemorrhoids.

Once the examination of the internal genitalia is completed and the speculum is removed, a bimanual examination is performed to estimate the size of the uterus to confirm dates and to palpate the ovaries. The ovaries should be small and nontender, without masses. At the conclusion of the bimanual examination, the health care provider reinserts the index finger into the vagina and the middle finger into the rectum to assess the strength and regularity of the posterior vaginal wall.

PELVIC SIZE, SHAPE, AND MEASUREMENTS

The size and shape of the women's pelvis can affect her ability to deliver vaginally. Pelvic shape is typically classified as one of four types: gynecoid, android, anthropoid, and platypelloid. Refer to Chapter 13 for an in-depth discussion of pelvic size and shape.

Taking internal pelvic measurements determines the actual diameters of the inlet and outlet through which the fetus will pass. This is extremely important if the woman has never given birth vaginally. Taking pelvic measurements is unnecessary for the woman who has given birth vaginally before (unless she has experienced some type of trauma to the area) because vaginal delivery demonstrates that the pelvis is adequate for the passage of the fetus.

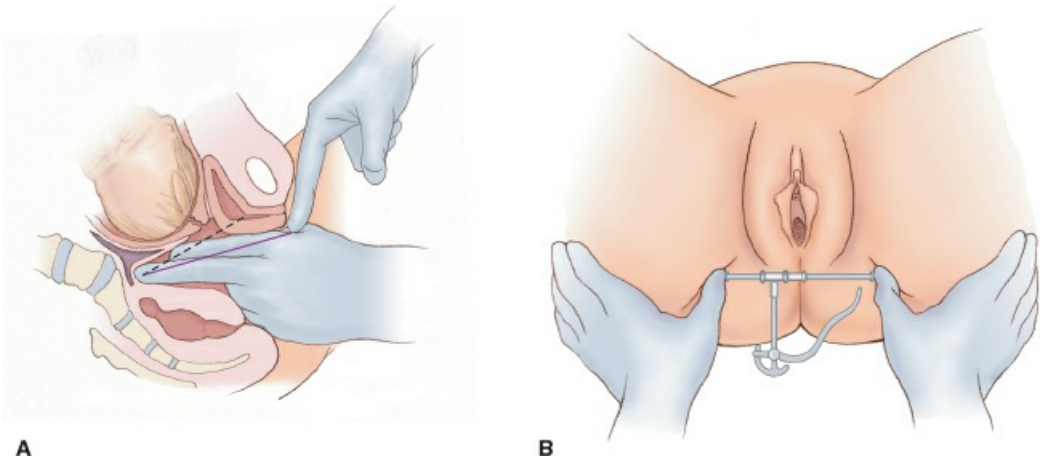

FIGURE 12.4 Pelvic measurements. A. Diagonal conjugate (*solid line*) and true conjugate (*dotted line*). B. Ischial tuberosity diameter.

Three measurements are assessed: diagonal conjugate, true conjugate, and ischial tuberosity (Fig. 12.4). The diagonal conjugate is the distance between the anterior surface of the sacral prominence and the anterior surface of the inferior margin of the symphysis pubis (Bope & Kellerman, 2015). This measurement, usually 12.5 cm or greater, represents the anteroposterior diameter of the pelvic inlet through which the fetal head passes first. The diagonal conjugate is the most useful measurement for estimating pelvic size because a misfit with the fetal head occurs if it is too small.

The true conjugate, also called the obstetric conjugate, is the measurement from the anterior surface of the sacral prominence to the posterior surface of the inferior margin of the symphysis pubis. This diameter cannot be measured directly; rather, it is estimated by subtracting 1 to 2 cm from the diagonal conjugate measurement. The average true conjugate diameter is at least 11.5 cm (Cunningham et al., 2014). This measurement is important because it is the smallest front-to-back diameter through which the fetal head must pass when moving through the pelvic inlet.

The ischial tuberosity diameter is the transverse diameter of the pelvic outlet. This measurement is made outside the pelvis at the lowest aspect of the ischial tuberosities. A diameter of 10.5 cm or more is considered adequate for passage of the fetal head (Tharpe, Farley, & Jordan, 2016).

Laboratory Tests

A series of tests is generally ordered during the initial visit so that baseline data can be obtained, allowing for early detection and prompt intervention if any problems occur. Tests that are generally conducted for all pregnant women include urinalysis and blood studies. The urine is analyzed for albumin, glucose, ketones, and bacteria casts. Blood studies usually include a complete blood count (hemoglobin, hematocrit, red and white blood cell counts, and platelets), blood typing and Rh factor, glucose screening for high-risk women, a rubella titer, hepatitis B surface antibody antigen, HIV, venereal disease research laboratory (VDRL) or rapid plasma reagin (RPR) tests, and cervical smears to detect STIs (Common Laboratory and Diagnostic Tests 12.1). In addition, most offices and clinics have ultrasound equipment available to validate an intrauterine pregnancy and assess early fetal growth.

The need for additional laboratory studies is determined by a woman's history, physical examination findings, current health status, and risk factors identified in the initial interview. Additional tests can be offered (e.g., screening for genetic diseases, blood lead screening, rubeola, and so on), but ultimately the woman and her partner make the decision about undergoing them. Educate the client and her partner about the tests, including the rationale. In addition, support the client and her partner in their decision-making process, regardless of whether you agree with the couple's decision. The couple's decisions about their health care are based on the ethical principle of autonomy, which allows an individual the right to make decisions about his or her own body.

Remember Linda and Rob, the couple who want to start a family? Ten months after the preconception appointment, Linda calls to make a first prenatal appointment. What key areas will be addressed at this first prenatal visit? What interventions might be suggested for Linda to implement in order to ensure a healthy newborn? What emotional support might be needed by Linda at this time in her first trimester of pregnancy?

COMMON LABORATORY AND DIAGNOSTIC TESTS 12.1

Test	Explanation
Complete blood cell count (CBC)	Evaluates hemoglobin (12–14 g) and hematocrit (42% ± 5) levels and red blood cell count (4.2–5.4 million/mm^3) to detect presence of anemia; identifies white blood cell level (5,000–10,000/mm^3), which if elevated may indicate an infection; determines platelet count (150,000–450,000 mL^3) to assess clotting ability
Blood typing	Determines woman's blood type and Rh status to rule out any blood incompatibility issues early; Rh-negative mother would likely receive RhoGAM (at 28 wks' gestation) and again within 72 hrs after childbirth, if she is Rh sensitive
Rubella titer	Detects antibodies for the virus that causes German measles; if titer is 1:8 or less, the woman is not immune; requires immunization after birth; and woman is advised to avoid people with undiagnosed rashes
Hepatitis B	Determines if mother has hepatitis B by detecting presence of hepatitis antibody surface antigen (HbsAg) in her blood
HIV testing	Detects HIV antibodies and if positive requires more specific testing, counseling, and treatment during pregnancy with antiretroviral medications to prevent transmission to fetus
STI screening: Venereal Disease Research Laboratory (VDRL) or rapid plasma reagin (RPR) serologic tests or by cervical smears, cultures, or visual identification of suspicious lesions	Detects STIs (such as syphilis, herpes, HPV, gonorrhea) so that treatment can be initiated early to prevent transmission to fetus
Cervical smears	Detects abnormalities such as cervical cancer (Pap test) or infections such as gonorrhea, chlamydia, or group B streptococcus so that treatment can be initiated if positive

(2014). *Ferri's best test: A practical guide to laboratory medicine and diagnostic imaging* (3rd ed.). Philadelphia, PA: Elsevier Health Sciences.

FOLLOW-UP VISITS

Continuous prenatal care is important for a successful pregnancy outcome. The recommended follow-up visit schedule for a healthy pregnant woman is as follows:

- Every 4 weeks up to 28 weeks (7 months)
- Every 2 weeks from 29 to 36 weeks
- Every week from 37 weeks to birth

At each subsequent prenatal visit the following assessments are completed:

- Weight and blood pressure, which are compared with baseline values
- Urine testing for protein, glucose, ketones, and nitrites
- Fundal height measurement to assess fetal growth
- Assessment for quickening/fetal movement to determine fetal well-being
- Assessment of fetal heart rate (should be 110 to 160 bpm)

At each follow-up visit answer questions, provide anticipatory guidance and education, review nutritional guidelines, and evaluate the client for adherence to prenatal vitamin therapy. Throughout the pregnancy, encourage the woman's partner to participate if possible.

Follow-Up Visit Intervals and Assessments

Up to 28 weeks' gestation, follow-up visits involve assessment of the client's blood pressure and weight. The urine is tested for protein and glucose. Fundal height and fetal heart rate are assessed at every office visit.

The best procedure for screening and diagnosing gestational diabetes remains controversial. All strategies involve an oral glucose test, but there remains

disagreement about how many grams of glucose (50, 75, or 100) the woman ingests and how long afterward, her blood sample is drawn. A recent *Cochrane Review* concluded that there was insufficient evidence to permit assessment of which is the best method to use to identify women who have gestational diabetes (Farrar et al., 2015). Screening for gestational diabetes is best done between 24 and 28 weeks' gestation, unless screening is warranted in the first trimester for high-risk reasons (obesity, >25 years old, family history of diabetes, history of gestational diabetes, or woman is of a certain ethnic group: Hispanic, Native Americans, Asian, or African American) (U.S. Preventive Services Task Force [USPSTF], 2015). Between weeks 24 and 28, a blood glucose level is obtained using an oral 50-g glucose load followed by a 1-hour plasma glucose determination. If the result is more than 130 (ADA) to 140 (ACOG) mg/dL, further testing, such as a 3-hour 100-g glucose tolerance test, is warranted to determine whether gestational diabetes is present (Farrar et al., 2015). Because insulin resistance increases as pregnancy advances, testing at this gestational point yields a higher rate of abnormal test results.

During this time, review the common discomforts of pregnancy, evaluate any client complaints, and answer questions. Reinforce the importance of good nutrition and use of prenatal vitamins, along with daily exercise.

Between 29 and 36 weeks' gestation, all the assessments of previous visits are completed, along with assessment for edema. Special attention is focused on the presence and location of edema during the last trimester. Pregnant women commonly experience dependent edema of the lower extremities from constriction of blood vessels secondary to the heavy gravid uterus. Periorbital edema around the eyes, edema of the hands, and pretibial edema (edema on the front, or shin part of the leg) are abnormal and could be signs of gestational hypertension. Inspecting and palpating both extremities, listening for complaints of tight rings on fingers, and observing for swelling around the eyes are important assessments. Abnormal findings in any of these areas need to be reported.

If the mother is Rh negative, her antibody titer is evaluated. RhoGAM is given if indicated. RhoGAM is used to prevent development of antibodies to Rh^+ red cells whenever fetal cells are known or suspected of entering the maternal circulation such as after a spontaneous abortion or **amniocentesis**. It is also recommended for prophylaxis at 28 weeks' gestation and following birth if the infant is Rh^+ (King et al., 2015). The client also is evaluated for risk of preterm labor. At each visit, ask if she is experiencing any common signs or symptoms of preterm labor (e.g., uterine contractions, dull backache, feeling of pressure in the pelvic area or thighs, increased vaginal discharge, menstrual-like cramps, vaginal bleeding). If the woman has had a previous preterm birth, she is at risk for another and close monitoring is warranted. An initial preterm labor evaluation if the woman reports signs and symptoms of preterm labor includes review of prenatal record for risk factors, evaluation of reported symptoms (uterine contractions, vital signs, fetal heart rate, pelvic examination for cervical dilation and effacement assessment, and status of fetal membranes), and a urine culture to diagnose asymptomatic bacteriuria (Jordan et al., 2014). If positive for preterm labor, the woman may be requested to rest and medications to stop contractions may be in order.

Counsel the woman about choosing a health care provider for the newborn, if she has not selected one yet. Along with completion of a breast assessment, the nurse

should discuss and educate the client about the choice of breast-feeding versus bottle-feeding. The American Academy of Pediatrics does encourage all mothers to breast-feed their offspring, but the decision to do so is the woman's ultimately. The nurse can refer the client to *Nursing Mothers* and *La Leche League* web sites for further information to assist her in making that decision. Reinforce the importance of daily fetal movement monitoring as an indicator of fetal well-being. Reevaluate hemoglobin and hematocrit levels to assess for anemia.

Between 37 and 40 weeks' gestation, the same assessments are done as for the previous weeks. In addition, screening for group B streptococcus, gonorrhea, and chlamydia is done. Fetal presentation and position (via Leopold maneuvers) are assessed. Review the signs and symptoms of labor and forward a copy of the prenatal record to the hospital labor department for future reference. Review the client's desire for family planning after birth as well as her decision to breast-feed or bottle-feed. Remind the client that an infant car seat is required by law and must be used to drive the newborn home from the hospital or birthing center.

Fundal Height Measurement

Fundal height is the distance (in centimeters) measured with a tape measure from the top of the pubic bone to the top of the uterus (fundus) with the client lying on her back with her knees slightly flexed (Fig. 12.5). Measurement in this way is termed the McDonald method. Fundal height typically increases as the pregnancy progresses; it reflects fetal growth and provides a gross estimate of the duration of the pregnancy.

FIGURE 12.5 Fundal height measurement.

Between 12 and 14 weeks' gestation, the fundus can be palpated above the symphysis pubis. The fundus reaches the level of the umbilicus at approximately 20 weeks and measures 20 cm. Fundal measurement should approximately equal the number of weeks of gestation until week 36. For example, a fundal height of 24 cm suggests a fetus at 24 weeks' gestation. After 36 weeks, the fundal height then drops due to lightening and may no longer correspond with the week of gestation.

It is expected that the fundal height will increase progressively throughout the pregnancy, reflecting fetal growth. However, if the growth curve flattens or stays stable, it may indicate the presence of FGR. If the fundal height measurement is greater than 4 cm from the estimated gestational age, further evaluation is warranted if a multifetal gestation has not been diagnosed or hydramnios has not

been ruled out (Weber & Kelley, 2014).

Fetal Movement Determination

Perception of fetal movement typically begins in the second trimester, and occurs earlier in multiparous women verses nulliparous women. The mother's first perception of fetal movement, termed "quickening," is commonly described as a gentle fluttering. This perceived fetal movement is most often related to trunk and limb motion and rollovers, or flips (Moses, 2015b). Maternal perception of fetal movement is an important screening method for fetal well-being, because decreased fetal movement is associated with a range of pregnancy pathologies and poor pregnancy outcomes. Decreased fetal movement may indicate asphyxia and FGR. If compromised, the fetus decreases its oxygen requirements by decreasing activity. Reduced fetal movement is thought to represent fetal compensation in a chronic hypoxic environment due to inadequacies in the placental supply of oxygen and nutrients (Fretts, 2014). A decrease in fetal movement may also be related to other factors as well, such as maternal use of central nervous system depressants, fetal sleep cycles, hydrocephalus, bilateral renal agenesis, stillbirth, placental dysfunction, and bilateral hip dislocation (Heazell, 2015).

Fetal movement counting is a method used by the mother to quantify her fetus's movement. However, the optimal number of movements and the ideal duration of counting them remain controversial. Many variations for determining fetal movement, also called fetal movement counts, have been developed, but the one most common method is described as follows. Determining fetal movement is a noninvasive method of screening and can be easily taught to all pregnant women. Any technique used requires client participation and cooperation.

Instruct the client about how to count fetal movements, the reasons for doing so, and the significance of decreased fetal movements. Urge the client to perform the counts in a relaxed environment and a comfortable position, such as semi-Fowler's or side-lying. Provide the client with detailed information concerning fetal movement counts and stress the need for consistency in monitoring (at approximately the same time each day) and the importance of informing the health care provider promptly of any reduced movements. Providing clients with "fetal kick count" charts to record movement helps promote adherence to your instructions. No values for fetal movement have been established that indicate fetal well-being, so the woman needs to be aware of a decrease in the number of movements when last assessed. The most common method used is "Count to 10," whereby a woman focuses her attention on her fetus's movement and records how long it takes to document 10 movements. If it takes longer than 2 hours, the woman should contact her health care provider for further evaluation. Fetal kick counting in current prenatal care appears to be underutilized and nurses need to educate women about this assessment in their pregnancy care.

Fetal Heart Rate Measurement

Fetal heart rate measurement is integral to fetal surveillance throughout the pregnancy. Auscultating the fetal heart rate with a handheld Doppler at each prenatal visit helps confirm that the intrauterine environment is still supportive to the growing fetus. The purpose of assessing fetal heart rate is to determine rate and

rhythm. The normal fetal heart rate range is 110 to 160 bpm. Nursing Procedure 12.1 lists the steps in measuring fetal heart rate.

Teaching About the Danger Signs of Pregnancy

It is important to educate the client about danger signs during pregnancy that require further evaluation. Explain that she should contact her health care provider immediately if she experiences any of the following:

- *During the first trimester:* spotting or bleeding (miscarriage), painful urination (infection), severe persistent vomiting (hyperemesis gravidarum), fever >100°F (37.7°C; infection), and lower abdominal pain with dizziness and accompanied by shoulder pain (ruptured ectopic pregnancy)
- *During the second trimester:* regular uterine contractions (preterm labor); pain in calf, often increased with foot flexion (blood clot in deep vein); sudden gush or leakage of fluid from vagina (premature rupture of membranes); and absence of fetal movement for more than 12 hours (possible fetal distress or demise)
- *During the third trimester:* sudden weight gain; periorbital or facial edema, severe upper abdominal pain, or headache with visual changes (gestational hypertension and/or preeclampsia); and a decrease in fetal daily movement for more than 24 hours (possible demise). Any of the previous warning signs and symptoms can also be present in this last trimester (March of Dimes, 2015a).

NURSING PROCEDURE 12.1

Measuring Fetal Heart Rate

Purpose: To assess fetal well-being

1. Assist the woman onto the examining table and have her lie down.
2. Cover her with a sheet to ensure privacy, and then expose her abdomen.
3. Palpate the abdomen to determine the fetal lie, position, and presentation.
4. Locate the back of the fetus (the ideal position to hear the heart rate).
5. Apply lubricant gel to abdomen in the area where the back has been located.
6. Turn on the handheld Doppler device and place it on the spot over the fetal back.
7. Listen for the sound of the amplified heart rate, moving the device slightly from side to side as necessary to obtain the loudest sound. Assess the woman's pulse rate and compare it to the amplified sound. If the rates appear the same, reposition the Doppler device.
8. Once the fetal heart rate has been identified, count the number of beats in 1 minute and record the results.
9. Remove the Doppler device and wipe off any remaining gel from the woman's abdomen and the device.
10. Record the heart rate on the woman's medical record; normal range is 110 to 160 bpm.
11. Provide information to the woman regarding fetal well-being based on findings.

Early Contractions

One of the warning signs that should be emphasized is early contractions, which can lead to preterm birth. The woman should not confuse these early preterm contractions with Braxton Hicks contractions, which are not true labor pains because they go away when walking around or resting. They often go away when the woman goes to sleep. Braxton Hicks contractions are usually felt in the abdomen versus in the lower back with true preterm labor contractions. Signs of preterm labor that a woman may experience include contractions every 10 minutes or more frequently, change in vaginal discharge, pelvic pressure, low, dull backache, pelvic cramps, and diarrhea (Nagtalon-Ramos, 2014).

All pregnant women need to be able to recognize early signs of contractions to prevent preterm labor, which is a major public health problem in the United States. Approximately 12% of all live births—or one out of nine infants—is born too soon. Our nation's rate of premature births has increased by 36% over the last 25 years. Worldwide, 15 million infants are born too soon each year (March of Dimes, 2015b). These preterm infants (born at less than 37 weeks' gestation) can suffer lifelong health consequences such as intellectual disability, chronic lung disease, cerebral palsy, seizure disorders, and blindness (March of Dimes, 2015c). Preterm labor can happen to any pregnant women at any time. In many cases it can be stopped with medications if it is recognized early, before significant cervical dilation has taken place. If the woman experiences menstrual-like cramps occurring every 10 minutes accompanied by a low, dull backache, she should stop what she is doing and lie down on her left side for 1 hour and drink two or three glasses of water. If the symptoms worsen or do not subside after 1 hour, she should contact her health care provider.

ASSESSMENT OF FETAL WELL-BEING

During the antepartum period, several tests are performed routinely to monitor fetal well-being and to detect possible problems. When a **high-risk pregnancy** is identified, additional antepartum testing can be initiated to promote positive maternal, fetal, and neonatal outcomes. High-risk pregnancies include those that are complicated by maternal or fetal conditions (coincidental with or unique to pregnancy) that jeopardize the health status of the mother and put the fetus at risk for uteroplacental insufficiency, hypoxia, and death (CDC, 2015d). However, additional antepartum fetal testing should take place only when the results obtained will guide future care, whether it is reassurance, more frequent testing, admission to the hospital, or the need for immediate delivery (Brown, 2015).

Ultrasonography

Since its introduction in the late 1950s, ultrasonography has become a very useful diagnostic tool in obstetrics. Real-time scanners can produce a continuous picture of the fetus on a monitor screen. A transducer that emits high-frequency sound waves is placed on the mother's abdomen and moved to visualize the fetus (Fig. 12.6). The fetal heartbeat and any malformations in the fetus can be assessed and measurements can be made accurately from the picture on the monitor screen.

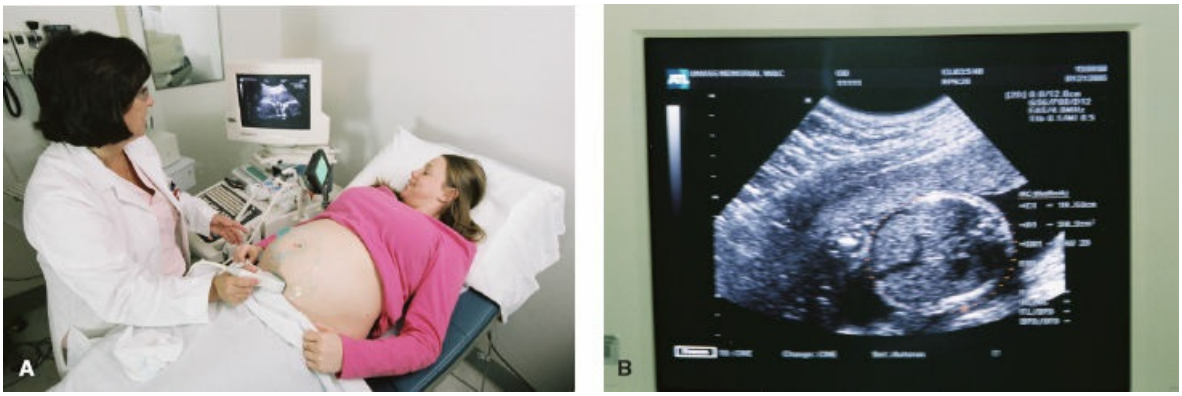

FIGURE 12.6 Ultrasound. A. Ultrasound device being applied to client's abdomen. B. View of monitor.

Obstetric ultrasound is a standard component of prenatal care used to identify pregnancy complications and to establish an accurate gestational age in order to improve pregnancy outcomes. Because the ultrasound procedure is noninvasive, it is a safe, but not evidence-based practice for low-risk women, accurate, and cost-effective tool. It provides important information about fetal activity, growth, and gestational age; assesses fetal well-being; and determines the need for invasive intrauterine tests (Maeda, 2015).

There are no hard-and-fast rules as to the number of ultrasounds a woman should have during her pregnancy. A low-risk woman does not necessarily require any, but most practices do them as part of their prenatal care routine. A transvaginal ultrasound may be performed in the first trimester to confirm pregnancy, exclude ectopic (in which a fertilized egg implants somewhere other than the main cavity of the uterus) or molar (hydatidiform mole, a benign tumor that develops in the uterus) pregnancies, and confirm cardiac pulsation. A second abdominal scan may be performed at about 18 to 20 weeks to look for congenital malformations, exclude multifetal pregnancies, and verify dates and growth. A third abdominal scan may be done at around 34 weeks to evaluate fetal size, assess fetal growth, and verify placental position (Everett & Peebles, 2015). An ultrasound is used to confirm placental location during amniocentesis and to provide visualization during **chorionic villus sampling (CVS)**. An ultrasound is also ordered whenever an abnormality is suspected.

During the past several years, ultrasound technology has advanced significantly. Now available for expecting parents is 3D/4D ultrasound imaging. Unlike traditional 2D imaging, which takes a look at the developing fetus from one angle (thus creating the "flat" image), 3D imaging takes a view of the fetus from three different angles. Software then takes these three images and merges them to produce a three-dimensional image. Because the fourth dimension is time and movement, with 4D parents are able to watch the live movements of their fetus in 3D.

Nursing management during the ultrasound procedure focuses on educating the woman about the ultrasound test and reassuring her that she will not experience any sensation from the sound waves during the test. No special client preparation is needed before performing the ultrasound, although in early pregnancy the woman may need to have a full bladder. Inform her that she may experience some discomfort from the pressure on the full bladder during the scan, but it will last only a short time. Tell the client that the conducting gel used on the abdomen during the

scan may feel cold initially.

Doppler Flow Studies

Comprehensive assessment of fetal well-being involves monitoring of fetal growth, placental function, central venous pressure, and cardiac function. Ultrasound evaluation of the fetus using 2D, color Doppler, and pulse-wave Doppler techniques forms the foundation of prenatal diagnosis of structural anomalies, rhythm abnormalities, and altered fetal circulation (Pruetz, Votava-Smith, & Miller, 2015). Doppler flow studies can be used to measure the velocity of blood flow via ultrasound. Doppler flow studies can detect fetal compromise in high-risk pregnancies. The test is noninvasive and has no contraindications. The color images produced help to identify abnormalities in diastolic flow within the umbilical vessels. The velocity of the fetal red blood cells can be determined by measuring the change in the frequency of the sound wave reflected off the cells. Thus, Doppler flow studies can detect the movement of red blood cells in vessels (Everett & Peebles, 2015). In pregnancies complicated by hypertension or FGRs diastolic blood flow may be absent or even reversed (Alfirevic, Stampalija, & Medley, 2015). Doppler flow studies also can be used to evaluate the blood flow through other fetal blood vessels, such as the aorta and those in the brain. Research continues to determine the indications for Doppler flow studies to improve pregnancy outcomes. Nursing management of the woman undergoing Doppler flow studies is similar to that described for an ultrasound.

Alpha-Fetoprotein Analysis

Alpha-fetoprotein (AFP) is a glycoprotein produced initially by the yolk sac and fetal gut, and later predominantly by the fetal liver. In a fetus, the serum AFP level increases until approximately 14 to 15 weeks, and then falls progressively. In normal pregnancies, AFP from fetal serum enters the amniotic fluid (in microgram quantities) through fetal urination, fetal gastrointestinal secretions, and transudation across fetal membranes (amnion and placenta). About 30 years ago, elevated levels of maternal serum AFP (MSAFP) or amniotic fluid AFP were first linked to the occurrence of fetal neural tube defects. This biomarker screening test is now recommended for all pregnant women along with other prenatal screening test depending on risk profile (Alexander et al., 2014; American College of Obstetricians and Gynecologists, 2015b).

AFP is present in amniotic fluid in low concentrations between 10 and 14 weeks of gestation and can be detected in maternal serum beginning at approximately 12 to 14 weeks of gestation (Callahan, 2016). If a developmental defect is present, such as failure of the neural tube to close, more AFP escapes into amniotic fluid from the fetus. AFP then enters the maternal circulation by crossing the placenta, and the level in maternal serum can be measured. The optimal time for AFP screening is 16 to 18 weeks of gestation. Currently, ACOG recommends offering screening and diagnostic tests to all pregnant women, regardless of age or risk factors present (2015b). Correct information about gestational dating, maternal weight, race, number of fetuses, and insulin dependency is necessary to ensure the accuracy of this screening test. If incorrect maternal information is submitted or the blood specimen is not drawn during the appropriate time frame, false-positive results may

occur, increasing the woman's anxiety. Subsequently, further testing might be ordered based on an inaccurate interpretation, resulting in additional financial and emotional costs to the woman.

A variety of situations can lead to elevation of MSAFP, including open neural tube defect, underestimation of gestational age, the presence of multiple fetuses, gastrointestinal defects, low birth weight, oligohydramnios, maternal age, diabetes, and decreased maternal weight (King et al., 2015). Lower-than-expected MSAFP levels are seen when fetal gestational age is overestimated or in cases of fetal death, hydatidiform mole, increased maternal weight, maternal type 1 diabetes, and fetal trisomy 21 (Down syndrome) or trisomy 18 (Edwards syndrome) (Khalil & Coates, 2015).

Measurement of MSAFP is minimally invasive, requiring only a venipuncture for a blood sample. AFP has now been combined with other biomarker screening tests to determine the risk of neural tube defects and Down syndrome.

Nursing management for AFP testing consists of preparing the woman for this screening test by gathering accurate information about the date of her LMP, weight, race, and gestational dating. Accurately determining the window of 16 to 18 weeks' gestation will help to ensure that the test results are correct. Also explain that the test involves obtaining a blood specimen.

Marker Screening Tests

Using maternal serum is an effective, noninvasive method for identifying fetal risk for aneuploidy (trisomies 13, 18, & 21) and neural tube defects. Prenatal screening for Down syndrome in the early second trimester with multiple maternal serum markers has been available for more than 15 years. Abnormalities in maternal serum marker levels and fetal measurements obtained during the first trimester screening can be markers for not only certain chromosomal disorders and anomalies in the fetus, but also for specific pregnancy complications. Pregnancy-associated plasma protein A (PAPP-A) is a key regulator of insulin-like growth factor essential for normal fetal development. In maternal blood, this protein increases with gestational age. It is routinely used for Down syndrome screening in the first trimester. A low maternal serum PAPP-A, at 11 to 13 weeks of gestation, is associated with stillbirth, infant death, preterm birth, preeclampsia, and chromosomal abnormalities (Kalousova, Muravska, & Zima, 2014; Patil, Panchanadikar, & Wagh, 2014). Multiple blood screening tests may be used to determine the risk of open neural tube defects and Down syndrome: the triple-marker screen (AFP, hCG, and unconjugated estriol) or the quad screen, which includes the triple screening tests with the addition of a fourth marker, inhibin A (glycoprotein secreted by the placenta). The quad screen is used to enhance the accuracy of screening for Down syndrome in women younger than 35 years of age. Low inhibin A levels indicate the possibility of Down syndrome (ACOG, 2015b). These biomarkers are merely screening tests and identify women who need further definitive procedures (i.e., ultrasound, amniocentesis, and genetic counseling) to make a diagnosis of neural tube defects (anencephaly, spina bifida, and encephalocele) or Down syndrome in the fetus. Most screening tests are performed between 15 to 22 weeks of gestation (16 to 18 weeks is ideal), except for the cffDNA test which can be performed around 9 to 10 weeks' gestation (Dempsey & Overton,

2015).

With these multiple screening tests, low MSAFP, unconjugated estriol levels, and a high hCG level suggest the possibility of Down syndrome. Elevated levels of MSAFP are associated with open neural tube defects, ventral wall defects, some renal abnormalities, multiple gestation, certain skin disorders, fetal demise, and placental abnormality. The multiple marker combination with the highest screening performance currently available is AFP, unconjugated estriol (uE3), hCG, and inhibin A, together with maternal age (the so-called quad marker test). With this combination, a detection rate of 80% at a 5% false-positive rate is achieved (Hixson et al., 2015).

A number of factors influence the interpretation of an MSAFP value. The most important is the accuracy of the gestational age determination. A variation of 2 weeks can be misleading and lead to a wrong interpretation. Maternal weight (>250 lb), ethnicity, maternal smoking habits, fetal gender, gravidity, para status, and women with insulin-dependent diabetes also may alter the levels of MSAFP and need to be taken into consideration when interpreting the results (Latendresse & Deneris, 2015). Recent research studies indicate prenatal testing with the use of cell free DNA (cfDNA) has significantly lower false positives and high positive predictive values for detection of trisomies than standard testing (Greeley, Kessler, & Vohra, 2015).

Nursing Management

Accurate test interpretation and risk determination are dependent on accurate pregnancy dating and reporting of relevant maternal characteristics. This is why it is so important for nurses, if an abnormal test result is reported, for them to confirm pregnancy dating and report any significant maternal factors relevant to test accuracy. In addition, nurses have a big role in providing education about the tests to the couples. Prenatal screening has become standard in prenatal care. However, for many couples it remains confusing, emotionally charged, and filled with uncertain risks. Offer a thorough explanation of the test, reinforcing the information given by the health care professional. Provide couples with a description of the risks and benefits of performing these screens, emphasizing that these tests are for screening purposes only. Remind the couple that a definitive diagnosis is not made without further tests such as an amniocentesis. Answer any questions about these prenatal screening tests and respect the couple's decision if they choose not to have them done. Many couples may choose not to know because they would not consider having an abortion regardless of the test results.

Nuchal Translucency Screening

Nuchal translucency screening (ultrasound) is also done in the first trimester between 11 and 14 weeks. This allows for early detection and diagnosis of some fetal chromosomal and structural abnormalities. Over the years, it has become clear that increased nuchal translucency is a marker for chromosomal abnormalities, and is also associated with a wide spectrum of structural anomalies, genetic syndromes, and high risk of abortion and fetal death (Rayburn, Jolley, & Simpson, 2015). Ultrasound is used to identify an increase in nuchal translucency, which is due to the subcutaneous accumulation of fluid behind the fetal neck. Increased nuchal

translucency is associated with chromosomal abnormalities such as trisomy 21, 18, and 13. Infants with trisomies tend to have more collagen and elastic connective tissue, allowing for accumulation. In addition, diaphragmatic hernias, cardiac defects, and fetal skeletal and neurologic abnormalities have been associated with increased nuchal translucency measurements (Evans, Andriole, & Evans, 2015). See Chapter 10 for more information.

Amniocentesis

Amniocentesis involves a transabdominal puncture of the amniotic sac to obtain a sample of amniotic fluid for analysis. The fluid contains fetal cells that are examined to detect chromosomal abnormalities and several hereditary metabolic defects in the fetus before birth. In addition, amniocentesis is used to confirm a fetal abnormality when other screening tests detect a possible problem.

Amniocentesis is performed in the second trimester, usually between 15 and 18 weeks' gestation. At this age, the amount of fluid is adequate (approximately 150 mL), and the ratio of viable to nonviable cells is greatest (Hehir, Dalrymple, & Malone, 2015). More than 40 different chromosomal abnormalities, inborn errors of metabolism, and neural tube defects can be diagnosed with amniocentesis. It can replace a genetic probability with a diagnostic certainty, allowing the woman and her partner to make an informed decision about the option of therapeutic abortion.

Amniocentesis can be performed in any of the three trimesters of pregnancy. An early amniocentesis (performed between weeks 11 and 14) is done to detect genetic anomalies. However, early amniocentesis has been associated with a high risk of spontaneous miscarriage and postprocedural amniotic fluid leakage compared with transabdominal chorionic villus screening (King et al., 2015).

In the second trimester the procedure is performed between 15 and 20 weeks to detect chromosomal abnormalities, evaluate the fetal condition when the woman is sensitized to the Rh-positive blood, diagnose intrauterine infections, and investigate amniotic fluid AFP when the MSAFP level is elevated (March of Dimes, 2015d).

In the third trimester amniocentesis is most commonly indicated to determine fetal lung maturity after the 35th week of gestation via analysis of lecithin-to-sphingomyelin ratios and to evaluate the fetal condition with Rh isoimmunization. Table 12.2 lists amniotic fluid analysis findings and their implications.

TABLE 12.2 AMNIOTIC FLUID ANALYSIS AND IMPLICATIONS

Test Component	Normal Findings	Fetal Implications of Abnormal Findings
Color	Clear with white flecks of vernix caseosa in a mature fetus	Blood of maternal origin is usually harmless. "Port wine" fluid may indicate abruptio placentae. Fetal blood may indicate damage to the fetal, placental, or umbilical cord vessels.
Bilirubin	Absent at term	High levels indicate hemolytic disease of the neonate in isoimmunized pregnancy.
Meconium	Absent (except in breech presentation)	Presence indicates fetal hypotension or distress.
Creatinine	More than 2 mg/dL in a mature fetus	Decrease may indicate immature fetus (less than 37 wks).
Lecithin-to-sphingomyelin ratio (L/S ratio)	More than 2 generally indicates fetal pulmonary maturity.	A ratio of less than 2 indicates pulmonary immaturity and subsequent respiratory distress syndrome.
Phosphatidylglycerol	Present	Absence indicates pulmonary immaturity.
Glucose	Less than 45 mg/dL	Excessive increases at term or near term indicate hypertrophied fetal pancreas and subsequent neonatal hypoglycemia.
Alpha-fetoprotein	Variable, depending on gestation age and laboratory technique; highest concentration (about 18.5 ng/mL) occurs at 13–14 wks	Inappropriate increases indicate neural tube defects such as spina bifida or anencephaly, impending fetal death, congenital nephrosis, or contamination of fetal blood.
Bacteria	Absent	Presence indicates chorioamnionitis.
Chromosomes	Normal karyotype	Abnormal karyotype may indicate fetal sex and chromosome disorders.
Acetylcholinesterase	Absent	Presence may indicate neural tube defects, exomphalos, or other serious malformations.

Procedure

Amniocentesis is performed after an ultrasound examination identifies an adequate pocket of amniotic fluid free of fetal parts, the umbilical cord, or the placenta (Fig. 12.7). The health care provider inserts a long pudendal or spinal needle, a 22-gauge, 5-in needle, into the amniotic cavity and aspirates amniotic fluid, which is placed in an amber or foil-covered test tube to protect it from light. When the desired amount of fluid has been withdrawn, the needle is removed and slight pressure is applied to the site. If there is no evidence of bleeding, a sterile bandage is applied to the needle site. The specimens are then sent to the laboratory immediately for the cytologist to evaluate.

Examining a sample of fetal cells directly produces a definitive diagnosis rather than a "best guess" diagnosis based on indirect screening tests. It is an invaluable diagnostic tool, but the risks include lower abdominal discomfort and cramping that may last up to 48 hours after the procedure, spontaneous abortion (1 in 200), maternal or fetal infection, postamniocentesis chorioamnionitis that has an insidious onset, fetal–maternal hemorrhage, leakage of amniotic fluid in 2% to 3% of women after the procedure, and higher rates of fetal loss in earlier amniocentesis procedures (<15 weeks' gestation) versus later ones (Akolekar et al., 2015). Obtaining the test results may take up to 3 weeks. Women today are choosing noninvasive prenatal testing rather than undergoing invasive testing such as

amniocentesis or CVS despite those tests not being 100% correct. Women with reassuring noninvasive results and normal ultrasound findings seem satisfied over the risk of procedure-related pregnancy loss (Biswas & Choolani, 2015). The number of invasive procedures has declined since the availability of noninvasive prenatal testing, and it is predicted that they will replace the more invasive procedures in the future.

FIGURE 12.7 **Technique for amniocentesis: Inserting needle.**

Nursing Management

When preparing the woman for an amniocentesis, explain the procedure and its potential complications, and encourage her to empty her bladder just before the procedure to avoid the risk of bladder puncture. Inform her that a 20-minute electronic fetal monitoring strip usually is obtained to evaluate fetal well-being and obtain a baseline to compare after the procedure is completed. Obtain and record maternal vital signs.

After the procedure, assist the woman to a position of comfort and administer RhoGAM intramuscularly if the woman is Rh negative to prevent potential sensitization to fetal blood. Assess maternal vital signs and fetal heart rate every 15 minutes for an hour after the procedure. Observe the puncture site for bleeding or drainage. Instruct the client to rest after returning home and remind her to report fever, leaking amniotic fluid, vaginal bleeding, or uterine contractions or any changes in fetal activity (increased or decreased) to the health care provider.

When the test results come back, be available to offer support, especially if a fetal abnormality is found. Also prepare the woman and her partner for the need for genetic counseling. Trained genetic counselors can provide accurate medical information and help couples to interpret the results of the amniocentesis so they can make the decisions that are right for them as a family.

Chorionic Villus Sampling

CVS is an invasive procedure involving an 18-gauge needle stick through the abdomen or passage of a suction catheter through the cervix under ultrasound

guidance. This test is used to obtain a sample of the chorionic villi from the placenta for prenatal evaluation of chromosomal disorders such as Down syndrome or cystic fibrosis, enzyme deficiencies, and fetal gender determination and to identify sex-linked disorders such as hemophilia, sickle cell anemia, and Tay–Sachs disease (Greeley, Kessler, & Vohra, 2015). Chorionic villi are finger-like projections that cover the embryo and anchor it to the uterine lining before the placenta is developed. Because they are of embryonic origin, sampling provides information about the developing fetus. CVS can be used to detect numerous genetic disorders, with the exception of neural tube defects (Latendresse & Deneris, 2015).

There has been an impetus to develop earlier prenatal diagnostic procedures so that couples can make an early decision to terminate the pregnancy if an anomaly is confirmed. Early prenatal diagnosis by CVS has been proposed as an alternative to routine amniocentesis, which carries fewer risks if done later in the pregnancy. In addition, results of CVS testing are available sooner than those of amniocentesis, usually within 48 hours.

Procedure

CVS is generally performed 10 to 13 weeks after the LMP. Earlier, chorionic villi may not be sufficiently developed for adequate tissue sampling and the risk of limb defects is increased (Khalil & Coates, 2015). First, an ultrasound is done to confirm gestational age and viability. Then, under continuous ultrasound guidance, CVS is performed using either a transcervical or transabdominal approach. With the transcervical approach, the woman is placed in the lithotomy position and a sterile catheter is introduced through the cervix and inserted in the placenta, where a sample of chorionic villi is aspirated. This approach requires the client to have a full bladder to push the uterus and placenta into a position that is more accessible to the catheter. A full bladder also helps in better visualization of the structures. With the transabdominal approach, an 18-gauge spinal needle is inserted through the abdominal wall into the placental tissue and a sample of chorionic villi is aspirated. Regardless of the approach used, the sample is sent to the cytogenetics laboratory for analysis.

Potential complications of CVS include postprocedure vaginal bleeding and cramping (most common), hematomas, spontaneous abortion, limb abnormalities, rupture of membranes, infection, chorioamnionitis, and fetal–maternal hemorrhage (March of Dimes, 2015e). The pregnancy loss rate or procedure-related miscarriage rate is approximately 0.5% to 1.0%, which is the same rate for amniocentesis. In addition, women who are Rh negative should receive immune globulin (RhoGAM) to avoid isoimmunization (Jordan et al., 2014).

Nursing Management

Explain to the woman that the procedure will last about 15 minutes. An ultrasound will be done first to locate the embryo, and a baseline set of vital signs will be taken before starting. Make sure she is informed of the risks related to the procedure, including their incidence. If a transabdominal CVS procedure is planned, advise her to fill her bladder by drinking increased amounts of water. Inform her that a needle will be inserted through her abdominal wall and samples will be collected. Once the samples are collected, the needle will be withdrawn and the samples will be sent to the genetics laboratory for evaluation.

For transcervical CVS, inform the women that a speculum will be placed into the vagina under ultrasound guidance. Then the vagina is cleaned and a small catheter is inserted through the cervix. The samples obtained through the catheter are then sent to a laboratory.

After either procedure, assist the woman to a position of comfort and clean any excess lubricant or secretions from the area. Instruct her about signs to watch for and report, such as fever, cramping, and vaginal bleeding. Urge her not to engage in any strenuous activity for the next 48 hours. Assess the fetal heart rate for changes and administer RhoGAM to an unsensitized Rh-negative woman after the procedure.

Nonstress Test

The nonstress test (NST) is the most common method of prenatal testing used in practice today. The NST provides an indirect measurement of uteroplacental function. Unlike the fetal movement counting done by the mother alone, this procedure requires specialized equipment and trained personnel. The basis for the NST is that the normal fetus produces characteristic fetal heart rate patterns in response to fetal movements. In the healthy fetus there is an acceleration of the fetal heart rate with fetal movement. Currently, an NST is recommended twice weekly (after 28 weeks of gestation) for clients with diabetes and other high-risk conditions, such as IUGR, preeclampsia, postterm pregnancy, renal disease, and multifetal pregnancies (Cunningham et al., 2014). NST is a noninvasive test that requires no initiation of contractions. It is quick to perform and there are no known side effects.

Procedure

Before the procedure the client eats a meal to stimulate fetal activity. Then she is placed in the left lateral recumbent position to avoid supine hypotension syndrome. An external electronic fetal monitoring device is applied to her abdomen. The device consists of two belts, each with a sensor. One of the sensors records uterine activity, while the second sensor records fetal heart rate. The client is handed an "event marker" with a button that she pushes every time she perceives fetal movement. When the button is pushed, the fetal monitor strip is marked to identify that fetal movement has occurred. The procedure usually lasts 20 to 30 minutes.

Nursing Management

Prior to the NST, explain the testing procedure and have the woman empty her bladder. Position her in a semi-Fowler position and apply the two external monitor belts. Document the date and time the test is started, client information, the reason for the test, and the maternal vital signs. Obtain a baseline fetal monitor strip over 15 to 30 minutes.

During the test, observe for signs of fetal activity with a concurrent acceleration of the fetal heart rate. Interpret the NST as reactive or nonreactive. A reactive NST includes at least two fetal heart rate accelerations from the baseline of at least 15 bpm for at least 15 seconds within the 20-minute recording period. If the test does not meet these criteria after 40 minutes, it is considered nonreactive. A nonreactive NST is characterized by the absence of two fetal heart rate accelerations using the 15-by-15 criterion in a 20-minute time frame. A nonreactive test has been correlated with a higher incidence of fetal distress during labor, fetal mortality, and IUGR.

Additional testing, such as a **biophysical profile (BPP)**, should be considered (King et al., 2015).

After the NST procedure, assist the woman off the table, provide her with fluids, and allow her to use the restroom. Typically the health care provider discusses the results with the woman at this time. Provide teaching about signs and symptoms to report. If serial NSTs are being done, schedule the next testing session.

Biophysical Profile

A BPP uses a real-time ultrasound and NST to allow assessment of various parameters of fetal well-being. A BPP includes ultrasound monitoring of fetal movements, fetal tone, and fetal breathing and ultrasound assessment of amniotic fluid volume with or without assessment of the fetal heart rate. A BPP is performed in an effort to identify infants who may be at risk of poor pregnancy outcome, so that additional assessments of well-being may be performed, or labor may be induced or a caesarean section performed to expedite birth. The primary objectives of the BPP are to reduce stillbirth and to detect hypoxia early enough to allow delivery in time to avoid permanent fetal damage resulting from fetal asphyxia. These parameters, together with the NST, constitute the BPP. Each parameter is controlled by a different structure in the fetal brain: fetal tone by the cortex; fetal movements by the cortex and motor nuclei; fetal breathing movements by the centers close to the fourth ventricle; and the NST by the posterior hypothalamus and medulla. The amniotic fluid is the result of fetal urine volume. Some facilities do not perform an NST unless other parameters of the profile are abnormal (King et al., 2015). The BPP is based on the concept that a fetus that experiences hypoxia loses certain behavioral parameters in the reverse order in which they were acquired during fetal development (normal order of development: tone at 8 weeks; movement at 9 weeks; breathing at 20 weeks; and fetal heart rate reactivity at 24 weeks).

Scoring and Interpretation

The BPP is a scored test with five components, each worth 2 points if present. A total score of 10 is possible if the NST is used. Thirty minutes are allotted for testing, although less than 10 minutes is usually needed. The following criteria must be met to obtain a score of 2; anything less is scored as 0 (Moses, 2015c):

- *Body movements:* three or more discrete limb or trunk movements
- *Fetal tone:* one or more instances of full extension and flexion of a limb or trunk
- *Fetal breathing:* one or more fetal breathing movements of more than 30 seconds
- *Amniotic fluid volume:* one or more pockets of fluid measuring 2 cm
- *NST:* normal NST = 2 points; abnormal NST = 0 points

Interpretation of the BPP score can be complicated, depending on several fetal and maternal variables. Because it is indicated as a result of a nonreassuring finding from previous fetal surveillance tests, this test can be used to quantify the interpretation, and intervention can be initiated if appropriate. A maximum score of 10 can be achieved and the test is complete once all of the variables have been observed. For the test to be judged abnormal and a score of zero awarded for the absence of fetal movement, fetal tone, or fetal breathing movements, a period of not less than 30 minutes must have elapsed. Because of the excellent sensitivity of fetal NST for fetal acidemia, it has been proposed that this acute marker alone may be

used for fetal assessment in combination with the amniotic fluid volume assessment, a chronic marker. This combination, also known as the modified BPP, has been shown to have excellent false-negative rates that compare with that of the complete BPP. In addition, a recent study reported that BPP scores correlate fairly closely with the APGAR scores obtained after birth (Nisa et al., 2015).

One of the important factors is the amniotic fluid volume, taken in conjunction with the results of the NST. Amniotic fluid is largely composed of fetal urine. As placental function decreases, perfusion of fetal organs, such as kidneys, decreases, and this can lead to a reduction of amniotic fluid. If oligohydramnios or decreased amniotic fluid is present, the potential exists for antepartum or intrapartum fetal compromise (Lakshmi & Jyothsna, 2015).

Overall, a score of 8 to 10 is considered normal if the amniotic fluid volume is adequate. A score of 6 or below is suspicious, possibly indicating a compromised fetus; further investigation of fetal well-being is needed.

Because the BPP is an ultrasonographic assessment of fetal behavior, it requires more extensive equipment and more highly trained personnel than other testing modalities. The cost is much greater than with less sophisticated tests. It permits conservative therapy and prevents premature or unnecessary intervention. There are fewer false-positive results than with the NST alone (Callahan, 2016).

Nursing Management

Nursing management focuses primarily on offering the client support and answering her questions. Expect to complete the NST before scheduling the BPP, and explain why further testing might be needed. Tell the woman that the ultrasound will be done in the diagnostic imaging department.

NURSING MANAGEMENT FOR THE COMMON DISCOMFORTS OF PREGNANCY

Most women experience common discomforts during pregnancy and ask a nurse's advice about ways to minimize them. However, other women will not bring up their concerns unless asked. Therefore, the nurse needs to address the common discomforts that occur in each trimester at each prenatal visit and provide realistic measures to help the client deal with them (Teaching Guidelines 12.1). Nursing Care Plan 12.1 (at the end of the chapter) applies the nursing process to the care of a woman experiencing some discomforts of pregnancy.

Teaching Guidelines 12.1

TEACHING TO MANAGE THE DISCOMFORTS OF PREGNANCY

Urinary Frequency or Incontinence

- Try pelvic floor exercises to increase control over leakage.
- Empty your bladder when you first feel a full sensation.
- Avoid caffeinated drinks, which stimulate voiding.
- Reduce your fluid intake after dinner to reduce nighttime urination.

Fatigue

- Attempt to get a full night's sleep, without interruptions.
- Eat a healthy balanced diet.
- Schedule a nap in the early afternoon daily.
- When you are feeling tired, rest.

Nausea and Vomiting

- Avoid an empty stomach at all times.
- Eat dry crackers/toast in bed before arising.
- Eat several small meals throughout the day.
- Avoid brushing teeth immediately after eating to avoid gag reflex.
- Acupressure wristbands can be worn daily.
- Drink fluids between meals rather than with meals.
- Avoid greasy, fried foods or ones with a strong odor, such as cabbage or Brussels sprouts.

Backache

- Avoid standing or sitting in one position for long periods.
- Apply heating pad (low setting) to the small of your back.
- Support your lower back with pillows when sitting.
- Use proper body mechanics for lifting anything.
- Avoid excessive bending, lifting, or walking without rest periods.
- Wear supportive low-heeled shoes; avoid high heels.
- Stand with your shoulders back to maintain correct posture.

Leg Cramps

- Elevate legs above heart level frequently throughout the day.
- If you get a cramp, straighten both legs and flex your feet toward your body.
- Ask your health care provider about taking additional calcium supplements, which may reduce leg spasms.

Varicosities

- Walk daily to improve circulation to extremities.
- Elevate both legs above heart level while resting.
- Avoid standing in one position for long periods of time.
- Don't wear constrictive stockings and socks.
- Don't cross the legs when sitting for long periods.
- Wear support stockings to promote better circulation.

Hemorrhoids

- Establish a regular time for daily bowel elimination.
- Avoid constipation and straining during defecation.
- Prevent straining by drinking plenty of fluids and eating fiber-rich foods and exercising daily.
- Use warm sitz baths and cool witch hazel compresses for comfort.

Constipation

- Increase your intake of foods high in fiber and drink at least eight 8-oz glasses of fluid daily.

- Ingest prunes or prune juice which are natural laxatives.
- Consume warm liquids (tea) on rising, to stimulate peristalsis.
- Exercise each day (brisk walking) to promote movement through the intestine.
- Reduce the amount of cheese consumed.

Heartburn/Indigestion

- Avoid spicy or greasy foods and eat small frequent meals.
- Sleep on several pillows so that your head is elevated 30 degrees.
- Stop smoking and avoid caffeinated drinks to reduce stimulation.
- Avoid lying down for at least 3 hours after meals.
- Try drinking sips of water to reduce burning sensation.
- Avoid foods that trigger symptoms—fried foods, citrus, soda, chocolate.
- Take antacids sparingly if burning sensation is severe.

Braxton Hicks Contractions

- Keep in mind that these contractions are a normal sensation. Try changing your position or engaging in mild exercise to help reduce the sensation.
- Drink more fluids if possible.

First-Trimester Discomforts

During the first 3 months of pregnancy, the woman's body is undergoing numerous changes. Some women experience many discomforts, but others have few. These discomforts are caused by the changes taking place within the body and they pass as the pregnancy progresses.

Urinary Frequency or Incontinence

Urinary frequency or incontinence is common in the first trimester because the growing uterus compresses the bladder. This also is a common complaint during the third trimester, especially when the fetal head settles into the pelvis. However, the discomfort tends to improve in the second trimester, when the uterus becomes an abdominal organ and moves away from the bladder region.

After infection and gestational diabetes have been ruled out as causative factors of increased urinary frequency, suggest that the woman decrease her fluid intake 2 to 3 hours before bedtime and limit her intake of caffeinated beverages. Increased voiding is normal, but encourage the client to report any pain or burning during urination. Also explain that increased urinary frequency may subside as she enters her second trimester, only to recur in the third trimester. Teach the client to perform pelvic floor muscle training exercises, formally termed Kegel exercises, to increase support of the uterus, bladder, small intestine, and rectum throughout the day to help strengthen perineal muscle tone, thereby enhancing urinary control and decreasing the possibility of incontinence.

Fatigue

Fatigue plagues all pregnant women, primarily in the first and third trimesters (the highest energy levels typically occur during the second trimester), even if they get their normal amount of sleep at night. First-trimester fatigue most often is related to

the many physical changes (e.g., increased oxygen consumption, increased levels of progesterone and relaxin, increased metabolic demands) and psychosocial changes (e.g., mood swings, multiple role demands) of pregnancy. Third-trimester fatigue can be caused by sleep disturbances from increased weight (many women cannot find a comfortable sleeping position due to the enlarging abdomen), physical discomforts such as heartburn, and insomnia due to mood swings, multiple role anxiety, and a decrease in exercise (Rigby, 2015).

Once anemia, infection, and blood dyscrasias have been ruled out as contributing to the client's fatigue, advise her to arrange work, child care, and other demands in her life to permit additional rest periods. Work with the client to devise a realistic schedule for rest. Using pillows for support in the left-side-lying position relieves pressure on major blood vessels that supply oxygen and nutrients to the fetus when resting (Fig. 12.8). Also recommend the use of relaxation techniques, providing instructions as necessary, and suggest she increase her daily exercise level.

Nausea and Vomiting

It is estimated that somewhere between 70% to 80% of pregnant women experience nausea and vomiting. In the United States, this translates to approximately 4 million women. It is found more often in Western countries and urban populations, and is rare among Africans, Native Americans, Eskimos, and most Asian populations (Callahan, 2016). The problem is generally time limited, with the onset about the fifth week after the LMP, a peak at 8 to 12 weeks, and resolution by 16 to 18 weeks. Despite popular use of the term *morning sickness,* nausea and vomiting of pregnancy persists throughout the day in the majority of affected women and has been found to be limited to the morning in less than 2% of women (Tyler & Nagtalon-Ramos, 2015). The physiologic changes that cause nausea and vomiting are unknown, but research suggests that unusually high levels of estrogen, progesterone, and hCG and a vitamin B_6 deficiency may be contributing factors. Symptoms generally last until the second trimester and are generally associated with a positive pregnancy outcome, in terms of lower rates of miscarriages, congenital malformations, and preterm births (Cunningham et al., 2014). In summary, the etiology of nausea and vomiting in pregnancy is physiologic, thus assessment of the condition focuses on severity, and the management is largely supportive.

FIGURE 12.8 Using pillows for support in the side-lying position.

Nausea and vomiting of pregnancy can take a physical and psychologic toll on the

pregnant woman, and may have an adverse effect on her partner, family members, and even coworkers. The burden it places on the woman is usually minimized, as it is considered a normal part of pregnancy, thus it may not be worthy of evaluation, diagnosis, management, and emotional support. As a result, it may not be taken seriously because it is so common and time-limited; leading some women to feel frustrated and feel guilty that they are even complaining about their symptoms. Nurses need to pick up on this, address it and provide support for her.

The goal of treatment is to improve symptoms while minimizing risks to mother and fetus. Treatment management ranges from simple dietary modifications to drug therapy. To help alleviate nausea and vomiting, advise the woman to eat small, frequent meals that are bland and low in fat (five or six a day) to prevent her stomach from becoming completely empty. Other helpful suggestions include eating dry crackers, Cheerios, or cheese or drinking lemonade before getting out of bed in the morning and increasing her intake of foods high in vitamin B_6, such as meat, poultry, bananas, fish, green leafy vegetables, peanuts, raisins, walnuts, and whole grains, or making sure she is receiving enough vitamin B_6 by taking her prescribed prenatal vitamins.

Pharmacologic treatment of nausea and vomiting in pregnancy is limited. The Food and Drug Administration (FDA) recently approved doxylamine-pyridoxine therapy for use in pregnancy, which seems to work fairly well based on the current reviews (Slaughter et al., 2014). Other pharmacotherapies that might be considered may include diphenhydramine (e.g., Benadryl), dimenhydrinate (e.g., Dramamine), meclinine (e.g., Antivert), prochlorperazine (e.g., Compazine), promethazine (e.g., Phenergan), or ondansetron (e.g., Zofran).

Other helpful tips to deal with nausea and vomiting include:

- Get out of bed in the morning very slowly.
- Avoid sudden movements.
- Avoid triggers that stimulate or exacerbate nausea-–strong food odors.
- Eat a high-protein snack before retiring at night to prevent an empty stomach.
- Take ginger (up to 1 g in divided doses daily; 250-mg capsules QID), which increases tone and peristalsis in the gastrointestinal tract.
- Open a window to remove odors of food being cooked.
- Eat more protein than carbohydrates and take in more liquids than solids.
- Limit intake of fluids or soups during meals (drink them between meals).
- Avoid fried foods and foods cooked with grease, oils, or fatty meats, because they tend to upset the stomach.
- Avoid highly seasoned foods such as those cooked with garlic, onions, peppers, and chili.
- Drink a small amount of caffeine-free carbonated beverage (ginger ale) if nauseated.
- Trying acupressure using a wristband has been FDA approved for nausea.
- Avoid wearing tight or restricting clothes, which might place increased pressure on the expanding abdomen.
- Avoid stress(Bope & Kellerman, 2015; Jordan et al., 2014; King et al., 2015).

Breast Tenderness

As a result of increased estrogen and progesterone levels, which cause the fat layer

of breasts to thicken and the number of milk ducts and glands to increase during the first trimester, many women experience breast tenderness. Offering a thorough explanation to the woman about the reasons for the breast discomfort is important. Wearing a larger bra with good support can help alleviate this discomfort. Advise her to wear a supportive bra, even while sleeping. As her breasts increase in size, advise her to change her bra size to ensure adequate support.

Constipation

Constipation affects up to 38% of pregnancies (Verghese, Futaba, & Latthe, 2015). Increasing levels of progesterone during pregnancy lead to decreased contractility of the gastrointestinal tract, slowed movement of substances through the colon, and a resulting increase in water absorption. All of these factors lead to constipation. Lack of exercise or too little fiber or fluids in the diet can also promote constipation. In addition, the large bowel is mechanically compressed by the enlarging uterus, adding to this discomfort. The iron and calcium in prenatal vitamins can also contribute to constipation during the first and third trimesters.

Explain how pregnancy exacerbates the symptoms of constipation and offer the following suggestions:

- Eat fresh or dried fruit daily.
- Eat more raw fruits and vegetables, including their skins.
- Eat whole-grain cereals and breads such as raisin bran or bran flakes.
- Participate in physical activity every day.
- Engage in pelvis floor exercises, stretching exercises, and yoga daily.
- Eat meals at regular intervals.
- Establish a time of day to defecate, and elevate feet on a stool to avoid straining.
- Drink six to eight glasses of water daily.
- Decrease intake of refined carbohydrates.
- Drink warm fluids on arising to stimulate bowel motility.
- Decrease consumption of sugary sodas.
- Avoid eating large amounts of cheese.

If the suggestions above are ineffective, suggest that the woman use a bulk-forming laxative such as Metamucil®.

Nasal Stuffiness, Bleeding Gums, Epistaxis (Nosebleeds)

Increased levels of estrogen cause edema of the mucous membranes of the nasal and oral cavities. Advise the woman to drink extra water for hydration of the mucous membranes or to use a cool mist humidifier in her bedroom at night. If she needs to blow her nose to relieve nasal stuffiness, advise her to blow gently, one nostril at a time. Advise her to avoid the use of nasal decongestants and sprays.

If a nosebleed occurs, advise the woman to loosen the clothing around her neck, sit with her head tilted forward, pinch her nostrils with her thumb and forefinger for 10 to 15 minutes, and apply an ice pack to the bridge of her nose.

If the woman has bleeding gums, encourage her to practice good oral hygiene by using a soft toothbrush and flossing daily. Warm saline mouthwashes can relieve discomfort. If the gum problem persists, instruct her to see her dentist.

Cravings

Food craving refers to an intense desire to consume a specific food. Desires for certain foods and beverages are likely to begin during the first trimester but do not appear to reflect any physiologic need. Foods with a high sodium or sugar content often are the ones craved. At times, some women crave nonfood substances such as clay, cornstarch, laundry detergent, baking soda, soap, paint chips, dirt, ice, or wax. As explained in Chapter 11, this craving for nonfood substances, termed *pica,* may indicate a severe dietary deficiency of minerals or vitamins, or it may have cultural roots (Jyothi, 2015).

Leukorrhea

Increased vaginal discharge begins during the first trimester and continues throughout pregnancy. The physiologic changes behind leukorrhea arise from the high levels of estrogen, which cause increased vascularity and hypertrophy of cervical glands as well as vaginal cells (Cunningham et al., 2014). The result is progressively increasing vaginal secretions throughout pregnancy.

Advise the woman to keep the perineal area clean and dry, washing the area with mild soap and water during her daily shower. Also recommend that she avoid wearing pantyhose and other tight-fitting nylon clothes that prevent air from circulating to the genital area. Encourage the use of cotton underwear and suggest wearing a nightgown rather than pajamas to allow for increased airflow. Also instruct the woman to avoid douching and tampon use.

Second-Trimester Discomforts

A sense of well-being typically characterizes the second trimester for most women. By this time, the fatigue, nausea, and vomiting have subsided and the uncomfortable changes of the third trimester are a few months away. Not every woman experiences the same discomforts during this time, so nursing assessments and interventions must be individualized.

Backache

Musculoskeletal pain is a common occurrence in pregnancy and postpartum. Half of women report having back pain at some point during pregnancy. This can seriously impact the quality of life of women and have socioeconomic issues from loss days at work. The pain can be lumbar or sacroiliac. The pain may also be present only at night. Back pain is thought to be due to multiple factors, which include shifting of the center of gravity caused by the enlarging uterus, increased joint laxity due to an increase in relaxin, stretching of the ligaments (which are pain-sensitive structures), and pregnancy-related circulatory changes.

Treatment is heat and ice, acetaminophen, massage, proper posturing, good support shoes, and a good exercise program for strength and conditioning. Pregnant women may also relieve back pain by placing one foot on a stool when standing for long periods of time and placing a pillow between the legs when lying down (Plastaras & Appasamy, 2015). After exploring other reasons that might cause backache, such as uterine contractions, urinary tract infection, ulcers, or musculoskeletal back disorders, the following instructions may be helpful:

- Maintain correct posture, with head up and shoulders back.
- Wear low-heeled shoes with good arch support.

• When standing for long periods, place one foot on a stool or box.
• Use good body mechanics when lifting objects.
• When sitting, use foot supports and pillows behind the back.
• Try pelvic tilt or rocking exercises to strengthen the back (ACOG, 2015c).

The pelvic tilt or pelvic rock is used to alleviate pressure on the lower back during pregnancy by stretching the lower back muscles. It can be done sitting, standing, or on all fours. To do it on all fours, the hands are positioned directly under the shoulders and the knees under the hips. The back should be in a neutral position with the head and neck aligned with the straight back. The woman then presses up with the lower back and holds this position for a few seconds, then relaxes to a neutral position. This action of pressing upward is repeated frequently throughout the day to prevent a sore back (Rigby, 2015).

Leg Cramps

Many women experience leg cramps in pregnancy. They become more common as pregnancy progresses and are especially troublesome at night. They occur primarily in the second and third trimesters and could be related to the pressure of the gravid uterus on pelvic nerves and blood vessels. During pregnancy, up to 50% of women can be affected by leg cramps, and up to 25% can be affected by restless legs syndrome (King et al., 2015). Along with lack of exercise, diet can also be a contributing factor if the woman is not consuming enough of certain minerals, such as calcium and magnesium. The sudden stretching of leg muscles may also play a role in causing leg cramps (Kondhare & Khodgire, 2015).

Encourage the woman to gently stretch the muscle by dorsiflexing the foot up toward the body. Wrapping a warm, moist towel around the leg muscle can also help the muscle to relax. Advise the client to avoid stretching her legs, pointing her toes, and walking excessively. Stress the importance of wearing low-heeled shoes and support hose and arising slowly from a sitting position. If the leg cramps are due to deficiencies in minerals, the condition can be remedied by eating more foods rich in these nutrients. Also instruct the woman on calf-stretching exercises: have her stand 3 ft from the wall and lean toward it, resting her lower arms against it, while keeping her heels on the floor. This may help reduce cramping if it is done before going to bed.

Elevating the legs throughout the day will help relieve pressure and minimize strain. Wearing support hose and avoiding curling the toes may help to relieve leg discomfort. Also instruct the client to avoid standing in one spot for a prolonged period or crossing her legs. If she must stand for prolonged periods, suggest that she change her position at least every 2 hours by walking or sitting to reduce the risk of leg cramps. Encourage her to drink eight 8-oz glasses of fluid throughout the day to ensure adequate hydration. Taking daily walks can also help reduce leg cramping because ambulation improves circulation to the muscles.

Varicosities of the Vulva and Legs

Varicosities of the vulva and legs are associated with the increased venous stasis caused by the pressure of the gravid uterus on pelvic vessels and the vasodilation resulting from increased progesterone levels. Progesterone relaxes the vein walls, making it difficult for blood to return to the heart from the extremities; pooling can

result. Genetic predisposition, inactivity, obesity, and poor muscle tone are also contributing factors.

Encourage the client to wear support hose and teach her how to apply them properly. Advise her to elevate her legs above her heart while lying on her back for 10 minutes before she gets out of bed in the morning, thus promoting venous return before she applies the hose. Instruct the client to avoid crossing her legs and avoid wearing knee-high stockings. They cause constriction of leg vessels and muscles and contribute to venous stasis. Also encourage the client to elevate both legs above the level of the heart for 5 to 10 minutes at least twice a day (Fig. 12.9); to wear low-heeled shoes; and to avoid long periods of standing or sitting, frequently changing her position. If the client has vulvar varicosities, suggest she apply ice packs to the area when she is lying down.

FIGURE 12.9 **Woman elevating her legs while working.**

Hemorrhoids

Hemorrhoids are varicosities of the rectum and may be external (outside the anal sphincter) or internal (above the sphincter) (ACOG, 2015d). They occur as a result of progesterone-induced vasodilation and from pressure of the enlarged uterus on the lower intestine and rectum. Hemorrhoids are more common in women with constipation, poor fluid intake or poor dietary habits, smokers, or those with a previous history of hemorrhoids (Zielinski, Searing, & Deibel, 2015).

Instruct the client in measures to prevent constipation, including increasing fiber intake and drinking at least 2 L of fluid per day. Recommend the use of topical anesthetics (e.g., Preparation H®, Anusol, witch hazel compresses such as Tucks®) to reduce pain, itching, and swelling, if permitted by the health care provider. Teach the client about local comfort measures such as warm sitz baths, witch hazel compresses, or cold compresses. To minimize her risk of straining while defecating, suggest that she elevate her feet on a stool. Also encourage her to avoid prolonged sitting or standing (ACOG, 2015d).

Flatulence With Bloating

Flatulence and gas pain are another result of decreased gastrointestinal motility. The physiologic changes that result in constipation (reduced gastrointestinal motility

and dilation secondary to progesterone's influence) may also result in increased flatulence. As the enlarging uterus compresses the bowel, it delays the passage of food through the intestines, thus allowing more time for gas to be formed by bacteria in the colon. The woman usually reports increased passage of rectal gas, abdominal bloating, or belching. Instruct the woman to avoid gas-forming foods, such as beans, cabbage, and onions, as well as foods that have a high content of white sugar. Adding more fiber to the diet, increasing fluid intake, and increasing physical exercise are also helpful in reducing flatus. In addition, reducing the amount of swallowed air, if chewing gum, will reduce gas build-up. The knee-chest position may also help with discomfort from unexpelled gas. Reducing the intake of carbonated beverages and cheese and eating mints can also help reduce flatulence during pregnancy (Almansa, De Vault, & Houghton, 2015).

Third-Trimester Discomforts

As women enter their third trimester, many experience a return of the first-trimester discomforts of fatigue, urinary frequency, leukorrhea, and constipation. These discomforts are secondary to the ever-enlarging uterus compressing adjacent structures, increasing hormone levels, and the metabolic demands of the fetus. In addition to these discomforts, many women experience shortness of breath, heartburn and indigestion, swelling, and Braxton Hicks contractions.

Shortness of Breath and Dyspnea

Dyspnea is a common complaint in pregnant women. Physiologic and hemodynamic changes can result in a significant dyspnea in such cases. In some women, dyspnea in normal daily activities can be a sign of heart and lung disease and may be associated with poor perinatal and cardiac outcome in which early detection can prevent adverse events. The increasing growth of the uterus prevents complete lung expansion late in pregnancy. As the uterus enlarges upward in the second and third trimesters, the expansion of the diaphragm is limited. Dyspnea can occur when the woman lies on her back and the pressure of the gravid uterus against the vena cava reduces venous return to the heart (Tara et al., 2015).

Explain to the woman that dyspnea is normal and will improve when the fetus drops into the pelvis (lightening). Instruct her to adjust her body position to allow for maximum expansion of the chest and to avoid large meals, which increase abdominal pressure. Raising the head of the bed on blocks or placing pillows behind her back is helpful too. Under normal circumstances, resting with the head elevated while taking slow, deep breaths reduces shortness of breath symptoms. In addition, stress to her that lying on her left side will displace the uterus off the vena cava and improve her breathing. Having the woman periodically stand up and stretch her arms above her head and take a deep breath is helpful to relieve dyspnea. Also, advise the woman to avoid exercise that precipitates dyspnea, to rest after exercise, and to avoid overheating in warm climates. If she still smokes, encourage her to stop.

Heartburn and Indigestion

Heartburn and indigestion result when high progesterone levels cause relaxation of the cardiac sphincter, allowing food and digestive juices to flow backward from the

stomach into the esophagus. Irritation of the esophageal lining occurs, causing the burning sensation known as heartburn. It occurs in up to 70% of women at some point during pregnancy, with an increased frequency seen in the third trimester (King et al., 2015). The pain may radiate to the neck and throat. It worsens when the woman lies down, bends over after eating, or wears tight clothes. Indigestion (vague abdominal discomfort after meals) results from eating too much or too fast; from eating when tense, tired, or emotionally upset; from eating food that is too fatty or spicy; and from eating heavy food or food that has been badly cooked or processed (Nagtalon-Ramos, 2014). In addition, the stomach is displaced upward and compressed by the large uterus in the third trimester, thus limiting the stomach's capacity to empty quickly. Food sits, causing heartburn and indigestion.

Review the client's usual dietary intake and suggest that she limit or avoid gas-producing or fatty foods and large meals. Instruct the woman to pay attention to the timing of the discomfort. Usually it is heartburn when the pain occurs 30 to 45 minutes after a meal. Encourage the client to maintain proper posture and remain in the sitting position for 1 to 3 hours after eating to prevent reflux of gastric acids into the esophagus by gravity. Urge the client to consume small, frequent meals, to eat slowly, chewing her food thoroughly to prevent excessive swallowing of air, which can lead to increased gastric pressure. Instruct the client to avoid foods that act as triggers such as caffeinated drinks, greasy, gas-forming foods, citrus, spiced foods, chocolate, coffee, alcohol, and spearmint or peppermint. These items stimulate the release of gastric digestive acids, which may cause reflux into the esophagus. Avoid late-night or large meals and gum chewing. Avoid lying down within 3 hours after eating. Finally, elevate the head of the bed by 10 to 30 degrees.

Dependent Edema

Swelling is the result of increased capillary permeability caused by elevated hormone levels and increased blood volume. Sodium and water are retained and thirst increases. Edema occurs most often in dependent areas such as the legs and feet throughout the day due to gravity; it improves after a night's sleep. Warm weather or prolonged standing or sitting may increase edema. Generalized edema, appearing in the face, hands, and feet, can signal preeclampsia if accompanied by dizziness, blurred vision, headaches, upper quadrant pain, or nausea (Rigby, 2015). This edema should be reported to the health care provider. Appropriate suggestions to minimize dependent edema include:

- Elevate your feet and legs above the level of the heart periodically throughout the day.
- Wear support hose when standing or sitting for long periods.
- Change position frequently throughout the day.
- Walk at a sensible pace to help contract leg muscles to promote venous return.
- When taking a long car ride, stop to walk around every 2 hours.
- When standing, rock from the ball of the foot to the toes to stimulate circulation.
- Lie on your left side to keep the gravid uterus off the vena cava to return blood to the heart.
- Avoid foods high in sodium, such as lunch meats, potato chips, and bacon.
- Avoid wearing knee-high stockings.
- Drink six to eight glasses of water daily to replace fluids lost through perspiration.
- Avoid high intake of sugar and fats, because they cause water retention.

Braxton Hicks Contractions

Braxton Hicks contractions are irregular, painless contractions that occur without cervical dilation. Typically they intensify in the third trimester in preparation for labor. In reality, they have been present since early in the pregnancy but may have gone unnoticed. They are thought to increase the tone of uterine muscles for labor purposes (Grant, Strevens, & Thornton, 2015).

Consider This

One has to wonder sometimes why women go through what they do. During my first pregnancy I was sick for the first 2 months. I would experience waves of nausea from the moment I got out of bed until midmorning. Needless to say, I wasn't the happiest camper around. After the third month, my life seemed to settle down and I was beginning to think that being pregnant wasn't too bad after all. For the moment, I was fooled. Then, during my last 2 months, another wave of discomfort struck—heartburn and constipation—a double whammy! I now feared eating anything that might trigger acid indigestion and also might remain in my body too long. I literally had to become the "fiber queen" to combat these two challenges. Needless to say, my "suffering" was well worth our bright-eyed baby girl in the end.

Thoughts: Despite the various discomforts associated with pregnancy, most women wouldn't change their end result. Do most women experience these discomforts? What suggestions could be made to reduce them?

Reassure the client that these contractions are normal. Instruct the client in how to differentiate between Braxton Hicks and labor contractions. Explain that true labor contractions usually grow longer, stronger, and closer together and occur at regular intervals. Walking usually strengthens true labor contractions, whereas Braxton Hicks contractions tend to decrease in intensity and taper off. Advise the client to keep herself well hydrated and to rest in a left-side-lying position to help relieve the discomfort. Suggest that she use breathing techniques such as Lamaze techniques to ease the discomfort.

NURSING MANAGEMENT TO PROMOTE SELF-CARE

Pregnancy is considered a time of health, not illness. Health promotion and maintenance activities are essential to promoting an optimal outcome for the woman and her fetus. Pregnant women commonly have many questions about the changes occurring during pregnancy: how these changes affect their usual routine, such as working, traveling, exercising, or engaging in sexual activity; how the changes influence their typical self-care activities, such as bathing, perineal care, or dental care; and whether these changes are signs of a problem.

Take Note!

Women may have heard stories about or been told by others what to do and what not to do during pregnancy, leading to many misconceptions and much misinformation.

Nurses can play a major role in providing anticipatory guidance and teaching to foster the woman's responsibility for self-care, helping to clarify misconceptions and correct any misinformation. Educating the client to identify threats to safety posed

by her lifestyle or environment and proposing ways to modify them to avoid a negative outcome are important. Counseling should also include healthy ways to prepare food, advice to avoid medications unless they are prescribed for her, and advice on identifying teratogens within her environment or at work and how to reduce her risk from exposure. The pregnant client can better care for herself and the fetus if her concerns are anticipated and identified by the nurse and are incorporated into teaching sessions at each prenatal visit.

Personal Hygiene

Hygiene is a necessity for the maintenance of good health. Cleansing the skin removes dirt, bacteria, sweat, dead skin cells, and body secretions. Counsel women to wash their hands and under their fingernails frequently throughout the day in order to lower the bacterial count on both. During pregnancy a woman's sebaceous (sweat) glands become more active under the influence of hormones, and sweating is more profuse. This increase may make it necessary to use a stronger deodorant and shower more frequently. The cervical and vaginal glands also produce more secretions during pregnancy. Frequent showering helps to keep the area dry and promotes better hygiene. Encourage the use of cotton underwear to allow greater air circulation. Taking a tub bath in early pregnancy is permitted, but closer to term, when the woman's center of gravity shifts, it is safer to shower to prevent the risk of slipping.

Hot Tubs and Saunas

Caution pregnant women to avoid using hot tubs, saunas, whirlpools, and tanning beds during pregnancy. The heat may cause fetal tachycardia as well as raise the maternal temperature. Exposure to bacteria in hot tubs that have not been cleaned sufficiently is another reason to avoid them during pregnancy.

Perineal Care

The glands in the cervical and vaginal areas become more active during pregnancy secondary to hormonal influences. This increase in activity will produce more vaginal secretions, especially in the last trimester. Advise pregnant women to shower frequently and wear all-cotton underwear to minimize the effects of these secretions. Caution pregnant women not to douche, because douching can increase the risk of infection, and not to wear panty liners, which block air circulation and promote moisture. Explain that they should also avoid perfumed soaps, lotions, perineal sprays, and harsh laundry detergents to help prevent irritation and potential infection.

Dental Care

Physiologic changes that occur in pregnant women can adversely affect oral health. Elevations in estrogen and progesterone enhance the inflammatory response and consequently alter gingival tissue. During pregnancy, the incidence of gingivitis and periodontitis increases (Anil et al., 2015). Pregnancy is a time when a woman can be very receptive to health messaging. Pregnancy is no longer a contraindication for dental treatment; it is also a time when nurses can help clients understand that good oral health is important to a healthy pregnancy and can decrease the risk of dental

caries in their children. When women see oral health as a priority for themselves, they are more likely to place a high priority on their children's oral health.

Periodontal disease is a contributing factor to systemic conditions, such as heart disease, respiratory diseases, diabetes mellitus, adverse pregnancy outcomes (preterm births, low-birth-weight infants, and small-for-gestational-age infants), anemia, and stroke (Trivedi, Lal, & Singhal, 2015). Research has established that the elevated levels of estrogen and progesterone during pregnancy cause women to be more sensitive to the effects of bacterial dental plaque, which can cause gingivitis, an oral infection characterized by swollen and bleeding gums (ACOG, 2013). Brushing and flossing teeth twice daily will help reduce bacteria in the mouth. Advise the woman to visit her dentist early in the pregnancy to address any dental caries and have a thorough cleaning to prevent possible infection later in the pregnancy. Advise her to avoid exposure to x-rays by informing the hygienist of the pregnancy. If x-rays are necessary, the abdomen should be shielded with a lead apron.

Researchers have reported an association between prematurity and periodontitis, an oral infection that spreads beyond the gum tissues to invade the supporting structures of the teeth. Periodontitis is characterized by bleeding gums, loss of tooth attachment, loss of supporting bone, and bad breath due to pus formation. Unfortunately, because this infection is chronic and often painless, women frequently do not realize they have it and a preterm birth can result. During pregnancy, gingivitis occurs in 35% to 100% of women, depending upon the study (Trivedi, Lal, & Singhal, 2015). Nurses should assess all pregnant women's oral health status by taking an oral health history; checking their mouths for swollen or bleeding gums, untreated dental decay, mucosal lesions, and signs of infection; and document findings in the prenatal record.

Additional guidelines that the nurse should stress regarding maintaining dental health include:

- Seek professional dental care during the first trimester for assessment and care.
- Be reassured that oral health care is safe during pregnancy.
- Obtain treatment for dental pain and infection promptly during pregnancy.
- Brush twice daily for 2 minutes, especially before bed, with fluoridated toothpaste and rinse well. Use a soft-bristled toothbrush and be sure to brush at the gum line to remove food debris and plaque to keep gums healthy.
- Floss teeth daily with dental floss and rinse well afterward with plain water.
- Eat healthy foods, especially those high in vitamins A, C, and D and calcium.
- Avoid sugary snacks.
- Chew sugar-free gum for 10 minutes after a meal if brushing is not possible.
- After vomiting, rinse your mouth immediately with baking soda (¼ teaspoon) and warm water (1 cup) to neutralize the acid (National Maternal and Child Oral Health Resource Center, 2015).

Breast Care

Because the breasts enlarge significantly and become heavier throughout pregnancy, stress the need to wear a firm, supportive bra with wide straps to balance the weight of the breasts. Instruct the woman to anticipate buying a larger-sized bra about halfway through her pregnancy because of the increasing size of the breasts. Advise her to avoid using soap on the nipple area because it can be very drying. Encourage

her to rinse the nipple area with plain water while bathing to keep it clean. The Montgomery glands (located in the areolar part of the nipple) secrete a lubricating substance that keeps the nipples moist and discourages growth of bacteria, so there is no need to use alcohol or other antiseptics on the nipples.

If the mother has chosen to breast-feed, nipple preparation is unnecessary unless her nipples are inverted and do not become erect when stimulated. Breast shells can be worn during the last 2 months to address this issue (Alexander et al., 2014).

Around week 16 of pregnancy, colostrum secretion begins, which the woman may notice as moisture in her bra. Advise the woman to place breast pads or a cotton cloth in her bra and change them frequently to prevent build-up, which may lead to excoriation.

Clothing

Many contemporary clothes are loose fitting and layered, so the woman may not need to buy an entirely new wardrobe to accommodate her pregnancy. Some pregnant women may continue to wear tight clothes. Point out that loose clothing will be more comfortable for the client and her expanding waistline.

Advise pregnant women to avoid wearing constricting clothes and girdles that compress the growing abdomen. Urge the woman to avoid knee-high hose, which might impede lower-extremity circulation and increase the risk of developing DVT. Low-heeled shoes will minimize pelvic tilt and possible backache. Wearing layered clothing that can be removed as the temperatures fluctuate may be more comfortable, especially toward term, when the woman may feel overheated.

Exercise

A physically inactive lifestyle is associated with an increase in chronic diseases such as cardiovascular disease, type 2 diabetes, osteoporosis, and cancer. The proportion of pregnant women who are overweight or obese is increasing globally, thus exercise is essential to reduce these risks and promote a healthy pregnancy. Exercise is well tolerated by a healthy woman during pregnancy. It promotes a feeling of well-being; improves circulation; helps reduce constipation, bloating, and swelling; may help prevent or treat gestational diabetes; promotes muscle tone, strength, and endurance; may improve the woman's ability to cope with labor; increases energy level; improves posture; helps sleep and promotes relaxation and rest; and relieves the lower back discomfort that often arises as the pregnancy progresses (Barakat, Lucia, & Ruiz, 2015). However, the duration and difficulty of exercise should be modified throughout pregnancy because of a decrease in performance efficiency with gestational age. Some women continue to push themselves to maintain their prior level of exercise, but most find that as their shape changes and their abdominal area enlarges, they must modify their exercise routines. Modification also helps to reduce the risk of injury caused by laxity of the joints and connective tissue due to the hormonal effects (Petrov Fieril, Glantz, & Fagevik Olsen, 2015).

Exercise during pregnancy is contraindicated in women with preterm labor, poor weight gain, anemia, facial and hand edema, pain, hypertension, threatened abortion, dizziness, shortness of breath, multiple gestation, decreased fetal activity, cardiac disease, and palpitations (Rigby, 2015).

Federal physical activity guidelines recommend at least 150 minutes of moderate-

intensity exercise per week during pregnancy (Dietz, 2015) (Fig. 12.10). It is believed that pregnancy is a unique time for behavior modification and that healthy behaviors maintained or adopted during pregnancy may improve the woman's health for the rest of her life. The excess weight gained in pregnancy, which some women never lose, is a major public health problem (Truong et al., 2015). Exercise helps the woman avoid gaining excess weight during pregnancy.

Exercise during pregnancy helps return a woman's body to good health after the baby is born. The long-term benefits of exercise that begin in early pregnancy include improved posture, weight control, and improved muscle tone. Exercise also aids in the prevention of osteoporosis after menopause, reduces the risk of hypertension and diabetes, and assists in keeping the birth weight of the fetus within the normal range (Barakat, Lucia, & Ruiz, 2015). Teaching Guidelines 12.2 highlights recommendations for exercise during pregnancy.

Teaching Guidelines 12.2
TEACHING TO PROMOTE EXERCISE DURING PREGNANCY

- Consume liquids before, during, and after exercising.
  - Ask your health care provider before you start a new exercise routine.
  - Avoid exercising in hot, humid weather or when you have a fever.
  - Stop exercising if you experience vaginal bleeding, dizziness, chest pain, headache, muscle weakness, calf pain or swelling, uterine contractions, decreased fetal movement, or fluid leaking from the vagina.
- Exercise three or four times each week, not sporadically.
- Engage in brisk walking, swimming, biking, or low-impact aerobics; these are considered ideal activities.
- Avoid getting overheated during exercise.
- Wear comfortable exercise footwear that gives strong ankle and arch support.
- Contact sports should be avoided during pregnancy.
- Include relaxation and stretching before and after your exercise program.
- Reduce the intensity of workouts in late pregnancy.
- Avoid jerky, bouncy, or high-impact movements.
- Avoid lying flat (supine) after the fourth month because of hypotensive effect.
- Use pelvic tilt and pelvic rocking to relieve backache.
- Start with 5 to 10 minutes of stretching exercises.
- Rise slowly following an exercise session to avoid dizziness.
- Avoid activities such as skiing, surfing, scuba diving, and ice hockey.
- Never exercise to the point of exhaustion.

FIGURE 12.10 Exercising during pregnancy.

Sleep and Rest

Getting enough sleep helps a person feel better and promotes optimal performance levels during the day. The body releases its greatest concentration of growth hormone during sleep, helping the body to repair damaged tissue and grow. Also, with the increased metabolic demands during pregnancy, fatigue is a constant challenge to many pregnant women, especially during the first and third trimesters. The following tips can help promote adequate sleep:

- Stay on a regular schedule by going to bed and waking up at the same times.
- Eat regular meals at regular times to keep external body cues consistent.
- Take time to unwind and relax before bedtime.
- Establish a bedtime routine or pattern and follow it.
- Create a proper sleep environment by reducing the light and lowering the room temperature.
- Go to bed when you feel tired; if sleep does not occur, read a book until you are sleepy.
- Reduce caffeine intake later in the day.
- Limit fluid intake after dinner to minimize trips to the bathroom.
- Exercise daily to improve circulation and well-being.
- Use a modified Sims position to improve circulation in the lower extremities.
- Avoid lying on your back after the fourth month, which may compromise circulation to the uterus.
- Avoid sharply bending your knees, which promotes venous stasis below the knees.
- Keep anxieties and worries out of the bedroom. Set aside a specific area in the home or time of day for them.

Sexual Activity and Sexuality

Sexuality is an important part of health and well-being. Pregnancy is characterized by intense biologic, psychological, and social changes. These changes have direct

and indirect, conscious and unconscious effects on a woman's sexuality. The woman experiences dramatic alterations in her physiology, her appearance, and her body, as well as her relationships. A woman's sexual responses during pregnancy vary widely. Common symptoms such as fatigue, nausea, vomiting, breast soreness, and urinary frequency may reduce her desire for sexual intimacy. However, many women report enhanced sexual desire due to increasing levels of estrogen. Usually sexual satisfaction does not change in pregnancy compared with the prepregnancy patterns despite a decline of sexual activity during the third trimester. A discussion of expected changes in sexuality should be routinely done in order to improve couples' perception of possible sexual modifications induced by pregnancy. It is clear that, despite some difficulties related to sexual activity during pregnancy, its need and importance are recognized for both participants.

Take Note!

Fluctuations in sexual desire are normal and a highly individualized response throughout pregnancy.

The physical and emotional adjustments of pregnancy can cause changes in body image, fatigue, mood swings, and sexual activity. The woman's changing shape, emotional status, fetal activity, changes in breast size, pressure on the bladder, and other common discomforts of pregnancy result in increased physical and emotional demands. These can produce stress on the sexual relationship of the pregnant woman and her partner. However, most women adjust well to the alterations and experience a satisfying sexual relationship. Research indicates that sexual intercourse is safe in the absence of ruptured membranes, bleeding, or placenta previa, but pregnant women engage in sex less often as the pregnancy progresses (ACOG, 2015f).

Often pregnant women ask whether sexual intercourse is allowed during pregnancy or whether there are specific times when they should refrain from having sex. This is a good opportunity to educate clients about sexual behavior during pregnancy and also to ask about their expectations and individual experience related to sexuality and possible changes. It is also a good time for nurses to address the impact of the changes associated with pregnancy on sexual desire and behavior. Couples may enjoy sexual activity more because there is no fear of pregnancy and no need to disrupt spontaneity by using birth control. An increase in pelvic congestion and lubrication secondary to estrogen influence may heighten orgasm for many women. Some women have a decrease in desire because of a negative body image, fear of harming the fetus by engaging in intercourse, and fatigue, nausea, and vomiting (Boynton, 2015). Condom use can be recommended to decrease the release of prostaglandins in the semen that may stimulate contractions. A couple may need assistance to adjust to the various changes brought about by pregnancy.

Reassure the women and her partner that sexual activity is permissible during pregnancy unless there is a history of any of the following:

- Vaginal bleeding
- Placenta previa
- Risk of preterm labor
- Cervical insufficiency
- Premature rupture of membranes
- Presence of infection (Rigby, 2015)

Inform the couple that the fetus will not be injured by intercourse. Suggest that alternative positions may be more comfortable (e.g., woman on top, side-lying), especially during the later stages of pregnancy. Some of the physical changes in pregnancy, which can affect a couple's relationship, for example, halitosis which can result from dehydration, but can be alleviated through extra fluids and better oral hygiene. Women can have breast tenderness and skin changes that can cause them feel unattractive to their partner during pregnancy. In addition, they can be worried about increases in vaginal discharge and need to know what is normal and what can be a sign of infection. Nurses should make women feel comfortable talking about their fears, encouraging them to take pride in their changing bodies.

Many women feel a particular need for closeness during pregnancy, and the woman should communicate this need to her partner (Halford, Petch, & Creedy, 2015). Emphasize to the couple that closeness and cuddling need not culminate in intercourse, and that other forms of sexual expression, such as mutual masturbation, foot massage, holding hands, kissing, and hugging can be very satisfying (Halford, Petch, & Creedy, 2015).

Sex in pregnancy is normal. Research suggests that prepregnancy sexuality plays an important role in maintaining sexuality during pregnancy and postpartum (Yildiz, 2015). There are very few proven contraindications and risks to intercourse in low-risk pregnancies, and therefore these clients should be reassured. In pregnancies complicated by placenta previa or an increased risk of preterm labor, the evidence to support abstinence is lacking, but it is a reasonable benign recommendation given the theoretical catastrophic consequences (Yeniel & Petri, 2014).

Women will experience a myriad of symptoms, feelings, and physical sensations during their pregnancy. Having a satisfying sexual relationship during pregnancy is certainly possible, but it requires honest communication between partners to determine what works best for them and a good relationship with their health care provider to ensure safety (March of Dimes, 2015f).

Employment

Nearly three quarters of pregnant women in the United States will continue to work outside the home until the last month of pregnancy (Jordan et al., 2014). For the most part, women can continue working until giving birth if they have no complications during their pregnancy and the workplace does not present any special hazards (Zolotor & Carlough, 2014). Hazardous occupations include health care workers, daycare providers, laboratory technicians, chemists, painters, hairstylists, veterinary workers, and carpenters (Guidotti, 2014). Jobs requiring strenuous work such as heavy lifting, climbing, carrying heavy objects, and standing for prolonged periods place a pregnant woman at risk if modifications are not instituted.

Assess for environmental and occupational factors that place a pregnant women and her fetus at risk for injury. Interview the woman about her employment environment. Ask about possible exposure to teratogens (substances with the potential to alter the fetus permanently in form or function) and the physical demands of employment: Is she exposed to temperature extremes? Does she need to stand for prolonged periods in a fixed position? A description of the work

environment is important in providing anticipatory guidance to the woman. Stress the importance of taking rest periods throughout the day, because constant physically intensive workloads increase the likelihood of low birth weight and preterm labor and birth (Cunningham et al., 2014).

Because of the numerous physiologic and psychosocial changes that women experience during their pregnancies, the employer may need to make special accommodations to reduce the pregnant woman's risk of hazardous exposures and heavy workloads. The employer may need to provide adequate coverage so that the woman can take rest breaks; remove the woman from any areas where she might be exposed to toxic substances; and avoid work assignments that require heavy lifting, hard physical labor, continuous standing, or constant moving. Some recommendations for working while pregnant are given in Teaching Guidelines 12.3.

Teaching Guidelines 12.3
TEACHING FOR THE PREGNANT WORKING WOMAN

- Plan to take two 10- to 15-minute breaks within an 8-hour work day.
- Be sure there is a place available for you to rest, preferably in the side-lying position, with a restroom readily available.
- Avoid jobs that require strenuous workloads; if this is not possible, then request a modification of work duties (lighter tasks) to reduce your workload.
- Change your position from standing to sitting or vice versa at least every 2 hours.
- Ensure that you are allowed time off without penalty, if necessary, to ensure a healthy outcome for you and your fetus.
- Make sure the work environment is free of toxic substances.
- Ensure the work environment is smoke-free so passive smoking is not a concern.
- Minimize heavy lifting if associated with bending.

Travel

Pregnancy does not curtail a woman's ability to travel in a car or in a plane. However, women should follow a few safety guidelines to minimize risk to themselves and their fetuses. According to ACOG (2015g), pregnant women can travel safely throughout their pregnancy, although the second trimester is perhaps the best time to travel because there is the least chance of complications. Pregnant women considering international travel should evaluate the problems that could occur during the journey as well as the quality of medical care available at the destination.

A woman in the third trimester should be advised to defer overseas travel because of concerns about access to medical care in case of problems such as hypertension, phlebitis, or premature labor (CDC, 2015e). Pregnant women should be advised to consult with their health care providers before making any travel decisions.

Take Note!

Clinical manifestations that indicate the need for immediate medical attention while traveling are vaginal

bleeding, passing tissue or clots, abdominal pain or cramps, contractions, ruptured membranes, excessive leg swelling or pain, headaches, or visual problems (Leggat & Zuckerman, 2015).

Advise pregnant women to be aware of the potential for injuries and traumas related to traveling, and teach women ways to prevent these from occurring. Teaching Guidelines 12.4 offers tips for safe travel on planes and to foreign areas.

Teaching Guidelines 12.4

TEACHING TO PROMOTE SAFE TRAVEL ON PLANES AND IN FOREIGN COUNTRIES

- Bring along a copy of the prenatal record if your travel will be prolonged in case there is a medical emergency away from home.
- When traveling abroad, carry a foreign dictionary that includes words or phrases for the most common pregnancy emergencies.
- Travel with at least one companion at all times for personal safety.
- Check with your health care provider before receiving any immunizations necessary for foreign travel; some may be harmful to the fetus.
- When in a foreign country, avoid fresh fruit, vegetables, and local water.
- Avoid any milk that is not pasteurized.
- Eat only meat that is well cooked to avoid exposure to toxoplasmosis.
- Request an aisle seat and walk about the airplane every 2 hours.
- While sitting on long flights, practice calf-tensing exercises to improve circulation to the lower extremities.
- Be aware of typical problems encountered by pregnant travelers, such as fatigue, heartburn, indigestion, constipation, vaginal discharge, leg cramps, urinary frequency, and hemorrhoids.
- Always wear support hose while flying to prevent the development of blood clots.
- Drink plenty of water to keep well hydrated throughout the flight.
- Postpone travel if risks outweigh benefits.

Adapted from American College of Obstetricians and Gynecologists. (2015e). Travel during pregnancy: FAQ 055. Retrieved from http://www.acog.org/~/media/for%20patients/faq055.ashx; and Centers for Disease Control and Prevention [CDC]. (2015e). Pregnant travelers. Retrieved from http://wwwnc.cdc.gov/travel/yellowbook/2014/chapter-8-advising-travelers-with-specific-needs/pregnant-travelers

When traveling by car, the major risk is a car accident. Motor vehicle accidents account for more than 50% of all traumas during pregnancy and 82% of fetal deaths occurring during these accidents (Eshaghabadi & Barati, 2015). The impact and momentum can lead to traumatic separation of the placenta from the wall of the uterus. Shock and massive hemorrhage might result. Tips that nurses can offer to promote safety during ground travel include:

- Always wear a three-point seat belt, no matter how short the trip, to prevent ejection or serious injury from collision.

- Apply a nonpadded shoulder strap properly; it should cross between the breasts and over the upper abdomen, above the uterus (Fig. 12.11).
- If no seat belts are available (buses or vans), ride in the back seat of the vehicle.
- Use a lap belt that crosses over the pelvis below the uterus.
- Deactivate the airbag if possible. If you can't, move the seat as far back from the dashboard as possible to minimize impact on the abdomen.
- Never use a cellular phone while driving to prevent distraction.
- Avoid driving when very fatigued in the first and third trimesters.
- Avoid late-night driving, when visibility might be compromised.
- Direct a tilting steering wheel away from the abdomen (CDC, 2015e).

FIGURE 12.11 Proper application of a seat belt during pregnancy.

Immunizations and Medications

Vaccines are among the greatest public health achievements of the 21st century, credited with significant reduction of morbidity and mortality from many diseases caused by bacteria and viruses (Senie, 2014). Ideally, clients should receive all childhood immunizations before conception to protect the fetus from any risk of congenital anomalies. If the client comes for a preconception visit, discuss immunizations such as measles, mumps, and rubella (MMR), hepatitis B, and diphtheria/tetanus (every 10 years); administer them at this time if needed.

The risk to a developing fetus from vaccination of the mother during pregnancy is primarily theoretical. Routine immunizations are not usually indicated during pregnancy. However, no evidence exists of risk from vaccinating pregnant women with inactivated virus or bacterial vaccines or toxoids. A number of other vaccines have not been adequately studied, and thus theoretical risks of vaccination must be weighed against the risks of the disease to mother and fetus (CDC, 2015f).

Take Note!

Advise pregnant women to avoid live virus vaccines (MMR and varicella) and to avoid becoming pregnant within 1 month of having received one of these vaccines because of the theoretical risk of transmission to the fetus

(CDC, 2015f).

CDC guidelines for vaccine administration are highlighted in Box 12.6.

Little is known about the effects of taking most medications during pregnancy. Less than 10% of medications approved by the FDA since 1980 have enough information to determine their risk for birth defects (CDC, 2015g). Based on this lack of evidence, it is best for pregnant women not to take any medications during their pregnancy. At the very least, encourage them to discuss with the health care provider their current medications and any herbal remedies they take so that they can learn about any potential risks should they continue to take them during pregnancy. Generally, if the woman is taking medicine for seizures, high blood pressure, asthma, or depression, the benefits of continuing the medicine during pregnancy outweigh the risks to the fetus. The safety profile of some medications may change according to the gestational age of the fetus. Embryogenesis is completed by the end of the first trimester, when all fetal organs are complete. Thus, to cause a malformation, fetal drug exposure must occur in the first 12 weeks of gestation (Gadot & Koren, 2015).

BOX 12.6

CDC GUIDELINES FOR VACCINE ADMINISTRATION DURING PREGNANCY

Vaccines That Should be Considered if Otherwise Indicated

- Hepatitis B
- Influenza (inactivated) injection
- Tetanus/diphtheria (Tdap)
- Meningococcal
- Rabies

Vaccines Contraindicated During Pregnancy

- Influenza (live, attenuated vaccine) nasal spray
- Measles
- Mumps
- Rubella
- Varicella
- BCG (tuberculosis)
- Meningococcal
- Typhoid

Adapted from Centers for Disease Control and Prevention [CDC]. (2015f). *Vaccines for pregnant women.* Retrieved from http://www.cdc.gov/vaccines/adults/rec-vac/pregnant.html; and March of Dimes (2015h). *Vaccinations during pregnancy.* Retrieved from http://www.marchofdimes.com/pregnancy/vaccinations-during-pregnancy.aspx

The FDA has developed a system of ranking drugs that appears on drug labels and package inserts. These risk categories are summarized in Box 12.7. Always advise women to check with the health care provider for guidance.

A common concern of many pregnant women involves the use of over-the-counter

medications and herbal agents. Many women consider these products benign simply because they are available without a prescription (King et al., 2015). Although herbal medications are commonly thought of as "natural" alternatives to other medicines, they can be just as potent as some prescription medications. A major concern about herbal medicine is the lack of consistent potency in the active ingredients in any given batch of product, making it difficult to know the exact strength by reading the label. Also, many herbs contain chemicals that cross the placenta and may cause harm to the fetus.

BOX 12.7

FDA PREGNANCY RISK CLASSIFICATION OF DRUGS

- *Category A:* These drugs have been tested and found safe during pregnancy. Examples: folic acid, vitamin B_6, and thyroid medicine.
- *Category B:* These drugs have been used frequently during pregnancy and do not appear to cause major birth defects or other fetal problems. Examples: antibiotics, acetaminophen (Tylenol), aspartame (artificial sweetener), famotidine (Pepcid), prednisone (cortisone), insulin, and ibuprofen. (Ibuprofen should not be used after 36 weeks of pregnancy to avoid increased blood loss during parturition and to avoid premature closure of the ductus arterious in the fetus.)
- *Category C:* These drugs are more likely to cause problems and safety studies have not been completed. Examples: prochlorperazine (Compazine), fluconazole (Diflucan), ciprofloxacin (Cipro), and some antidepressants.
- *Category D:* These drugs have clear health risks for the fetus. Examples: alcohol, lithium (treats bipolar disorders), phenytoin (Dilantin); all chemotherapeutic agents used to treat cancer.
- *Category X:* These drugs have demonstrated positive evidence of fetal abnormalities and are contraindicated in women who are or may become pregnant. Examples: Accutane (treats cystic acne), androgens (treat endometriosis), Coumadin (prevents blood clots), antithyroid medications for overactive thyroid; radiation therapy (cancer treatment), Tegison or Soriatane (treats psoriasis), streptomycin (treats tuberculosis); thalidomide (treats insomnia), diethylstilbestrol (DES) (treats menstrual disorders), and organic mercury from contaminated food.

Adapted from King, T. L., Brucker, M. C., Kriebs, J. M., Fahey, J. O., Gegor, C. L., & Varney, H. (2015). *Varney's midwifery* (5th ed.). Burlington, MA: Jones & Bartlett Learning; and Rigby, F.B. (2015). Common pregnancy complaints and questions. *eMedicine.* Retrieved from http://emedicine.medscape.com/article/259724-overview

Nurses are often asked about the safety of over-the-counter medicines and herbal agents. Unfortunately, many drugs have not been evaluated in controlled studies, and it is difficult to make general recommendations for these products. Therefore, encourage pregnant women to check with their health care provider before taking anything. Questions about the use of over-the-counter and herbal products are part of the initial prenatal interview.

NURSING MANAGEMENT TO PREPARE THE WOMAN AND HER PARTNER FOR LABOR, BIRTH, AND PARENTHOOD

Pregnancy and birth are unique to every woman. Women and families hold different expectations during childbearing based on their knowledge, experiences, belief systems, culture, and social and family backgrounds. These differences should be understood and respected by the nurse, and care to them adapted to meet the individual needs of the women and families. Knowing a woman's needs, values, cultural background, preferences, and expectations during childbirth helps nurses to provide high-quality care to them. Childbirth today is a very different experience from childbirth in previous generations. In the past, women were literally "put to sleep" with anesthetics, and they woke up with a baby. Most women never remembered the details and had a passive role in childbirth as the physician delivered the newborn. In the 1950s, consumers began to insist on taking a more active role in their health care, and couples desired to be together during the extraordinary event of childbirth. Beginning in the 1970s, the father or significant other support person remained with the mother throughout labor and birth. Fathers today want to be seen as individuals who are part of the laboring couple. If fathers are left out, they tend to feel helpless; this can result in a feeling of panic and can put their support for their partner at risk (Schytt & Bergstrom, 2014).

Health beliefs related to pregnancy and childbirth exist in various cultures globally. A woman's perception of her own status is critical to her decision-making process, because her personal behaviors can significantly alter her pregnancy-related risks. Pregnant women of diverse cultures hold a number of beliefs related to diet, behavior related to prenatal care, and the use of herbs during pregnancy and postnatally. Nurses need to be aware of these cultural beliefs so as to incorporate those into their practices, while those posing a health risk should be discouraged respectfully (M'soka, Mabuza, & Pretorius, 2015).

Childbirth education began because women demanded to become more involved in their birthing experience rather than simply turning control over to a health care provider. Nurses played a pivotal role in bringing about this change by providing information and supporting clients and their families, fostering a more active role in preparing for the upcoming birth.

Traditional childbirth education classes focused on developing and practicing techniques for use in managing pain and facilitating the progress of labor. Recently, the focus of this education has broadened: it now encompasses not only preparation for childbirth, but also preparation for breast-feeding, infant care, transition to new parenting roles, relationship skills, family health promotion, and sexuality (Varner, 2015). The term used to describe this broad range of topics is perinatal education. Subjects commonly addressed in perinatal education include:

- Anatomy and physiology of reproduction
- Fetal growth and development
- Prenatal maternal exercise
- Physiologic and emotional changes during pregnancy
- Sex during pregnancy
- Infant growth and development
- Nutrition and healthy eating habits during pregnancy
- Teratogens and their impact on the fetus

- Signs and symptoms of labor
- Preparation for labor and birth (for parents, siblings, and other family members)
- Options for birth
- Infant nutrition, including preparation for breast-feeding
- Infant care, including safety, CPR, and first aid
- Family planning (March of Dimes, 2015g)

Childbirth Education Classes

Childbirth education classes teach pregnant women and their support person about pregnancy, birth, and parenting. The classes are offered in local communities or online and are usually taught by certified childbirth educators. Most childbirth classes support the concept of **natural childbirth** (a birth without pain-relieving medications) so that the woman can be in control throughout the experience as much as possible. The classes differ in their approach to specific comfort techniques and breathing patterns. The three most common childbirth methods are the Lamaze (psychoprophylactic) method, the Bradley (partner-coached childbirth) method, and the Dick-Read (natural childbirth) method.

Lamaze Method

Lamaze is a psychoprophylactic ("mind prevention") method of preparing for labor and birth that promotes the use of specific breathing and relaxation techniques. Dr. Fernand Lamaze, a French obstetrician, popularized this method of childbirth preparation in the 1960s. Lamaze believed that conquering fear through knowledge and support was important. He also believed women needed to alter the perception of suffering during childbirth. This perception change would come about by learning conditioned reflexes that, instead of signaling pain, would signal the work of producing a child, and thus would carry the woman through labor awake, aware, and in control of her own body (Lamaze International, 2015). Lamaze felt strongly that all women have the right to deliver their babies with minimal or no medication while maintaining their dignity, minimizing their pain, maximizing their self-esteem, and enjoying the miracle of birth.

Lamaze classes include information on toning exercises, relaxation exercises and techniques, and breathing methods for labor. The breathing techniques are used in labor to enhance relaxation and to reduce the woman's perception of pain. The goal is for women to become aware of their own comfortable rate of breathing in order to maintain relaxation and adequate oxygenation of the fetus. The following breathing techniques are an effective attention-focusing strategy to reduce pain:

- *Paced breathing* involves breathing techniques used to decrease stress responses and therefore decrease pain. This type of breathing implies self-regulation by the woman. The woman starts off by taking a cleansing breath at the onset and end of each contraction. This cleansing breath symbolizes freeing her mind from worries and concerns. This breath enhances oxygenation and puts the woman in a relaxed state.
- *Slow-paced breathing* is associated with relaxation and should be half the normal breathing rate (six to nine breaths per minute). This type of breathing is the most relaxed pattern and is recommended throughout labor. Abdominal or chest breathing may be used. It is generally best to breathe in through the nose and

breathe out either through the nose or mouth, whichever is more comfortable for the woman.

- *Modified-paced breathing* can be used for increased work or stress during labor to increase alertness or focus attention or when slow-paced breathing is no longer effective in keeping the woman relaxed. The woman's respiratory rate increases, but it does not exceed twice her normal rate. Modified-paced breathing is a quiet upper chest breath that is increased or decreased according to the intensity of the contraction. The inhalation and the exhalation are equal. This breathing technique should be practiced during pregnancy for optimal use during labor.
- *Patterned-paced breathing* is similar to modified-paced breathing but with a rhythmic pattern. It uses a variety of patterns, with an emphasis on the exhalation breath at regular intervals. Different patterns can be used, such as 4/1, 6/1, 4/1. A 4/1 rhythm is four upper chest breaths followed by an exhalation (a sighing out of air, like blowing out a candle). Random patterns can be chosen for use as long as the basic principles of rate and relaxation are met.

Couples practice these breathing patterns typically during the last few months of the pregnancy until they feel comfortable using them. Focal points (visual fixation on a designated object), effleurage (light abdominal massage by woman or partner), massage, and imagery (journey of the mind to a relaxing place) are also added to aid in relaxation. From the nurse's perspective, encourage the woman to breathe at a level of comfort that allows her to cope. Always remain quiet during the woman's periods of imagery and focal point visualization to avoid breaking her concentration.

Bradley (Partner-Coached) Method

The Bradley method uses various exercises and slow, controlled abdominal breathing to accomplish relaxation. Dr. Robert Bradley, a Denver-based obstetrician, advocated a completely unmedicated labor and birth experience. The Bradley method emphasizes the pleasurable sensations of childbirth, teaching women to concentrate on these sensations while "turning on" to their own bodies (Bradley Method, 2014). In 1965, Bradley wrote *Husband-Coached Childbirth,* which advocated the active participation of the husband as labor coach.

A woman is conditioned to work in harmony with her body using breath control and deep abdominopelvic breathing to promote general body relaxation during labor. This method stresses that childbirth is a joyful, natural process and emphasizes the partner's involvement during pregnancy, labor, birth, and the early newborn period. Thus, the training techniques are directed toward the coach, not the mother. The coach is educated in massage/comfort techniques to use on the mother throughout the labor and birth process.

Dick-Read Method

In 1944 Grantly Dick-Read, a British obstetrician, wrote *Childbirth Without Fear*. He believed that the attitude of a woman toward her birthing process had a considerable influence on the ease of her labor, and he believed that fear is the primary pain-producing agent in an otherwise normal labor. He felt that fear builds a state of tension, creating an antagonistic effect on the laboring muscles of the uterus, which results in pain. A private, undisturbed and dark environment, where

women can feel safe can promote the release of oxytocin, the hormone responsible for uterine contractions and though to promote the release of the pain-relieving hormones endorphins. When this is not achieved, women can experience fear–tension–pain syndrome, impeding labor progress and causing increased levels of pain (Westbury, 2015). Dick-Read sought to interrupt the circular pattern of fear, tension, and pain during the labor and birthing process. He promoted the belief that the degree of fear could be diminished with increased understanding of the normal physiologic response to labor (Alexander et al., 2014).

Dick-Read believed that prenatal instruction was essential for pain relief and that emotional factors during labor interfered with the normal labor progression. The woman achieves relaxation and reduces pain by arming herself with the knowledge of normal childbirth and using abdominal breathing during contractions.

Nursing Management and Childbirth Education

Childbirth education is less about methods than about mastery. The overall aim of any of the methods is to promote an internal locus of control that will enable each woman to yield her body to the process of birth. As the woman gains success and tangible benefits from the exercises she is taught, she begins to reframe her beliefs and gains practical knowledge, and the impetus will be there for her to engage in the conscious use of the techniques (Fig. 12.12). Nurses play a key role in supporting and encouraging each couple's use of the techniques taught in childbirth education classes.

FIGURE 12.12 **A couple practicing the techniques taught in a childbirth education class.**

Every woman's labor is unique, and it is important for nurses not to generalize or stereotype women. The most effective support a nurse can offer a couple using prepared childbirth methods is encouragement and presence. These nursing measures must be adapted to each individual throughout the labor process. Offering encouraging phrases such as "great job" or "you can do it" helps to reinforce their efforts and at the same time empowers them to continue. Using eye-to-eye contact to engage the woman's total attention is important if she appears overwhelmed or appears to lose control during the transition phase of labor.

Nurses play a significant role in enhancing the couple's relationship by respecting the involvement of the partner and demonstrating concern for his needs throughout labor. Offering to stay with the woman to give him a break periodically allows him to meet his needs while at the same time still actively participating. Offer

anticipatory guidance to the couple and assist during critical times in labor. Demonstrate many of the coping techniques to the partner and praise their successful use, which increases self-esteem. Focus on their strengths and the positive elements of the labor experience. Congratulating the couple for a job well done is paramount.

Throughout the labor experience, demonstrate personal warmth and project a friendly attitude. Frequently, a nurse's touch may help to prevent a crisis by reassuring the mother that she is doing fine.

Options for Birth Settings and Care Providers

From the moment a woman discovers she is pregnant, numerous decisions await her —where the infant will be born, what birth setting is best, and who will assist with the birth. The majority of women are well and healthy and can consider the full range of birth settings—hospital, birth center, or home setting—and care providers. They should be given information about each to ensure the most informed decision.

Birth Settings

HOSPITALS

Hospitals are the most common site for birth in the United States. If the woman has a serious medical condition or is at high risk for developing one, she will probably need to plan to give birth in a hospital setting under the care of an obstetrician. Giving birth in a hospital is advantageous for several reasons. Hospitals are best equipped to diagnose and treat women and newborns with complications; trained personnel are available if necessary; and no transportation is needed if a complication should arise during labor or birth. Disadvantages include the high-tech atmosphere; strict policies and restrictions that might limit who can be with the woman; and the medical model of care.

Within the hospital setting, however, choices do exist regarding birth environments. The conventional delivery room resembles an operating room, where the health care professional delivers the newborn from the woman, who is positioned in stirrups. The woman is then transferred to the recovery area on a stretcher and then again to the postpartum unit. The birthing suite is the other option within the hospital setting. In the birthing suite, the woman and her partner remain in one place for labor, birth, and recovery. The birthing suite is a private room decorated to look as homelike as possible. For example, the bed converts to allow for various birthing positions, and there may be a rocking chair or an easy chair for the woman's partner. Despite the homey atmosphere, the room is still equipped with emergency resuscitative obstetric equipment and electronic fetal monitors in case they are needed quickly (Fig. 12.13A). Such settings provide a more personal childbirth experience in a less formal and intimidating atmosphere compared to the traditional delivery room.

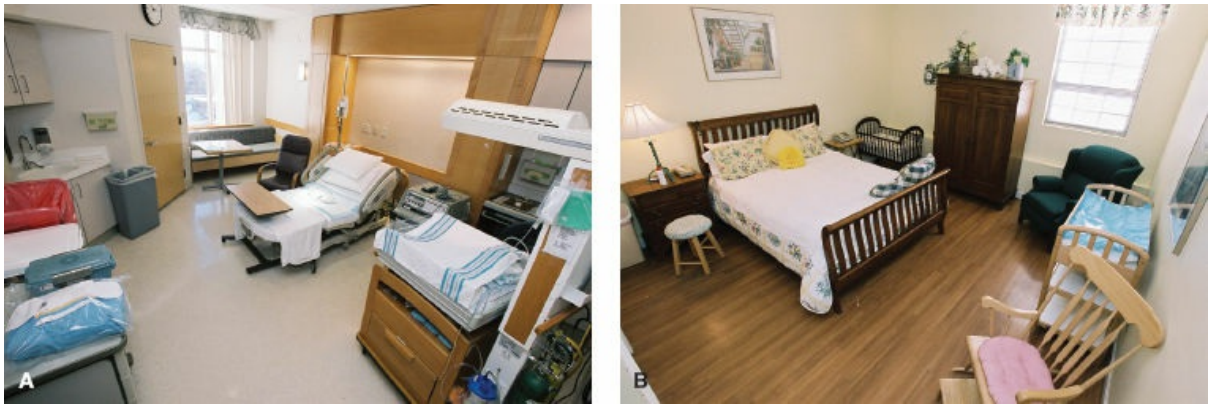

FIGURE 12.13 A. Birthing suite in hospital setting. B. Childbirth room in Birthing Center.

FREESTANDING BIRTH CENTER

A freestanding birth center offers women a comfortable setting where they can receive maternity care with appropriate levels of intervention. A freestanding birth center (Fig. 12.13B) can be a good choice for a woman who wants more personalized care than in a hospital but does not feel comfortable with a home birth. In contrast to the institutional environment in hospitals, most freestanding birth centers have a homelike atmosphere, and many are, in fact, located in converted homes. Some are located on hospital property and are affiliated with them. Birth centers are designed to provide maternity care to women judged to be at low risk for obstetric complications. Women are allowed and encouraged to give birth in the position most comfortable for them. Care in birth centers is often provided by midwives and is more relaxed, with no routine intravenous lines, fetal monitoring, and restrictive protocols. A disadvantage of the birth center is the need to transport the woman to a hospital quickly if an emergency arises, because emergency equipment is not readily available. In a research study comparing homelike to conventional institutional settings, the author concluded that there appeared to be some benefits from homelike settings for childbirth, although increased support from caregivers may be more important (Alliman, Jolles, & Summers, 2015).

HOME BIRTHS

Rates of planned home births have been increasing since the 1970s, with 1 in 49 non-Hispanic White women giving birth outside the hospital setting now (Zielinski, Ackerson, & Low, 2015). Most women who choose a home birth believe that birth is a natural process that requires little medical intervention (Lewis, 2015). Research has shown that women believe that planned home births increase privacy, comfort, and convenience; are associated with reduced rates of medical interventions; and facilitate family involvement in a relaxed, peaceful atmosphere (Budin, 2015).

The safety of home births is an ongoing debate in the United States. The American College of Nurse Midwives (ACNM), the American Public Health Association (APHA), and World Health Organization (WHO) state that planned home births is safe, as long as the woman falls under certain criteria, such as a low-risk pregnancy, singleton fetus, cephalic fetus at term, and the absence of pre-existing conditions (Declercq & Stotland, 2015). Home births can be safe if there are qualified, experienced attendants and an emergency transfer system in place in case of serious

complications. Many women choose the home setting out of a strong desire to control their child's birth and to give birth surrounded by family members. Most home birth caregivers are midwives who have provided continuous care to the woman throughout the pregnancy. Disadvantages include the need to transport the woman to the hospital during or after labor if a problem arises, and the limited pain management available in the home setting.

Care Providers

While most women in the United States still receive pregnancy care from an obstetrician, an increasing number are choosing a midwife for their care. The difference is a matter of degrees. Obstetricians must finish a 4-year residency in obstetrics and gynecology in addition to medical school. Certified nurse-midwives are registered nurses who have graduated from a nurse-midwifery education program accredited by the Accreditation Commission for Midwifery Education (ACME) and have passed a national certification examination to receive the professional designation of certified nurse-midwife. As of 2010, a graduate degree is required for entry into midwifery practice in the United States. Midwives usually care for low-risk women in a variety of settings. They are able to write prescriptions, provide prenatal care, childbirth care, postpartum care, newborn care, and well women's care throughout the life span. Family practice doctors also provide maternity, woman's care, and well-baby care. Many deliver their clients' newborns in the hospital or birthing centers. Obstetricians can handle high-risk pregnancies and delivery emergencies; can administer or order pain-relief drugs; and are assisted by a support staff in the hospital setting. Midwives work in hospitals, birthing centers, and home settings to deliver care. They believe in the normalcy of birth and tolerate wide variations of what is considered normal during labor, which leads to fewer interventions applied during the childbirth process. Midwives attend approximately 8% of total United States births (American College of Nurse-Midwives, 2015). Midwives do handle high risk and emergency births because many are not always predictable—they typically have an obstetrician as back up when they do occur to assist them.

In addition to the woman's primary health care provider, some women hire a doula to be with them during the childbearing process. *Doula* is a Greek word that means "woman's servant." A doula is a laywoman trained to provide women and their families with encouragement, emotional and physical support, and information through late pregnancy, labor, birth, and postpartum. Doulas provide the woman with continuous support throughout labor but do not perform any clinical procedures.

Preparation for Breast-Feeding or Bottle-Feeding

Pregnant women are faced with a decision about which method of feeding to choose. Educate the pregnant client about the advantages and disadvantages of each method, allowing the woman and her partner to make an informed decision about the best method for their situation. Providing the client and her partner with this information will increase the likelihood of a successful experience regardless of the method of feeding chosen. As part of health promotion/evidence-based interventions, nurses should be encouraging and educating all women on breast-

feeding.

Breast-Feeding

Substantial scientific evidence exists documenting the health benefits of breast-feeding for newborns. Current evidence cited by the American Academy of Pediatrics (AAP) showed improved outcomes for breast-fed infants with regard to otitis media, lower respiratory infections, gastroenteritis, atopic dermatitis, childhood asthma, childhood obesity, type 1 and type 2 diabetes, childhood leukemia, sudden infant death syndrome, and cognitive development and for their mothers with regard to breast cancer, ovarian cancer, and type 2 diabetes. The AAP recommends that infants be breast-fed exclusively until the age 6 months, and continue to be breast-fed for a year and for as long as it is mutually desired (2012). In addition, a lack of breast-feeding has a negative impact on the health care system by increasing the number of client visits, hospital admissions, rate of obesity, and health care costs. Most researchers agree that the duration of breast-feeding is inversely associated with overweight risk. Breast-feeding is a cost-effective, natural, and effective prevention strategy for reducing childhood obesity. A recent study estimates that $13 billion a year would be saved and 1,000 deaths prevented each year if 90% of infants in the United States were exclusively breast-fed until 6 months (Office on Women's Health, 2014).

Human milk provides an ideal balance of nutrients for newborns (ACOG, 2015h). Breast-feeding is advantageous for the following reasons:

- Human milk is digestible and economical and requires no preparation.
- Bonding between mother and child is promoted.
- Cost is less than purchasing formula.
- Ovulation is suppressed (however, this is not a reliable birth control method).
- The risk of ovarian cancer and the incidence of premenopausal breast cancer are reduced for the woman.
- Extra calories are used, which promotes weight loss gradually without dieting.
- Oxytocin is released to promote more rapid uterine involution with less bleeding.
- Sucking helps to develop the muscles in the infant's jaw.
- Absorption of lactose and minerals in the newborn is improved.
- The immunologic properties of breast milk help prevent infections in the baby.
- The composition of breast milk adapts to meet the infant's changing needs.
- Constipation in the baby is not a problem with adequate intake.
- Food allergies are less likely to develop in the breast-fed baby.
- The incidence of otitis media and upper respiratory infections in the infant is reduced.
- Breast-fed babies are less likely to be overfed, thus reducing the risk of adult obesity.
- Breast-fed newborns are less prone to vomiting (American Academy of Family Physicians (2015); AAP (2015); ACOG (2015h); and Women, Infant & Children [WIC], 2015).

One could say that lactation and breast-feeding are so natural that they should just happen on their own accord, but this is not the case. Learning to breast-feed takes practice, requires support from the partner, and requires dedication and patience on the part of the mother; it may be necessary to work closely with a

lactation consultant to be successful and comfortable when breast-feeding (Fig. 12.14 shows the different positions that may be used for breast-feeding). Nurses can encourage breast-feeding for all mothers except those who are HIV+, and are untreated, have active tuberculosis, use illicit drugs, or take prescribed cancer chemotherapeutic agents.

Breast-feeding also has some side effects. These include breast discomfort, sore nipples, mastitis, engorgement, milk stasis, vaginal dryness, and decreased libido (Alekseev, Vladimir, & Nadezhda, 2015). The most common cause of nipple pain is an improper latch and such discomfort is piercing, immediate and short lived, typically occurring as soon as the baby starts nursing and gradually subsiding during the feeding. Some mothers feel it is inconvenient or embarrassing, limits other activities, limits partner involvement, increases their dependency by being tied to the infant all the time, and restricts their use of alcohol or drugs. Nurses can help mothers to cope with their fear of dependency and feelings of obligation by emphasizing the positive aspects of breast-feeding and encouraging bonding experiences. Nurses can be instrumental in helping mothers prepare and continue to breast-feed after they return to work.

PREPARATION FOR BREAST-FEEDING

Nipple preparation is not necessary during the prenatal period unless the nipples are inverted and do not become erect when stimulated. Assess for this by placing the forefinger and thumb above and below the areola and compressing behind the nipple. If it flattens or inverts, advise the client to wear breast shields during the last 2 months of pregnancy. Breast shields exert a continuous pressure around the areola, pushing the nipple through a central opening in the inner shield (La Leche League International, 2016). The shields are worn inside the bra. Initially the shields are worn for 1 hour, and then the woman progressively increases the wearing time up to 8 hours daily. The client maintains this schedule until after childbirth, and then she wears the shield 24 hours a day until the infant latches on easily (La Leche League International, 2016). In addition, suggest that the woman wear a supportive nursing bra 24 hours a day.

Encourage the woman to request a certified lactation specialist (CLS) at the hospital, if giving birth there. Lactation specialists are health care providers who specialize in the clinical management of breast-feeding. Some run their own breast-feeding support groups as well. In addition, suggest that the woman attend a breast-feeding support group (e.g., La Leche League), provide her with sources of information about infant feeding, and suggest that she read a good reference book about lactation. All of these activities will help in her decision-making process and will be invaluable to her should she choose to breast-feed her newborn. Women returning to work can pump their breasts and store the milk in the freezer for future use.

Bottle-Feeding

Recent research indicates that infants who are fed formula within the first 6 months do have an increased incidence of otitis media, diabetes, asthma, atopic dermatitis, reflux, diarrhea, colic, constipation, and lower respiratory infections (Schram, 2014). It is important to inform mothers and their partners of this.

Bottle-feeding an infant is not just a matter of “open, pour, and feed.” Parents

need information on types of formulas, preparation and storage of formula, equipment, and feeding positions. It is recommended that normal full-term infants receive conventional cow's milk-based formula; the physician should direct this choice. If the infant has a reaction (diarrhea, vomiting, abdominal pain, excessive gas) to the first formula, another formula should be tried. Sometimes a soy-based formula is substituted. In terms of preparation of formula and its use, the following guidelines should be stressed:

- Obtain adequate equipment (six 4-oz bottles, eight 8-oz bottles, and nipples).
- Consistency is important. Stay with a nipple that is comfortable to the infant.
- Frequently assess nipples for any loose pieces of rubber at the opening.
- Correct formula preparation is critical to the health and development of the infant. Formula is available in three forms: ready-to-feed, concentrate, and powder.
- Read the formula label thoroughly before mixing.
- Correct formula dilution is important to avoid fluid imbalances. For ready-to-use formula, use as is without dilution. For concentrated formulas, dilute with equal parts of water. For powdered formulas, mix one scoop of powder with 2 oz of water.
- If the water supply is safe, sterilization is not necessary.
- Bottles and nipples should be washed in hot, sudsy water using a bottle brush.
- Formula should be served at room temperature.
- If the water supply is questionable, water should be boiled for 5 minutes before use.
- Formula should not be heated in a microwave oven, because it is heated unevenly.
- Formula can be prepared 24 hours ahead of time and stored in the refrigerator.

FIGURE 12.14 Positions for breast-feeding: cradle (A), cross-cradle (B), clutch or football (C), side-lying (D), and laid-back (E). (From *Lippincott Procedures*.)

Teach the woman and other caretakers to feed the infant in a semi-upright

position using the cradle hold in the arms. This position allows for face-to-face contact between the infant and caretaker. Advise the caretaker to hold the bottle so that the nipple is kept full of formula to prevent excessive air swallowing. Instruct the caretaker to feed the infant every 3 to 4 hours and adapt the feeding times to the infant's needs. Frequent burping of the infant (every ounce) helps prevent gas from building up in the stomach. Caution the caretaker not to prop the bottle; propping the bottle can cause choking.

Bottle-feeding should mirror breast-feeding as closely as possible. While nutrition is important, so are the emotional and interactive components of feeding. Encourage the caretaker to cuddle the infant closely and position the infant so that his or her head is in a comfortable position. Also encourage communication with the infant during feedings. Nurses should know the different types of formulas available to provide advice to mothers who have made the informed choice not to breast-feed or to stop breast-feeding.

Take Note!

Warn the caretaker about the danger of putting the infant to bed with a bottle. This can lead to "baby bottle tooth decay" (nursing caries) because sugars in the formula stay in contact with the infant's developing teeth for prolonged periods.

Final Preparation for Labor and Birth

The nurse has played a supportive/education role for the couple throughout the pregnancy and now needs to assist in preparing them for their "big event" by making sure they have made informed decisions and completed the following checklist:

- Attended childbirth preparation classes and practiced breathing techniques
- Selected a birth setting and made arrangements there
- Know what to expect during labor and birth
- Toured the birthing facility
- Packed a suitcase to take to the birthing facility when labor starts
- Made arrangements to have siblings and/or pets taken care of during labor
- Been instructed on signs and symptoms of labor and what to do
- Know what to do if membranes rupture prior to going into labor
- Know how to reach their health care provider when labor starts
- Communicated their needs and desires concerning pain management
- Discussed the possibility of a cesarean birth if complications occur
- Discussed possible names for the newborn
- Selected a feeding method (breast or bottle) with which they feel comfortable
- Made a decision regarding circumcision if they have a boy
- Purchased an infant safety car seat in which to bring their newborn home
- Decided on a pediatrician
- Have items needed to prepare for the newborn's homecoming:
  - Infant clothes in several sizes
  - Nursing bras
  - Infant crib with spaces between the slats that are 2 in or less apart
  - Diapers (cloth or disposable)
  - Feeding supplies (bottles and nipples if bottle-feeding)

• Infant thermometer
• Selected a family planning method to use after the birth

At each prenatal visit the nurse has had the opportunity to discuss and reinforce the importance of being prepared for the birth of the child with the parents. It is now up to the parents to use the nurse's guidance and put it into action to be ready for the upcoming birth.

A recent national survey entitled *Listening to Mothers III: Pregnancy and Birth* revealed concerns about overuse of maternity care practices and women's readiness to make informed decisions. Key findings point to the need for quality improvement, consumer engagement, and shared decision making (Declercq, Sakala, Corry, Applebaum, & Herrlick, 2014). These findings present a challenge for all nurses caring for maternity clients to thoroughly explain all procedures, along with their rationales, and truly listen to what the woman desires to make her childbirth experience outcome a positive one for her.

All nurses have the responsibility to impart their knowledge to all women and their families—and that starts with teaching themselves first. The evidence is clear that women have better outcomes when nurses intervene only when needed in the childbirth process. Nurses need to personalize their care to every woman based on her needs, her desires, and her state of health. Nurses must focus on teaching women and their families to understand the value of birth and its long-lasting effects on the family. In addition, nurses must provide birth settings that are safe, whether in the hospital, birth center, or at home. This includes, but is not limited to, providing continuous support in labor, allowing women the freedom to move and assume positions of choice, offering nourishment of the woman's body and spirit, using nonpharmacologic pain relief modalities whenever possible, and ensuring seamless, collaborative teamwork. Continuous labor support is a nonpharmacologic, evidence-based strategy associated with reduced cesarean rates (Baum, Crawford, & Humphrey-Shelton, 2015).

NURSING CARE PLAN 12.1

Overview of the Woman Experiencing Common Discomforts of Pregnancy

Alicia, a 32-year-old, G1 P0, at 10 weeks' gestation, comes to the clinic for a visit. During the interview she tells you, "I'm running to the bathroom to urinate it seems like all the time, and I'm so nauseous that I'm having trouble eating." She denies any burning or pain on urination. Vital signs are within acceptable limits.

NURSING DIAGNOSIS: Impaired urinary elimination related to frequency secondary to physiologic changes of pregnancy

Outcome Identification and Evaluation

The client will report a decrease in urinary complaints, as evidenced by a decrease in the number of times she uses the bathroom to void, reports that she feels her bladder is empty after voiding, and use of Kegel exercises.

Interventions: ***Promoting Normal Urinary Elimination Patterns***

• Assess client's usual bladder elimination patterns to establish a baseline for comparison.

- Obtain a urine specimen for analysis to rule out infection or glucosuria.
- Review with client the physiologic basis for the increased frequency during pregnancy; inform client that frequency should abate during the second trimester and that it most likely will return during her third trimester. This will promote understanding of the problem.
- Encourage the client to empty her bladder when first feeling a sensation of fullness to minimize risk of urinary retention.
- Suggest client avoid caffeinated drinks, which can stimulate the need to void.
- Encourage client to drink adequate amounts of fluid throughout the day; however, have client reduce her fluid intake before bedtime to reduce nighttime urination.
- Urge client to keep perineal area clean and dry to prevent irritation and excoriation from any leakage.
- Instruct client in Kegel exercises to increase perineal muscle tone and control over leakage.
- Teach client about the signs and symptoms of urinary tract infection and urge her to report them should they occur to ensure early detection and prompt intervention.

NURSING DIAGNOSIS: Imbalanced nutrition, less than body requirements, related to nausea and vomiting

Outcome Identification and Evaluation

The client will ingest adequate amounts of nutrients for maternal and fetal well-being as evidenced by acceptable weight gain pattern and statements indicating an increase in food intake with a decrease in the number of episodes of nausea and vomiting.

Interventions: ***Promoting Adequate Nutrition***

1. Obtain weight and compare to baseline to determine effects of nausea and vomiting on nutritional intake.
2. Review client's typical dietary intake over 24 hours to determine nutritional intake and patterns so that suggestions can be individualized.
3. Encourage client to eat five or six small frequent meals throughout the day to prevent her stomach from becoming empty.
4. Suggest that she munch on dry crackers, toast, cereal, or cheese or drink a small amount of lemonade before arising to minimize nausea.
5. Encourage client to arise slowly from bed in the morning and avoid sudden movements to reduce stimulation of the vomiting center.
6. Advise client to drink fluids between meals rather than with meals to avoid overdistention of the abdomen and subsequent increase in abdominal pressure.
7. Encourage her to increase her intake of foods high in vitamin B_6 such as meat, poultry, bananas, fish, green leafy vegetables, peanuts, raisins, walnuts, and whole grains, as tolerated, to ensure adequate nutrient intake.
8. Advise the client to avoid greasy, fried, or highly spiced foods and to avoid strong odors, including foods such as cabbage, to minimize gastrointestinal upset.
9. Encourage the client to avoid wearing tight or restricting clothes to minimize pressure on the expanding abdomen.
10. Arrange for consultation with nutritionist as necessary to assist with diet planning.

KEY CONCEPTS

- Preconception care is the promotion of the health and well-being of a woman and her partner before pregnancy. The goal of preconception care is to identify any areas such as health problems, lifestyle habits, or social concerns that might unfavorably affect pregnancy.
- A thorough history and physical examination are performed on the initial prenatal visit.
- A primary aspect of nursing management during the antepartum period is counseling and educating the pregnant women and her partner to promote healthy outcomes for all involved.
- Nagele rule can be used to establish the estimated date of birth. Using this rule, subtract 3 months from the month of their last LMP, add 7 days to the first day of the last normal menstrual period, then correct the year by adding 1 to it. This date is within plus or minus 2 weeks (margin of error).
- Pelvic shape is typically classified as one of four types: gynecoid, android, anthropoid, and platypelloid. The gynecoid type is the typical female pelvis and offers the best shape for a vaginal delivery.
- Continuous prenatal care is important for a successful outcome. The recommended schedule is every 4 weeks up to 28 weeks (7 months); every 2 weeks from 29 to 36 weeks; and every week from 37 weeks to birth.
- The height of the fundus is measured when the uterus arises out of the pelvis to evaluate fetal growth.
- The fundus reaches the level of the umbilicus at approximately 20 weeks and measures 20 cm. The fundal measurement should approximately equal the number of weeks of gestation until week 36.
- At each visit the woman is asked whether she is having any common signs or symptoms of preterm labor, which might include uterine contractions, dull backache, pressure in the pelvic area or thighs, increased vaginal discharge, menstrual-like cramps, and vaginal bleeding.
- Prenatal screening has become standard in prenatal care to detect neural tube defects and genetic abnormalities.
- The nurse should address matter of factly common discomforts that occur in each trimester at all prenatal visits and should provide realistic measures to help the client deal with them effectively.
- The pregnant client can better care for herself and the fetus if her concerns are anticipated by the nurse and incorporated into guidance sessions at each prenatal visit.
- Iron and folic acid need to be supplemented because their increased requirements during pregnancy are usually too great to be met through diet alone.

- Throughout pregnancy, a well-balanced diet is critical for a healthy baby.
- Perinatal education has broadened its focus to include preparation for pregnancy and family adaptation to the new parenting roles. Childbirth education began because of increasing pressure from consumers who wanted to become more involved in their birthing experience.
- Three common childbirth education methods are Lamaze (psychoprophylactic), Bradley (partner-coached childbirth), and Dick-Read (natural childbirth).
- The great majorities of women in the United States are well and healthy and can consider the full range of birth settings: hospital, birth center, or home setting.
- All pregnant women need to be able to recognize early signs of contractions to prevent preterm labor.

CHAPTER WORKSHEET

MULTIPLE-CHOICE QUESTIONS

1. Which of the following biophysical profile findings indicate poor oxygenation to the fetus?
   a. Two pockets of amniotic fluid
   b. Well-flexed arms and legs
   c. Nonreactive fetal heart rate
   d. Fetal breathing movements noted
2. The nurse teaches the pregnant client how to perform Kegel exercises as a way to accomplish which of the following?
   a. Prevent perineal lacerations
   b. Stimulate labor contractions
   c. Increase pelvic muscle tone
   d. Lose pregnancy weight quickly
3. During a clinic visit, a pregnant client at 30 weeks' gestation tells the nurse, "I've had some mild cramps that are pretty irregular. What does this mean?" The cramps are probably:
   a. The beginning of labor in the very early stages
   b. An ominous finding indicating that the client is about to have a miscarriage
   c. Related to over hydration of the woman
   d. Braxton Hicks contractions, which occur throughout pregnancy
4. The nurse is preparing her teaching plan for a woman who has just had her pregnancy confirmed. Which of the following should be included in it? Select all that apply.
   a. Prevent constipation by taking a daily laxative
   b. Balance your dietary intake by increasing your calories by 300 daily
   c. Continue your daily walking routine just as you did before this pregnancy
   d. Tetanus, measles, mumps, and rubella vaccines will be given to you now
   e. Avoid tub baths now that you are pregnant to prevent vaginal infections
   f. Sexual activity is permitted as long as your membranes are intact
   g. Increase your consumption of milk to meet your iron needs
5. A pregnant client's last normal menstrual period was on August 10. Using Nagele rule, the nurse calculates that her estimated due date (EDD) will be which of the following?
   a. June 23
   b. July 10
   c. July 30
   d. May 17
6. Which of the following is not true about breast-feeding?

a. Breast-fed infants experience more obesity and allergies
b. Breast milk is perfectly suited to the infant's nutritional needs
c. Breast milk contains maternal antibodies to stimulate infant's immunity
d. Breast-feeding enhances maternal bonding and attachment

7. Practicing good oral hygiene is important for all women throughout their pregnancy. As a nurse providing anticipatory guidance for pregnant women, what condition can result from periodontal disease if good dental care isn't practiced?
   a. Post-dates pregnancy
   b. Large for gestational age infant
   c. Advanced reproductive cancer
   d. Preterm or low-birth-weight infant
8. Anticipatory guidance regarding sexual activity during pregnancy includes which of the following? Select all that apply:
   a. Sexual activity is contraindicated throughout pregnancy
   b. Most women don't desire intimacy after the first trimester
   c. Sexual activity may continue up until the end of the second trimester
   d. Sexual intercourse is prohibited if a history of preterm labor exists
   e. Women's sexual desire may change throughout the pregnancy
   f. Couples can try a variety of positions of comfort during pregnancy
9. Which of the following would be considered risk factors for psychologic well-being in pregnancy? Select all that apply:
   a. Limited support system and network of friends and family
   b. Introverted personality at any point in the pregnancy
   c. Ambivalence any time during the pregnancy
   d. High levels of stress due to family discord
   e. History of previous high-risk pregnancy with complications
   f. Depression prior to pregnancy and on medication

CRITICAL THINKING EXERCISES

1. Mary Jones comes to the Women's Health Center, where you work as a nurse. She is in her first trimester of pregnancy and tells you her main complaints are nausea and fatigue, to the point that she wants to sleep most of the time and eats one meal daily. She appears pale and tired. Her mucous membranes are pale. She reports that she gets 8 to 9 hours of sleep each night but still can't seem to stay awake and alert at work. She tells you she knows that she is not eating as she should, but she isn't hungry. Her hemoglobin and hematocrit are low.
   a. What subjective and objective data do you have to make your assessment?
   b. What is your impression of this woman?
   c. What nursing interventions would be appropriate for this client?
   d. How will you evaluate the effectiveness of your interventions?
2. Monica, a 16-year-old African American high school student, is here for her first prenatal visit. Her last normal menstrual period was 2 months ago, and she states she has been "sick ever since." She is 5 ft, 6 in tall, and weighs 110 lb. In completing her dietary assessment, the nurse asks about her intake of milk and

dairy products. Monica reports that she doesn't like "that stuff" and doesn't want to put on too much weight because it "might ruin my figure."
   a. In addition to the routine obstetric assessments, which additional ones might be warranted for this teenager?
   b. What dietary instruction should be provided to this teenager based on her history?
   c. What follow-up monitoring should be included in subsequent prenatal visits?
3. Maria, a 27-year-old Hispanic woman in her last trimester of pregnancy (34 weeks), complains to the clinic nurse that she is constipated and feels miserable most of the time. She reports that she has started taking laxatives, but they don't help much. When questioned about her dietary habits, she replies that she eats beans and rice and drinks tea with most meals. She says she has tried to limit her fluid intake so she doesn't have to go to the bathroom so much because she doesn't want to miss any of her daytime soap operas on television.
   a. What additional information would the nurse need to assess her complaint?
   b. What interventions would be appropriate for Maria?
   c. What adaptations will Maria need to make to alleviate her constipation?

STUDY ACTIVITIES

1. Visit a freestanding birth center and compare it to a traditional hospital setting in terms of restrictions, type of pain management available, and costs.
2. Arrange to shadow a nurse-midwife for a day to see her role in working with the childbearing family.
3. Visit the student resources on and select two of the supplied websites that correspond to this chapter. Note their target audience, the validity of information offered, and their appeal to expectant couples. Present your findings.
4. Request permission to attend a childbirth education class in your local area and help a woman without a partner practice the paced breathing exercises. Present the information you learned and think about how you can apply it while taking care of a woman during labor.
5. A laywoman with a specialized education and experience in assisting women during labor is a _____.

BRINGING IT ALL TOGETHER: A CASE STUDY

A 19-year-old female came to the public health clinic. This was her first prenatal visit, although she was 8 months pregnant. Her explanation as to why she hadn't been there before was: "It was summer and everything had been going good until my back started hurting two days ago."

ASSESSMENT

Her vital signs were within normal range. Weight was 175 lb. On physical examination, the back area was normal without tenderness when palpated. Fundal height was 36 cm; fetal heart rate was 150 bpm; urinalysis was negative for blood, glucose, or leukocytes. The pelvic examination showed the cervix to be long, thick, and closed. Missed routine prenatal lab work was done since this was her first visit. When questioned further about when her back seemed to cause her the most

discomfort, she stated that she was a waitress and when she finished her shift, she could barely walk home.

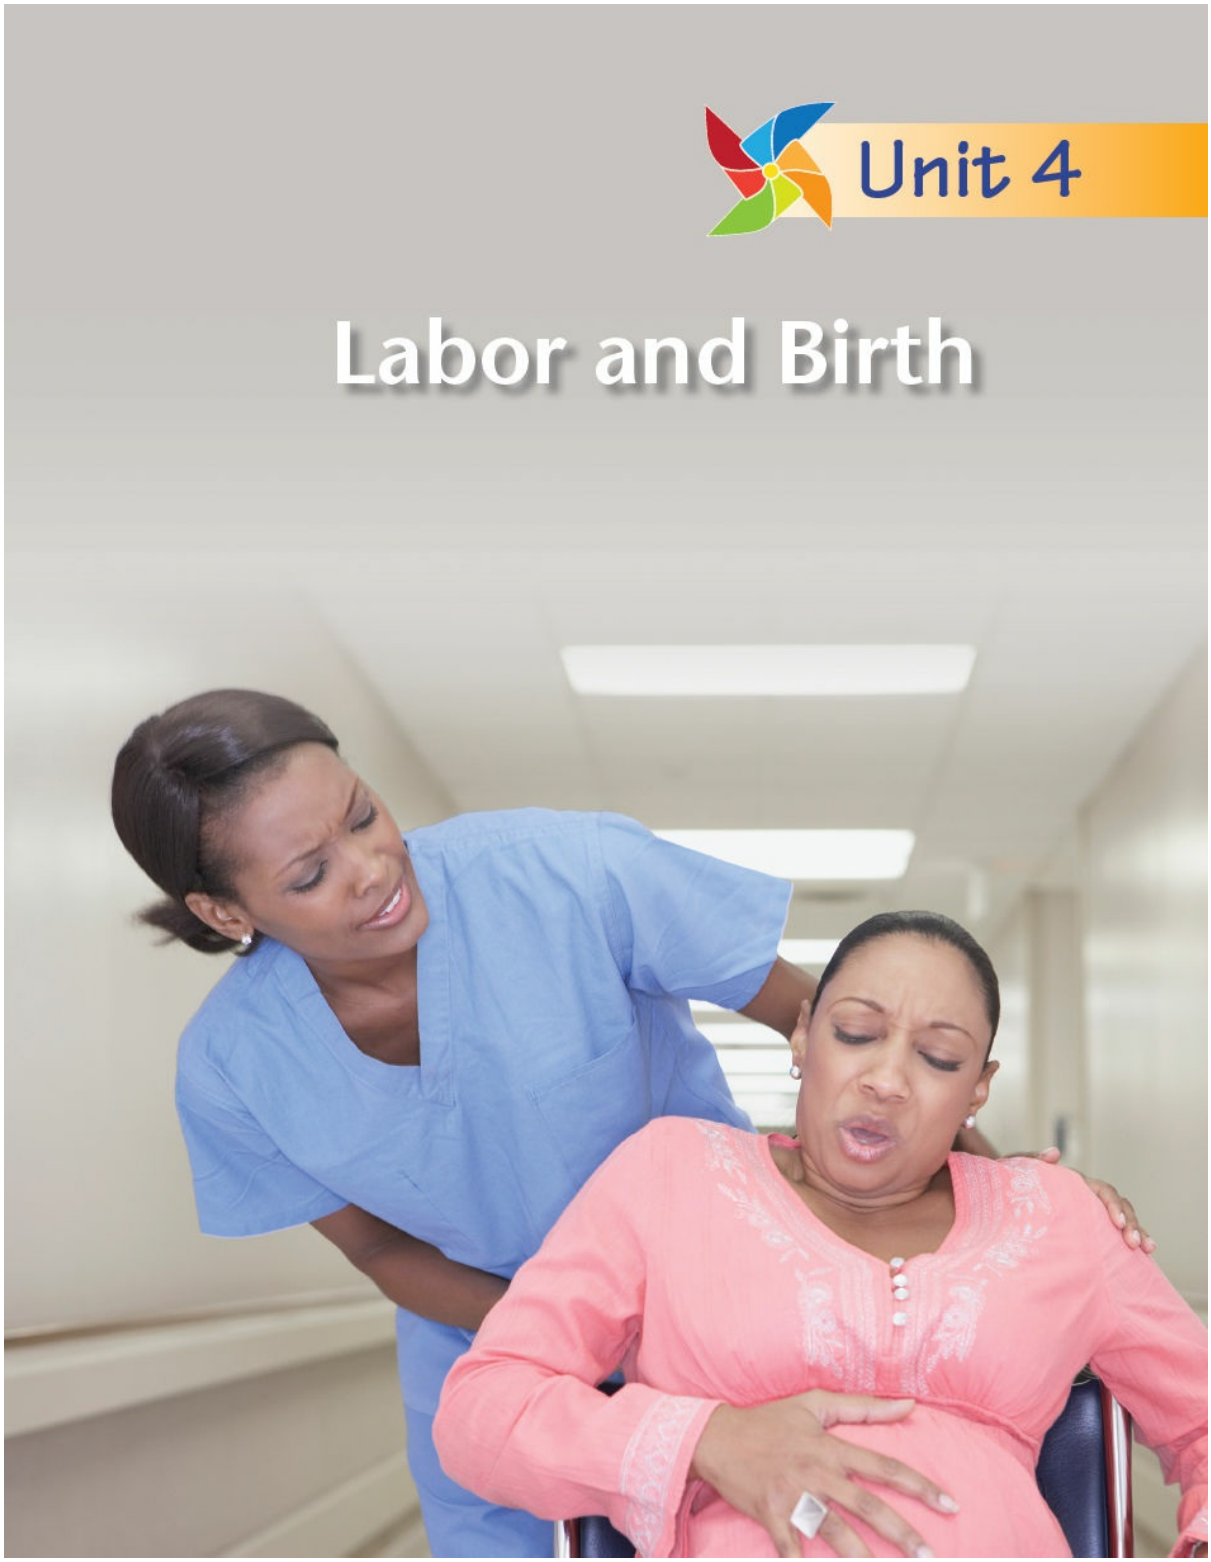
1. What additional information is needed to make a diagnosis?
2. Based on the assessment, what might be suspected as the cause of her back pain?
3. What lab work might be included in her routine prenatal assessment that was missed?

It would be important to know what her prepregnant weight was to compare it with her present weight. If she has gained a large amount of weight during this pregnancy, it might be a contributing factor to her low back pain. Low back pain can also be a symptom of early labor, but in her case, she hasn't noticed any contractions and no cervical changes have taken place based on the examination. Low back pain in the lumbosacral region generally occurs in the last trimester and increases in intensity as the pregnancy progresses secondary to the increasing weight of the enlarged uterus and relaxation of the sacroiliac ligaments. The normal lordosis of pregnancy strains the back muscles and causes pain. Routine lab work may include a complete blood count (CBC), blood type, Rh type, and antibody screen, Hepatitis B surface antigen, HIV screening test, syphilis screening test, diabetic screening, and urinalysis or dipstick for protein.

PLAN

1. What health teaching by the nurse is needed for this client?
2. What specific relief measures are helpful to address her concern?
3. What changes in her work environment might be suggested?
4. How can her lack of prenatal care be addressed by the nurse?

Since this is her first prenatal visit, she has not had the benefit of any health teaching throughout her pregnancy thus far. Since she is in her last trimester, focus should be on preparing her for labor and birth, making arrangements for her childbirth at a local hospital, and referring her to obtain Women/Infants/Children (WIC) and other community resources available. Specific relief measures for low back pain would include instructing her to rest in a side-lying position to take the weight off her back; use proper body mechanics for lifting, stooping rather than bending so that the legs, rather than the back bear the weight and strain; and wearing low-heeled shoes. Excessive standing for long periods of time can contribute to low back pain, so periodic rest periods may need to be instituted in her work environment to reduce her low back pain. Since this client is already in her 8th month of pregnancy, the nurse should encourage her to keep her weekly prenatal appointments without placing judgment on her previous behavior. Making judgments and placing blame are not therapeutic interventions that provide an accepting environment to any client. Stressing the importance of prenatal care to the health of her baby and herself are important.



Unit 4
Labor and Birth

Learning Objectives

Upon completion of the chapter, you will be able to:

1. Relate premonitory signs of labor.
2. Compare and contrast true versus false labor.
3. Categorize the critical factors affecting labor and birth.
4. Analyze the cardinal movements of labor.
5. Evaluate the maternal and fetal responses to labor and birth.
6. Classify the stages of labor and the critical events in each stage.
7. Characterize the normal physiologic/psychological changes occurring during all four stages of labor.
8. Formulate the concept of pain as it relates to the woman in labor.

***Kathy and Chuck* have been eagerly awaiting the birth of their first child for what seems to them an eternity. When Kathy finally feels contractions in her abdomen, she and Chuck rush to the birthing center. After the OB nurse finishes a complete history and physical assessment, she informs Kathy and her husband that she must have experienced "false labor" and that they should return home until she starts true labor.**

INTRODUCTION

The process of labor and birth involves more than the birth of a newborn. Numerous physiologic and psychological events occur that ultimately result in the birth of a newborn and the creation or expansion of the family. This chapter describes labor and birth as a process. It addresses initiation of labor, the premonitory signs of labor, including true and false labor, critical factors affecting labor and birth, maternal and fetal response to the laboring process, and the four stages of labor. The chapter also identifies critical factors related to each stage of labor: the "10 P's of labor."

INITIATION OF LABOR

Labor is a physiologic event involving a sequential, integrated set of changes within the myometrium, decidua, and cervix that occurs gradually over a period of days to weeks in order to expel the fetus from the uterus. It is difficult to determine exactly why labor begins and what initiates it. Although several theories have been proposed to explain the onset and maintenance of labor, none of these has been proved scientifically. It is widely believed that labor is influenced by a cascade of events, including uterine stretch from the fetus and amniotic fluid volume, progesterone withdrawal to estrogen dominance, increased oxytocin sensitivity, and increased release of prostaglandins.

One theory suggests that labor is initiated by a change in the estrogen-to-

progesterone ratio. During the last trimester of pregnancy, estrogen levels increase and progesterone levels decrease. This change leads to an increase in the number of myometrium gap junctions. Gap junctions are proteins that connect cell membranes and facilitate coordination of uterine contractions and myometrial stretching (Norwitz, 2015).

Although physiologic evidence for the role of oxytocin in the initiation of labor is inconclusive, the number of oxytocin receptors in the uterus increases at the end of pregnancy. This creates an increased sensitivity to oxytocin. Estrogen, the levels of which are also rising, increases myometrial sensitivity to oxytocin. With the increasing levels of oxytocin in the maternal blood in conjunction with increasing fetal cortisol levels that synthesize prostaglandins, uterine contractions are initiated. Oxytocin also aids in stimulating prostaglandin synthesis through receptors in the decidua. Prostaglandins lead to additional contractions, cervical softening, gap junction induction, and myometrial sensitization, thereby leading to a progressive cervical **dilation** (the opening or enlargement of the external cervical os). Uterine contractions have two main functions: to dilate the cervix and to push the fetus through the birth canal (Funai & Norwitz, 2015).

PREMONITORY SIGNS OF LABOR

Before the onset of labor, a pregnant woman's body undergoes several changes in preparation for the birth of the newborn. The changes that occur often lead to characteristic signs and symptoms that suggest that labor is near. These premonitory signs and symptoms can vary, and not every woman experiences every one of them.

Cervical Changes

Before labor begins, cervical softening and possible cervical dilation with descent of the presenting part into the pelvis occur. These changes can occur 1 month to 1 hour before actual labor begins.

As labor approaches, the cervix changes from an elongated structure to a shortened, thinned segment. Cervical collagen fibers undergo enzymatic rearrangement into smaller, more flexible fibers that facilitate water absorption, leading to a softer, more stretchable cervix. These changes occur secondary to the effects of prostaglandins and pressure from Braxton Hicks contractions. The ripening and softening of the cervix are essential for **effacement** and dilation, which reflect the enhanced collagen breakdown that was previously inhibited by progesterone (Grant, Strevens, & Thornton, 2015).

Lightening

Lightening occurs when the fetal presenting part begins to descend into the true pelvis. The uterus lowers and moves into a more anterior **position**. The shape of the abdomen changes as a result of the change in the uterus. With this descent, the woman usually notes that her breathing is much easier and that there is a decrease in gastric reflux. However, she may complain of increased pelvic pressure, leg cramping, dependent edema in the lower legs, and low back discomfort. She may notice an increase in vaginal discharge and more frequent urination. In primiparas, lightening can occur 2 weeks or more before labor begins; among multiparas it may not occur until labor starts (Cheng & Caughey, 2015a).

Increased Energy Level

Some women report a sudden increase in energy before labor. This is sometimes referred to as nesting, because many women will focus this energy toward childbirth preparation by cleaning, cooking, preparing the nursery, and spending extra time with other children in the household. The increased energy level usually occurs 24 to 48 hours before the onset of labor. It is thought to be the result of an increase in epinephrine release caused by a decrease in progesterone (Jordan, et al., 2014).

Bloody Show

At the onset of labor or before, the mucous plug that fills the cervical canal during pregnancy is expelled as a result of cervical softening and increased pressure of the presenting part. These ruptured cervical capillaries release a small amount of blood that mixes with mucus, resulting in the pink-tinged secretions known as bloody show.

Braxton Hicks Contractions

Braxton Hicks contractions, which the woman may have been experiencing throughout the pregnancy, may become stronger and more frequent. Braxton Hicks contractions are typically felt as a tightening or pulling sensation of the top of the uterus. They occur primarily in the abdomen and groin and gradually spread downward before relaxing. In contrast, true labor contractions are more commonly felt in the lower back. These contractions aid in moving the cervix from a posterior position to an anterior position. They also help in ripening and softening the cervix. However, the contractions are irregular and can be decreased by walking, voiding, eating, increasing fluid intake, or changing position.

Braxton Hicks contractions usually last about 30 seconds but can persist for as long as 2 minutes. As birth draws near and the uterus becomes more sensitive to oxytocin, the **frequency** and **intensity** of these contractions increase. However, if the contractions last longer than 30 seconds and occur more often than four to six times an hour, advise the woman to contact her health care provider so that she can be evaluated for possible preterm labor, especially if she is less than 38 weeks pregnant.

Take Note!

An infant born between 34 0/7 and 36 6/7 weeks of gestation is identified as "late preterm" and experiences many of the same health issues as other preterm birth infants (Horgan, 2015).

Spontaneous Rupture of Membranes

Rupture of membranes with loss of amniotic fluid prior to the onset of labor is termed prelabor rupture of membranes (PROM). It occurs in 8% to 10% of women with term pregnancies, the majority of whom will begin labor spontaneously within 24 hours (King, et al., 2015). The rupture of membranes can result in either a sudden gush or a steady leakage of amniotic fluid. Although much of the amniotic fluid is lost when the rupture occurs, a continuous supply is produced to ensure protection of the fetus until birth.

After the amniotic sac has ruptured, the barrier to infection is gone and an

ascending infection is possible. In addition, there is a danger of cord prolapse if **engagement** has not occurred with the sudden release of fluid and pressure with rupture. Due to the possibility of these complications, advise women to notify their health care provider and go in for an evaluation.

Consider This

I always pictured myself a dignified woman and behaved in ways to demonstrate that, for that was the way I was raised. My mother and grandmother always stressed that you should look good, dress well, and do nothing to embarrass yourself in public. I did a fairly good job of living up to their expectations until an incident occurred at the end of my first pregnancy. I recall I was overdue according to my dates and was miserable in the summer heat. I decided to go to the store for some ice cream. As I waddled down the grocery aisles, all of a sudden my water broke and came pouring down my legs all over the floor. Not wanting to make a spectacle of myself and remembering what my mother always said about being dignified at all times in public, I quickly reached up onto the grocery shelf and "accidentally" knocked off a large jar of pickles right where my puddle was. As I walked hurriedly away from that mess without my ice cream, I heard on the store loudspeaker, "Clean-up on aisle 13!"

Thoughts: We tend to live by what we are taught, and in this case, this woman needed to save face from her ruptured membranes. Many women experience ruptured membranes before the onset of labor, so it is not out of the ordinary for this to happen in public. What risks can occur when membranes do rupture? What action should this woman take now to minimize these risks? How will the nurse validate this woman's ruptured membranes?

TRUE VERSUS FALSE LABOR

False labor is a condition occurring during the latter weeks of some pregnancies in which irregular uterine contractions are felt, but the cervix is not affected. In contrast, true labor is characterized by contractions occurring at regular intervals that increase in frequency, **duration**, and intensity. True labor contractions bring about progressive cervical dilation and effacement. Table 13.1 summarizes the differences between true and false labor. False labor, prodromal labor, and Braxton Hicks contractions are all names for contractions that do not contribute in a measurable way toward the goal of birth. Distinguishing between true and false labor is an essential nursing assessment skill and one that develops with experience.

TABLE 13.1 DIFFERENCES BETWEEN TRUE AND FALSE LABOR

Parameters	True Labor	False Labor
Contraction timing	Regular, becoming closer together, usually 4–6 min apart, lasting 30–60 sec	Irregular, not occurring close together
Contraction strength	Become stronger with time, vaginal pressure is usually felt	Frequently weak, not getting stronger with time or alternating (a strong one followed by weaker ones)
Contraction discomfort	Starts in the back and radiates around toward the front of the abdomen	Usually felt in the front of the abdomen
Any change in activity	Contractions continue no matter what positional change is made	Contractions may stop or slow down with walking or making a position change
Stay or go?	Stay home until contractions are 5 min apart, last 45–60 sec, and are strong enough so that a conversation during one is not possible—then go to the hospital or birthing center.	Drink fluids and walk around to see if there is any change in the intensity of the contractions; if the contractions diminish in intensity after either or both—stay home.

Adapted from Cunningham, F. G., Leveno, K. J., Bloom, S. L., Spong, C. Y., Dashe, J. S., Hoffman, B. L., Casey, B. M., & Sheffield, J. S. (2014). *Williams obstetrics* (24th ed.). New York, NY: McGraw-Hill Education; King, T. L., Brucker, M. C., Kriebs, J. M., Fahey, J. O., Gegor, C. L., & Varney, H. (2015). *Varney's midwifery* (5th ed.). Sudbury, MA: Jones & Bartlett.

Many women fear being sent home from the hospital with false labor. All women feel anxious when they feel contractions, but they should be informed that labor could be a long process, especially if it is their first pregnancy. Encourage the woman to think of false labor or prelabor signs as positive, because they are part of the entire labor continuum. With first pregnancies, the cervix can take up to 20 hours to dilate completely (Cunningham et al., 2014).

Remember Kathy and Chuck, the anxious couple who came to the hospital too early? Kathy felt sure she was in labor and is now confused. What explanations and anticipatory guidance should be offered to this couple? What term would describe her earlier contractions?

FACTORS AFFECTING THE LABOR PROCESS

Traditionally, the critical factors that affect the process of labor and birth are outlined as the "five P's":

1. **P**assageway (birth canal)
2. **P**assenger (fetus and placenta)
3. **P**owers (contractions)
4. **P**osition (maternal)
5. **P**sychological response

These critical factors are commonly accepted and discussed by health care providers. However, five additional "P's" can also affect the labor process:

1. **P**hilosophy (low tech, high touch)
2. **P**artners (support caregivers)
3. **P**atience (natural timing)
4. **P**atient (client) preparation (childbirth knowledge base)

5. **P**ain management (comfort measures)

These five additional P's are helpful in planning care for the laboring family. These client-focused factors are an attempt to foster labor that can be managed through the use of high touch, patience, support, knowledge, and pain management.

Passageway

The birth passageway is the route through which the fetus must travel to be born vaginally. Compared to other primates, childbirth is remarkably difficult in humans because the head of the neonate is large relative to the birth-relevant dimensions of the maternal pelvis. The passageway consists of the maternal pelvis and soft tissues. Of the two, however, the maternal bony pelvis is more important because it is relatively unyielding (except for the coccyx). Typically the pelvis is assessed and measured during the first trimester, often at the first visit to the health care provider, to identify any abnormalities that might hinder a successful vaginal birth. As the pregnancy progresses, the hormones relaxin and estrogen cause the connective tissues to become more relaxed and elastic and cause the joints to become more flexible to prepare the mother's pelvis for birth. Additionally, the soft tissues usually yield to the forces of labor.

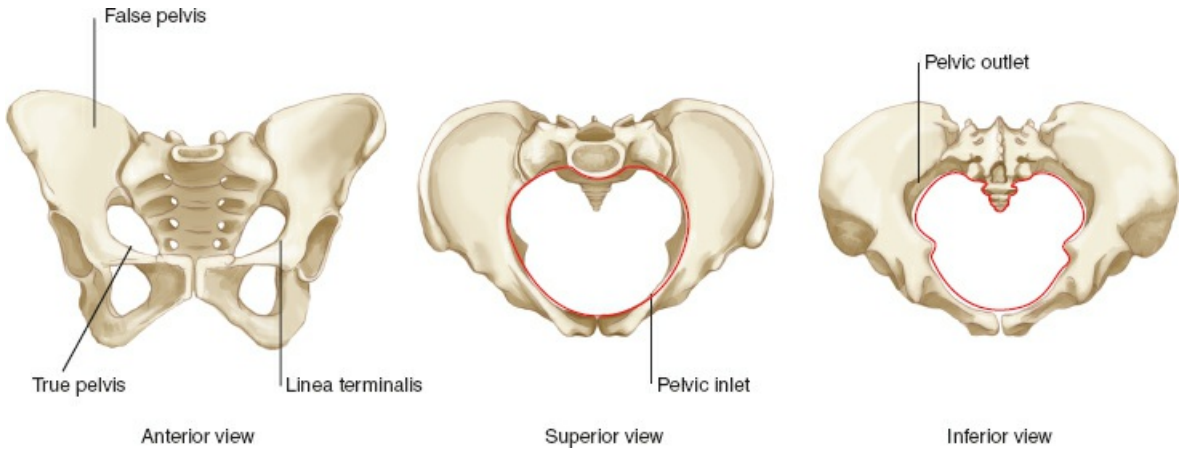

FIGURE 13.1 The bony pelvis.

Bony Pelvis

The maternal bony pelvis can be divided into the true and false portions. The false (or greater) pelvis is composed of the upper flared parts of the two iliac bones with their concavities and the wings of the base of the sacrum. The false pelvis is divided from the true pelvis by an imaginary line drawn from the sacral prominence at the back to the superior aspect of the symphysis pubis at the front of the pelvis. This imaginary line is called the linea terminalis. The false pelvis lies above this imaginary line; the true pelvis lies below it (Fig. 13.1). The true pelvis is the bony passageway through which the fetus must travel. It is made up of three planes: the inlet, the mid-pelvis (cavity), and the outlet.

PELVIC INLET

The pelvic inlet allows entrance to the true pelvis. It is bounded by the sacral prominence in the back, the ilium on the sides, and the superior aspect of the

symphysis pubis in the front (Jones & Lopez, 2014). The pelvic inlet is wider in the transverse aspect (sideways) than it is from front to back.

MID-PELVIS

The mid-pelvis (cavity) occupies the space between the inlet and outlet. It is through this snug, curved space that the fetus must travel to reach the outside. As the fetus passes through this small area its chest is compressed, causing lung fluid and mucus to be expelled. This expulsion removes the space-occupying fluid so that air can enter the lungs with the newborn's first breath.

PELVIC OUTLET

The pelvic outlet is bound by the ischial tuberosities, the lower rim of the symphysis pubis, and the tip of the coccyx. In comparison with the pelvic inlet, the outlet is wider from front to back. For the fetus to pass through the pelvis, the outlet must be large enough. To ensure the adequacy of the pelvic outlet for vaginal birth, the following pelvic measurements are assessed:

- Diagonal conjugate of the inlet (distance between the anterior surface of the sacral prominence and the anterior surface of the inferior margin of the symphysis pubis)
- Transverse or ischial tuberosity diameter of the outlet (distance at the medial and lowest aspect of the ischial tuberosities, at the level of the anus; a known hand span or clenched-fist measurement is generally used to obtain this measurement)
- True or obstetric conjugate (distance estimated from the measurement of the diagonal conjugate; 1.5 cm is subtracted from the diagonal conjugate measurement)

For more information about pelvic measurements, see Chapter 12.

If the diagonal conjugate measures at least 11.5 cm and the true or obstetric conjugate measures 10 cm or more (1.5 cm less than the diagonal conjugate, or about 10 cm), then the pelvis is large enough for a vaginal birth of what would be considered a normal-size newborn.

Pelvic Shape

In addition to size, the shape of a woman's pelvis is a determining factor for a vaginal birth. Each plane of the pelvis has a shape, which is defined by the anterior-posterior and transverse diameters. The pelvis is divided into four main shapes: gynecoid, anthropoid, android, and platypelloid (Fig. 13.2).

GYNECOID PELVIS

The gynecoid pelvis is considered the true female pelvis, occurring in about 40% of all women; it is less common in men (Fischer & Mitteroecker, 2015). Vaginal birth is most favorable with this type of pelvis because the inlet is round and the outlet is roomy. This shape offers the optimal diameters in all three planes of the pelvis. This type of pelvis allows early and complete fetal internal rotation during labor.

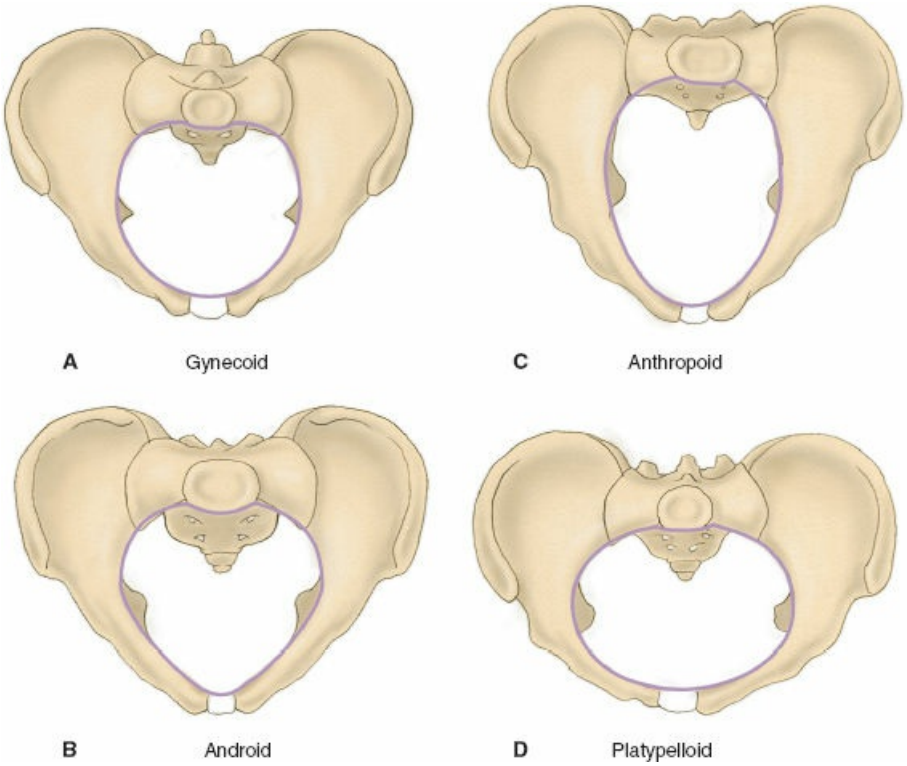

FIGURE 13.2 **Pelvic shapes. A. Gynecoid. B. Android. C. Anthropoid. D. Platypelloid.**

ANTHROPOID PELVIS

The anthropoid pelvis is common in men and is most common in non-White women. It occurs in approximately 25% of women (Marani & Koch, 2014). The pelvic inlet is oval and the sacrum is long, producing a deep pelvis (wider front to back [anterior to posterior] than side to side [transverse]). Vaginal birth is more favorable with this pelvic shape compared with the android or platypelloid shape (Tharpe, Farley, & Jordan, 2016).

ANDROID PELVIS

The android pelvis is considered the male-shaped pelvis and is characterized by a funnel shape. It occurs in approximately 20% of women (Cunningham et al., 2014). The pelvic inlet is heart-shaped and the posterior segments are reduced in all pelvic planes. Descent of the fetal head into the pelvis is slow, and failure of the fetus to rotate is common. The prognosis for labor is poor, subsequently leading to cesarean birth.

PLATYPELLOID (FLAT) PELVIS

The platypelloid or flat pelvis is the least common type of pelvic structure among men and women, with an approximate incidence of 3% (King, et al., 2015). The pelvic cavity is shallow but widens at the pelvic outlet, making it difficult for the fetus to descend through the mid-pelvis. Labor prognosis is poor with arrest at the inlet occurring frequently. It is not favorable for a vaginal birth unless the fetal head can pass through the inlet. Women with this type of pelvis usually require cesarean birth.

An important principle is that most pelvises are not purely defined but occur in nature as mixed types. Many women have a combination of these four basic pelvis

types, with no two pelves being exactly the same. Regardless of the shape, the newborn can be born vaginally if size and positioning remain compatible. The narrowest part of the fetus attempts to align itself with the narrowest pelvic dimension (e.g., biparietal to interspinous diameters, which means the fetus generally tends to rotate to the most ample portion of the pelvis).

Soft Tissues

The soft tissues of the passageway consist of the cervix, the pelvic floor muscles, and the vagina. Through effacement, the cervix effaces (thins) to allow the presenting fetal part to descend into the vagina.

Take Note!

The process of cervical effacement and dilation is similar to that of pulling a turtleneck sweater over your head.

The pelvic floor muscles help the fetus to rotate anteriorly as it passes through the birth canal. The soft tissues of the vagina expand to accommodate the fetus during birth.

Passenger

The fetus (with placenta) is the passenger. The fetal head (size and presence of **molding**), fetal **attitude** (degree of body flexion), fetal lie (relationship of body parts), fetal **presentation** (first body part), fetal position (relationship to maternal pelvis), fetal station, and fetal engagement are all important factors that have an impact on the ultimate outcome in the birthing process.

Fetal Head

The fetal head is the largest fetal structure, making it an important factor in relation to labor and birth. Considerable variation in the size and diameter of the fetal skull is often seen.

Compared with an adult's head, the fetal head is large in proportion to the rest of the body, usually about one quarter of the body surface area (Martin, Fanaroff, & Walsh, 2014). The bones that make up the face and cranial base are fused and essentially fixed. However, the five bones that make up the rest of the cranium (two frontal bones, two parietal bones, and the occipital bone) are not fused; rather, they are soft and pliable, with gaps between the plates of bone. These gaps, membranous spaces between the cranial bones, are called sutures, and the intersections of these sutures are called fontanelles. Sutures are important because they allow the cranial bones to overlap in order for the head to adjust in shape (elongate) when pressure is exerted on it by uterine contractions or the maternal bony pelvis. Some diameters shorten, whereas others lengthen as the head is molded during the labor and birthing process. This malleability of the fetal skull may decrease fetal skull dimensions by 0.5 to 1 cm (King, et al., 2015). After birth, the sutures close as the bones grow and the brain reaches its full growth.

The changed (elongated) shape of the fetal skull at birth as a result of overlapping of the cranial bones is known as molding. Along with molding, fluid can also collect in the scalp (caput succedaneum) or blood can collect beneath the scalp (cephalohematoma), further distorting the shape and appearance of the fetal head.

Caput succedaneum can be described as edema of the scalp at the presenting part. This swelling crosses suture lines and disappears within 3 to 4 days. Cephalohematoma is a collection of blood between the periosteum and the bone that occurs several hours after birth. It does not cross suture lines and is generally reabsorbed over the next 6 to 8 weeks (Collins & Reed, 2014).

Take Note!

Parents may become concerned about the distortion of their newborn's head. However, reassurance that the oblong shape is only temporary is usually all that is needed to reduce their anxiety.

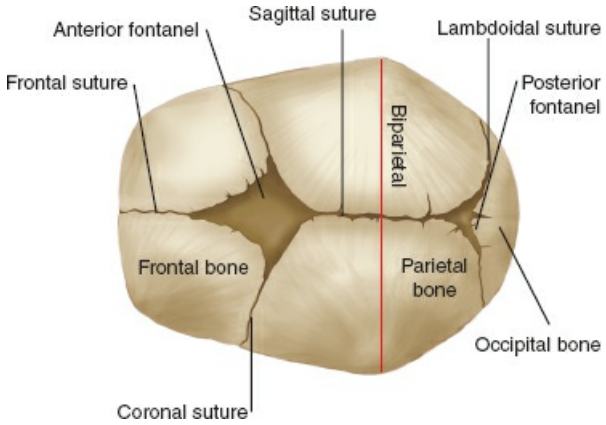

FIGURE 13.3 Fetal skull.

Sutures also play a role in helping to identify the position of the fetal head during a vaginal examination. Figure 13.3 shows a fetal skull. During a pelvic examination, palpation of these sutures by the examiner reveals the position of the fetal head and the degree of rotation that has occurred.

The anterior and posterior fontanelles are also useful in helping to identify the position of the fetal head. They allow for molding, and are important when evaluating the newborn. The anterior fontanelle is the famous "soft spot" of the newborn's head. It is a diamond-shaped space that measures from 1 to 4 cm. It remains open for 12 to 18 months after birth to allow for growth of the brain (Verklan & Walden, 2014). The posterior fontanelle corresponds to the anterior one but is located at the back of the fetal head; it is triangular. This one closes within 8 to 12 weeks after birth and measures, on average, 1 to 2 cm at its widest diameter (Weber & Kelley, 2014).

The diameter of the fetal skull is an important consideration during the labor and birth process. Fetal skull diameters are measured between the various landmarks of the skull. Diameters include occipitofrontal, occipitomental, suboccipitobregmatic, and biparietal (Fig. 13.4). The two most important diameters that can affect the birth process are the suboccipitobregmatic (approximately 9.5 cm at term) and the biparietal (approximately 9.25 cm at term) diameters. The suboccipitobregmatic diameter, measured from the base of the occiput to the center of the anterior fontanelle, identifies the smallest anteroposterior diameter of the fetal skull. The biparietal diameter measures the largest transverse diameter of the fetal skull: the distance between the two parietal bones. In a cephalic (head first) presentation, which occurs in 95% of all term births, if the fetus presents in a flexed position in which the chin is resting on the chest, the optimal or smallest fetal skull dimensions

for a vaginal birth are demonstrated. If the fetal head is not fully flexed at birth, the anteroposterior diameter increases. This increase in dimension might prevent the fetal skull from entering the maternal pelvis.

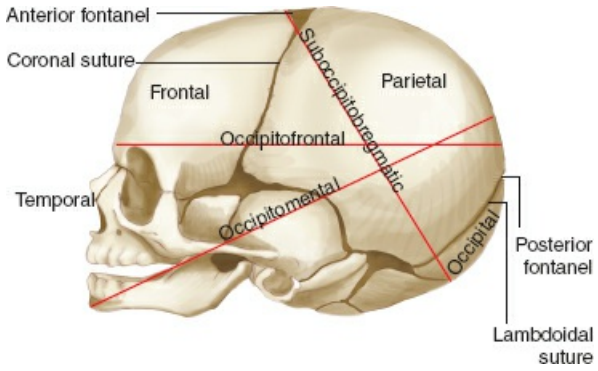

FIGURE 13.4 Fetal skull diameters.

Fetal Attitude

Fetal attitude is another important consideration related to the passenger. Fetal attitude refers to the posturing (flexion or extension) of the joints and the relationship of fetal parts to one another. The most common fetal attitude when labor begins is with all joints flexed—the fetal back is rounded, the chin is on the chest, the thighs are flexed on the abdomen, and the legs are flexed at the knees (Fig. 13.5). This normal fetal position is most favorable for vaginal birth, presenting the smallest fetal skull diameters to the pelvis.

FIGURE 13.5 Fetal attitude: full flexion. Note that the smallest diameter presents to the pelvis.

When the fetus presents to the pelvis with abnormal attitudes (no flexion or extension), their nonflexed position can increase the diameter of the presenting part as it passes through the pelvis, increasing the difficulty of birth. An attitude of extension tends to present larger fetal skull diameters, which may make birth difficult.

Fetal Lie

Fetal **lie** refers to the relationship of the long axis (spine) of the fetus to the long axis (spine) of the mother. There are three possible lies: longitudinal (which is the most common), transverse (Fig. 13.6), and oblique.

A longitudinal lie occurs when the long axis of the fetus is parallel to that of the mother (fetal spine to maternal spine side-by-side). A transverse lie occurs when the long axis of the fetus is perpendicular to the long axis of the mother (fetal spine lies

across the maternal abdomen and crosses her spine). In an oblique lie, the fetal long axis is at an angle to the bony inlet, and no palpable fetal part is presenting. This lie is usually transitory and occurs during fetal conversion between other lies. A fetus in a transverse or oblique lie position cannot be delivered vaginally (Cunningham, et al., 2014).

Fetal Presentation

Fetal presentation refers to the body part of the fetus that enters the pelvic inlet first (the "presenting part"). This is the fetal part that lies over the inlet of the pelvis or the cervical os. Knowing which fetal part is coming first at birth is critical for planning and initiating appropriate interventions.

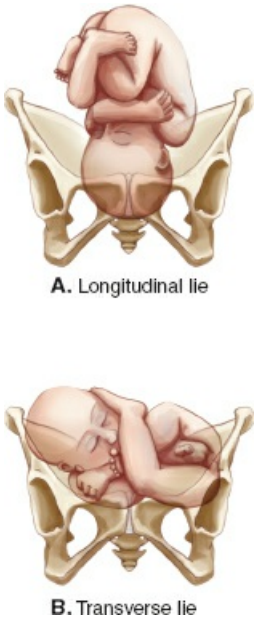

FIGURE 13.6 **Fetal lie.**

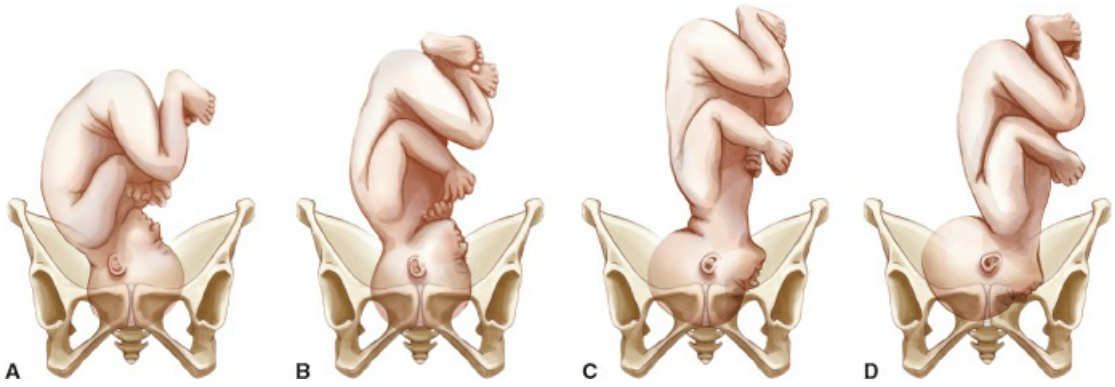

FIGURE 13.7 **Fetal presentation: cephalic presentations. A. Vertex. B. Military. C. Brow. D. Face.**

The three main fetal presentations are cephalic (head first), breech (pelvis first), and shoulder (scapula first). The majority of term newborns (95%) enter this world in a cephalic presentation; breech presentations account for 3% of term births, and shoulder presentations for approximately 2% (Tharpe et al., 2016).

In a cephalic presentation, the presenting part is usually the occipital portion of the fetal head (Fig. 13.7). This presentation is also referred to as a vertex

presentation. Variations in a vertex presentation include the military, brow, and facial presentations.

BREECH PRESENTATION

By term, approximately 97% of infants actively turn to a cephalic presentation. It is determined by abdominal palpation (Hofmeyr, 2015). Breech presentation occurs when the fetal buttocks or feet enter the maternal pelvis first and the fetal skull enters last. This abnormal presentation poses several challenges at birth. Primarily, the largest part of the fetus (skull) is born last and may become "hung up" or stuck in the pelvis. In addition, the umbilical cord can become compressed between the fetal skull and the maternal pelvis after the fetal chest is born because the head is the last to exit. Moreover, unlike the hard fetal skull, the buttocks are soft and are not as effective as a cervical dilator during labor compared with a cephalic presentation. Finally, there is the possibility of trauma to the head as a result of the lack of opportunity for molding.

The types of breech presentations are determined by the positioning of the fetal legs (Fig. 13.8). In a frank breech (50% to 70%), the buttocks present first with both legs extended up toward the face. In a full or complete breech (5% to 10%), the fetus sits crossed-legged above the cervix. In a footling or incomplete breech (10% to 30%), one or both legs are presenting. Breech presentations are associated with prematurity, placenta previa, multiparity, uterine abnormalities (fibroids), and some congenital anomalies such as hydrocephaly (Hofmeyr, 2015). A frank breech can result in a vaginal birth, but complete, footling, and incomplete breech presentations generally necessitate a cesarean birth.

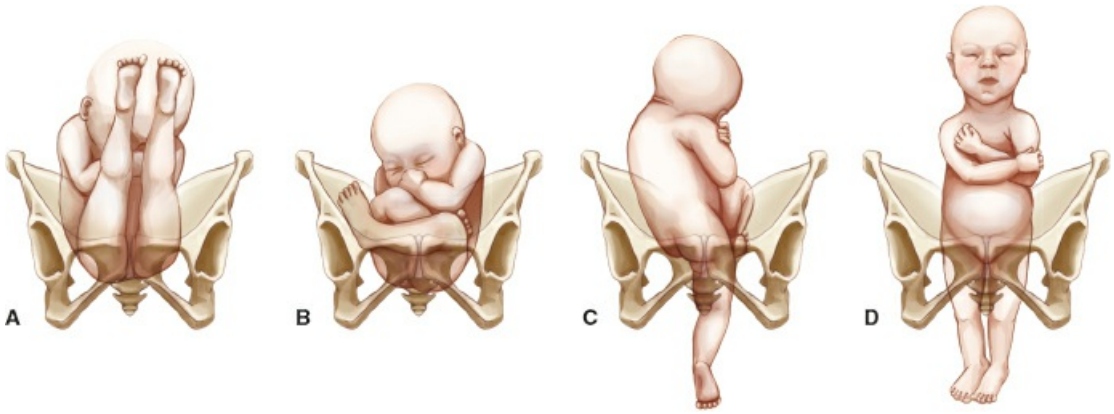

FIGURE 13.8 Breech presentations. A. Frank breech. B. Complete breech. C. Single footling breech. D. Double footling breech.

SHOULDER PRESENTATION

A shoulder presentation or shoulder dystocia occurs when the fetal shoulders present first, with the head tucked inside. Clinically, signs of shoulder dystocia appear while the woman is pushing as the neonate's head slowly extends and emerges over the perineum, but then retracts back into the vagina, commonly referred to as the "turtle sign." Odds of a shoulder presentation are 1 in 300 births (Cunningham et al., 2014). The fetus is in a transverse lie with the shoulder as the presenting part. Conditions associated with shoulder dystocia include placenta previa, prematurity, high parity, premature rupture of membranes, multiple

gestation, or fetal anomalies. A cesarean birth is usually necessary if identified before labor begins, but will be evaluated based on the length of gestation, the size of the fetus, the position of the placenta, and whether the membranes have ruptured (Sharshiner & Silver, 2015).

Fetal Position

Fetal position describes the relationship of a given point on the presenting part of the fetus to a designated point of the maternal pelvis (King, et al., 2015). The landmark fetal presenting parts include the occipital bone (O), which designates a vertex presentation; the chin (mentum [M]), which designates a face presentation; the buttocks (sacrum [S]), which designate a breech presentation; and the scapula (acromion process [A]), which designates a shoulder presentation.

In addition, the maternal pelvis is divided into four quadrants: right anterior, left anterior, right posterior, and left posterior. These quadrants designate whether the presenting part is directed toward the front, back, left, or right side of the pelvis. Fetal position is determined by identifying first the presenting part and then the maternal quadrant the presenting part is facing (Fig. 13.9). Position is indicated by a three-letter abbreviation as follows:

- The first letter defines whether the presenting part is tilted toward the left (L) or the right (R) side of the maternal pelvis.
- The second letter represents the particular presenting part of the fetus: O for occiput, S for sacrum (buttocks), M for mentum (chin), A for acromion process, and D for dorsal (refers to the fetal back) when denoting the fetal position in shoulder presentations (Cheng & Caughey, 2015a).
- The third letter defines the location of the presenting part in relation to the anterior (A) portion of the maternal pelvis or the posterior (P) portion of the maternal pelvis. If the presenting part is directed to the side of the maternal pelvis, the fetal presentation is designated as transverse (T).

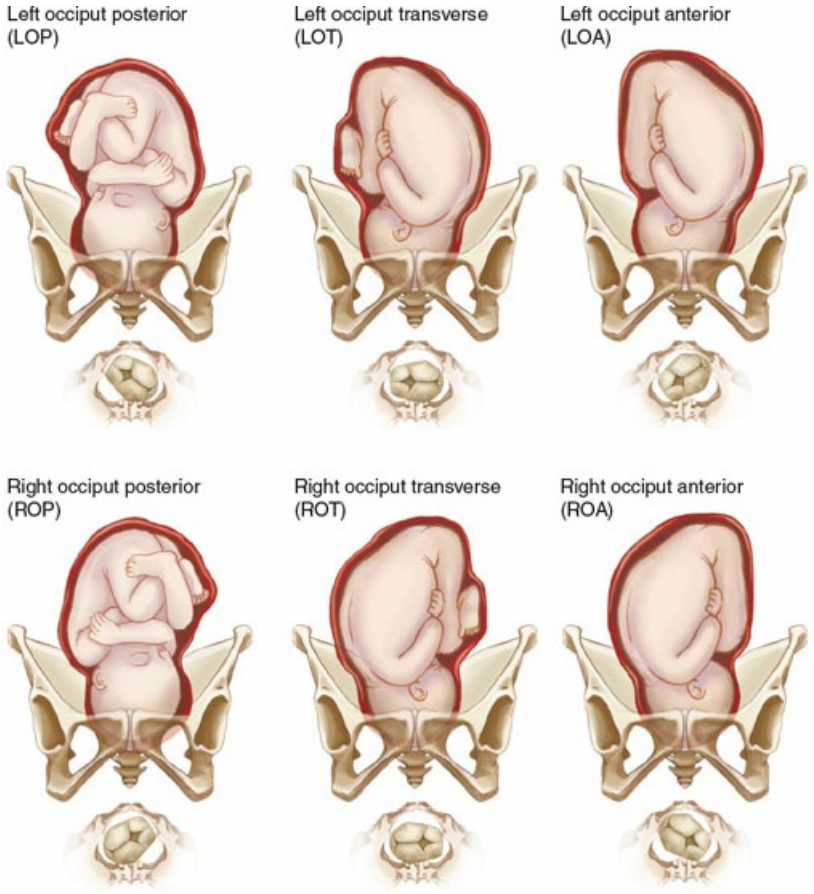

FIGURE 13.9 Examples of fetal positions in a vertex presentation. The lie is longitudinal for each illustration. The attitude is one of flexion. Notice that the view of the top illustration is seen when facing the pregnant woman. The bottom view is that seen with the woman in a dorsal recumbent position.

For example, if the occiput is facing the left anterior quadrant of the pelvis, then the position is termed left occiput anterior and is recorded as LOA.

Take Note!

LOA is the most common (and most favorable) fetal position for birthing today, followed by right occiput anterior (ROA). The positioning of the fetus allows the fetal head to contour to the diameters of the maternal pelvis. LOA and ROA are optimal positions for a vaginal birth.

An occiput posterior position may lead to a long and difficult birth, and other positions may or may not be compatible with vaginal birth.

Fetal Station

Fetal **station** refers to the relationship of the presenting part to the level of the maternal pelvic ischial spines. Fetal station is measured in centimeters and is referred to as a minus or plus, depending on its location above or below the ischial spines. Typically, the ischial spines are the narrowest part of the pelvis and are the natural measuring point for the birth progress.

Zero (0) station is designated when the presenting part is at the level of the maternal ischial spines. When the presenting part is above the ischial spines, the distance is recorded as minus stations. When the presenting part is below the ischial

spines, the distance is recorded as plus stations. For instance, if the presenting part is above the ischial spines by 1 cm, it is documented as being a –1 station; if the presenting part is below the ischial spines by 1 cm, it is documented as being a +1 station.

An easy way to understand this concept is to think in terms of meeting the goal, which is the birth. If the fetus is descending downward (past the ischial spines) and moving toward meeting the goal of birth, then the station is positive and the centimeter numbers grow bigger from +1 to +4. If the fetus is not descending past the ischial spines, then the station is negative and the centimeter numbers grow bigger from –1 to –4. The farther away the presenting part from the outside, the larger the negative number (–4 cm). The closer the presenting part of the fetus is to the outside, the larger the positive number (+4 cm). Figure 13.10 shows stations of the presenting part.

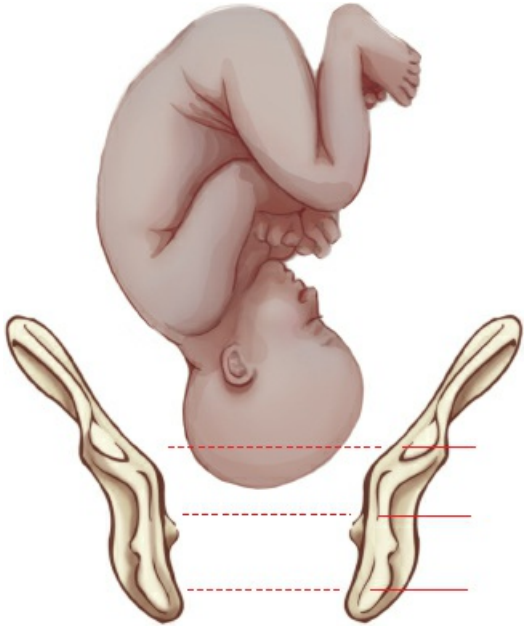

FIGURE 13.10 Fetal stations.

Fetal Engagement

Fetal engagement signifies the entrance of the largest diameter of the fetal presenting part (usually the fetal head) into the smallest diameter of the maternal pelvis (Alexander, et al., 2014). The fetus is said to be engaged in the pelvis when the presenting part reaches 0 station. Engagement is determined by pelvic examination.

The largest diameter of the fetal head is the biparietal diameter. It extends from one parietal prominence to the other. It is an important factor in the navigation through the maternal pelvis. Engagement typically occurs in primigravidas 2 weeks before term, whereas multiparas may experience engagement several weeks before the onset of labor or not until labor begins.

Take Note!

The term floating is used when engagement has not occurred, because the presenting part is freely movable above the pelvic inlet.

Cardinal Movements of Labor

The fetus goes through many positional changes as it travels through the passageway. These positional changes are known as the cardinal movements of labor. They are deliberate, specific, and very precise movements that allow the smallest diameter of the fetal head to pass through a corresponding diameter of the mother's pelvic structure. Although cardinal movements are conceptualized as separate and sequential, the movements are typically concurrent (Fig. 13.11).

ENGAGEMENT

Engagement occurs when the greatest transverse diameter of the head in vertex (biparietal diameter) passes through the pelvic inlet (usually 0 station). The head usually enters the pelvis with the sagittal suture aligned in the transverse diameter.

DESCENT

Descent is the downward movement of the fetal head until it is within the pelvic inlet. Descent occurs intermittently with contractions and is brought about by one or more of the following forces:

- Pressure of the amniotic fluid
- Direct pressure of the fundus on the fetus's buttocks or head (depending on which part is located in the top of the uterus)
- Contractions of the abdominal muscles (second stage)
- Extension and straightening of the fetal body

Descent occurs throughout labor, ending with birth. During this time, the mother experiences discomfort, but she is unable to isolate this particular fetal movement from her overall discomfort.

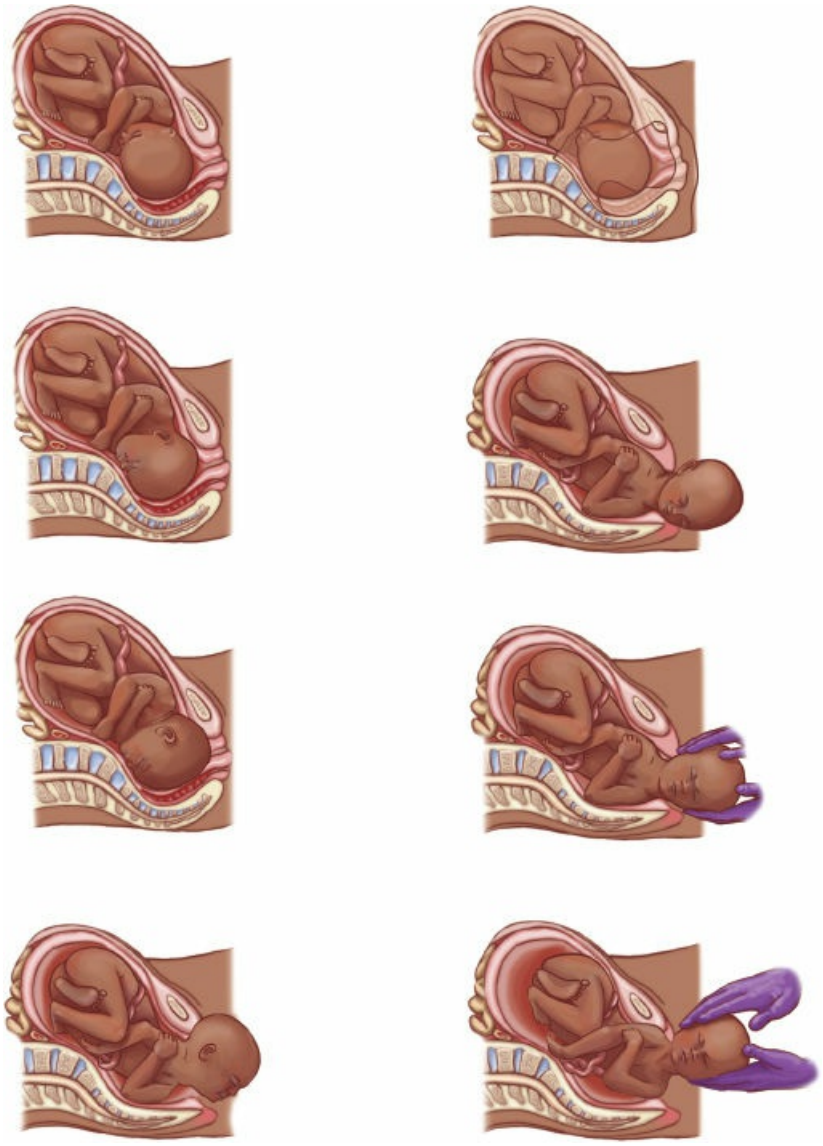

FIGURE 13.11 **Cardinal movements of labor.**

FLEXION

Flexion occurs as the vertex meets resistance from the cervix, the walls of the pelvis, or the pelvic floor. As a result, the chin is brought into contact with the fetal thorax and the presenting diameter is changed from occipitofrontal to suboccipitobregmatic (9.5 cm), which achieves the smallest fetal skull diameter presenting to the maternal pelvic dimensions.

INTERNAL ROTATION

After engagement, as the head descends, the lower portion of the head (usually the occiput) meets resistance from one side of the pelvic floor. As a result, the head rotates about 45 degrees anteriorly to the midline under the symphysis. This movement is known as *internal rotation*. Internal rotation brings the anteroposterior diameter of the head in line with the anteroposterior diameter of the pelvic outlet. It aligns the long axis of the fetal head with the long axis of the maternal pelvis. The widest portion of the maternal pelvis is the anteroposterior diameter, and thus the fetus must rotate to accommodate the pelvis.

EXTENSION

With further descent and full flexion of the head, the nucha (the base of the occiput) becomes impinged under the symphysis. Resistance from the pelvic floor causes the fetal head to extend so that it can pass under the pubic arch. *Extension* occurs after internal rotation is complete. The head emerges through extension under the symphysis pubis along with the shoulders. The anterior fontanel, brow, nose, mouth, and chin are born successively.

EXTERNAL ROTATION (RESTITUTION)

After the head is born and is free of resistance, it untwists, causing the occiput to move about 45 degrees back to its original left or right position (restitution). The sagittal suture has now resumed its normal right-angle relationship to the transverse (bisacromial) diameter of the shoulders (i.e., the head realigns with the position of the back in the birth canal). *External rotation* of the fetal head allows the shoulders to rotate internally to fit the maternal pelvis.

EXPULSION

Expulsion of the rest of the body occurs more smoothly after the birth of the head and the anterior and posterior shoulders (Cheng & Caughey, 2015a). See Figure 13.3 for an image of a fetal skull.

Powers

The primary stimulus powering labor is uterine contraction. Contractions cause complete dilation and effacement of the cervix during the first stage of labor. The secondary powers in labor involve the use of intra-abdominal pressure (voluntary muscle contractions) exerted by the woman as she pushes and bears down during the second stage of labor.

Uterine Contractions

Uterine contractions are involuntary and therefore cannot be controlled by the woman experiencing them, regardless of whether they are spontaneous or induced. Uterine contractions are rhythmic and intermittent, with a period of relaxation between contractions. This pause allows the woman and the uterine muscles to rest. In addition, this pause restores blood flow to the uterus and placenta, which is temporarily reduced during each uterine contraction.

Uterine contractions are responsible for thinning and dilating the cervix, then thrusting the presenting part toward the lower uterine segment. The cervical canal reduces in length from 2 cm to a paper-thin entity and is described in terms of percentages from 0% to 100%. In primigravidas, effacement typically starts before the onset of labor and usually begins before dilation; in multiparas, however, neither effacement nor dilation may start until labor ensues (Fig. 13.12). On clinical examination the following may be assessed:

• Cervical canal 2 cm in length would be described as 0% effaced.

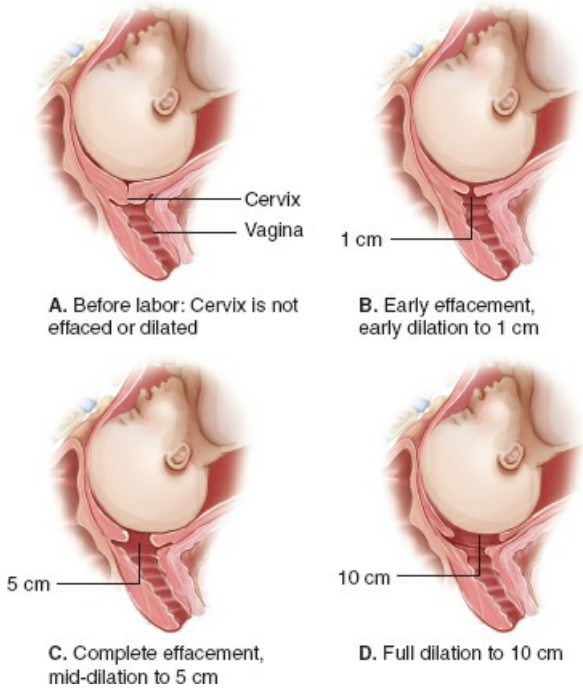

FIGURE 13.12 Cervical effacement and dilation. Cervical dilation is expressed in centimeters. A. Shows cervix not effaced or dilated. B. 50% effaced. C. 100% effaced. D. Fully dilated at 10 centimeters.

- Cervical canal 1 cm in length would be described as 50% effaced.
- Cervical canal 0 cm in length would be described as 100% effaced.

Dilation is dependent on the pressure of the presenting part and the contraction and retraction of the uterus. The diameter of the cervical os increases from less than 1 cm to approximately 10 cm to allow for birth. When the cervix is fully dilated, it is no longer palpable on vaginal examination. Descriptions may include the following:

- External cervical os closed: 0 cm dilated
- External cervical os half open: 5 cm dilated
- External cervical os fully open: 10 cm dilated

During early labor, uterine contractions are described as mild, they last about 30 seconds, and they occur about every 5 to 7 minutes. As labor progresses, contractions last longer (60 seconds), occur more frequently (2 to 3 minutes apart), and are described as being moderate to high in intensity. Each contraction has three phases: increment (buildup of the contraction), acme (peak or highest intensity), and decrement (descent or relaxation of the uterine muscle fibers; Fig. 13.13).

Uterine contractions are monitored and assessed according to three parameters: frequency, duration, and intensity.

1. *Frequency* refers to how often the contractions occur and is measured from the beginning of one contraction to the beginning of the next contraction.
2. *Duration* refers to how long a contraction lasts and is measured from the beginning of one contraction to the end of that same contraction.
3. *Intensity* refers to the strength of the contraction determined by manual palpation or measured by an internal intrauterine pressure catheter. The catheter is positioned in the uterine cavity through the cervix after the membranes have
